Abstract: Plants are under constant pressure from herbivores and have therefore acquired countless traits to defend themselves against their attackers. In response, herbivores have acquired their own traits to cope with the resistances of plants. Decades of research have meticulously mapped the resistance mechanisms of plants. Especially the way and extent in which plants can align their defenses to the type of attacker is well documented. However, as we have come to understand more of these mechanisms, we have come to realize that plants not always succeed in successfully establishing the necessary defenses. It turned out that there are quite a few herbivores who manipulate their host plant by gaining control of its metabolism via tempering with hubs in molecular signal networks. We have discovered that some herbivorous mites are able to suppress plant defenses. They do this by injecting saliva into their host that contains substances (proteins) that alter or down regulate the defense mechanisms of the plant. This has obvious advantages when these mites are alone on their host plant, but it can also have adverse effects in communities when facilitating competitors. In this talk I will explain what we currently know about how mites manipulate their host plant and how we can use this knowledge to make our crops more resilient.

Radiations or Oscillations? Insights into the diversification of butterflies

Authors: Janz Niklas, Department of Zoology, Stockholm University, Sweden

Abstract: Ever since the publication of Ehrlich and Raven's classical paper on coevolution between butterflies and plants, the potential codiversification of herbivorous insects and the plants they feed on have been at the heart of the coevolution discussion. This is not surprising, considering that both these groups have seen remarkable levels of diversification over the last 100M years, so that they now together make up about half of all species on Earth. Ehrlich and Raven's theory of "escape-and radiation" remains the most well-known hypothesis to account for this diversification, but it has more recently been challenged by an alternative scenario that relies more on retaining variability in host interactions than on key innovations leading to radiations. Here I will explore the differences between the two scenarios and relate some recent efforts to evaluate their relative importance for the diversification of nymphalid butterflies.

Molecular systematics and evolution of host plant associations in Lymantriinae:Support for the oscillation hypothesis from extreme polyphagous feeders

Authors: Janz Niklas[4], Wahlberg Niklas[5], Wang Houshuai[1], D. Holloway Jeremy[2], P. Braga Mariana[3], Wang Min[6] and Nylin Sören[3], [1]Department of Entomology, China, [2]Department of Life Sciences, Natural History Museum, London, United Kingdom, [3]Department of Zoology, Stockholm University, Sweden, [4]Department of Zoology, Stockholm University, Sweden, [5]Lund University, Sweden, [6]South China Agricultural University, Japan

Abstract: Plant-feeding insects represent about one-quarter of all described species on earth, but the mechanisms that have driven the diversification of these insects are poorly understood. An oscillation hypothesis on insect-plant associations suggests that the diversification of plant-feeding insects has been promoted by expansion of their host plant range, but the evidence for this hypothesis comes mainly from butterflies that are mostly specialized feeders. The moth subfamily Lymantriinae, belonging to Erebidae in Lepidoptera, represents a species-rich group of plant-feeding insects in terrestrial ecosystem, and comprises over 2500 described species. The subfamily is well known for extreme levels of polyphagy in host plant use, and thus can be used to further test the generality of the oscillation hypothesis as a suitable polyphagous insect group. In our studies, we firstly presented a broad-scale molecular phylogenetic framework for Lymantriinae by employing multi-locus sequence data and sampling 154 exemplars from 55 genera representing all recognized tribes drawn from all major biogeographic regions, proposed that the subfamily was composed of seven well-supported tribes: Arctornithini, Leucomini, Lymantriini, Orgyiini, Nygmiini, Daplasini and Locharnini, and revealed that Heracula discivitta, a mysterious taxon placed previously in Lymantriinae, represented a new subfamily of Pseudobistonidae. Based on the phylogenetic framework, we investigated the evolutionary patterns of host use at the order levels of plants in Lymantriinae using the method of comparative phylogenetic analysis between sister clades. Our results showed that Lymantriinae clades with higher diversity of host use contained more species than their sister clades, and these clades also consistently contained the most extremely polyphagous species, which meant the increased species diversity of Lymantriinae could be promoted by expansion of their host plant range. These results provided a further support for the oscillation hypothesis.

Results of faunistic studies in Lagodekhi Protected Areas

Authors: Japoshvili George, Professor, Director, Institute of Entomology, Agricultural University of Georgia, Tbilisi Head of the Board, Invertebrate Research Center, Telavi, Georgia

Abstract: The survey was completed during 2014 vegetation season in Lagodekhi Protected area. Seven Malaise traps were located in single transect from 500 to 3500 m asl and replaced every 10 days. From Arthropoda only Class Aracnida, orders Neuroptera and Mecoptera, and families Encyrtidae, Ichneumonidae (Hymenoptera) and Chrysomelidae (Coleoptera) has been identified completely to species level. Others such as families Eulophidae, Aphelinidae (Hymenoptera) are identified only partially. Total 699 species has been identified up to now. Fourteen are species new to science, 5 new genera records for Caucasus, 284 new species records for Caucasus and 146 new for Georgia. Thus Arthropod fauna of Georgia Increased by 5 genera and 444 species in total.

Halyomorpha halys (Hemiptera: Pentatomidae) in Georgia and potential for its biological control

Authors: Japoshvili George[2], Kirkitadze Giorgi[1], Salakaia Meri[1] and Arabuli Tea[1], [1]Institute of Entomology, Agricultural University of Georgia, Georgia, [2]Professor, Director, Institute of Entomology, Agricultural University of Georgia, Tbilisi Head of the Board, Invertebrate Research Center, Telavi, Georgia

Abstract: Since brown marmorated stink bug (Halyomorpha halys Stal) first appeared in Georgia in 2015, intensive chemical control measures have been applied for its management. During our study in the 2019 growing season, we found 15 species of Pentatomidae in Georgia, including at least four polyphagous pests: Graphosoma lineatum (L.), Halyomorpha halys Stal, Palomena prasina (L.) and Pentatoma rufipes (L.). Georgian literature records 71 species of Pentatomidae, including Nezara viridula (L.), which has quite wide host plant range as well. Except for H. halys, no any other pentatomid has been recorded as an important pest for Georgian agriculture, even though some other species have been found damaging different agricultural crops in neighboring countries. Biocontrol agents may be controlling some of these bugs. Literature surveys list ten species of Trissolcus (Platygastridae), which have been recorded from the Caucasus region and one more from Georgia in particular. Ooencyrtus telenomicida (Encyrtidae), which is considered as a potential effective natural enemy for H. halys, has also previously been recorded from Georgia. Therefore, these parasitoids may be important biocontrol agents of these pest stink bugs in Georgia, holding them below their economic thresholds. Our studies identified that damage by insects (including H. halys) on hazelnut was varied between 11-25% (loss of nuts), while damage by fungus was between 10-41%.

Omnivorous zoophytophagous and non-zoophytophagous phytoseiids can induce plant defense responses of interest for crop protection

Authors: Jaques Josep A.[1], Cruz-Miralles Joaquín[1] and Flors Víctor[1], [1]Universitat Jaume I, SpainI

Abstract: Citrus aurantium L. (sour orange) displays higher constitutive and earlier inducible direct defenses against the two-spotted spider mite, Tetranychus urticae Koch (Acari: Tetranychidae), than Citrus reshni hort. ex Tanaka (Cleopatra mandarin). We have characterized the response of these citrus species to three predatory mites (Acari: Phytoseiidae) co-occurring with T. urticae in citrus. These predators display different levels of specialization on this herbivore: Phytoseiulus persimilis (Athias-Henriot) is a strict entomophagous whereas Neoseiulus californicus (McGregor) and Euseius stipulatus (Athias-Henriot) are omnivores. The latter is suspected to engage in cell-sap feeding in citrus. We have characterized (1) the volatile blends associated to these mites and to plants harbouring them through gas-chromatography, (2) plant gene expression induced by these predators through qRT-PCR, (3) the behavior of these mites when exposed to the volatile blends produced by infested and uninfested plants in Y-tube two-choice tests, and (4) non consumptive-effects of these predators on the herbivore. As expected, zoophytophagous E. stipulatus was able to trigger genotype-dependent defensive responses in citrus similar to T. urticae. Likewise, the strict entomophagous P. persimilis was not. However, unexpectedly, omnivorous N. californicus could also activate citrus species-specific defensive responses. These responses included the production of different volatile blends triggering different behavioral responses in these mites. Furthermore, the presence of either N. californicus or E. stipulatus on the plant reduced T. urticae densities in distal leaves. Therefore, these mites can affect their potential prey beyond predation through plant-mediated non consumptive effects. Our results may pave the way to develop new more sustainable tools to manipulate these agriculturally relevant species.

Phytoseiids can induce plant defense responses of interest in crop protection

Authors: Jaques Josep A.[1], Cruz-Miralles Joaquín[1], Guzzo Michela[1], Flors Víctor[1] and Ibáñez-Gual M. Victoria[1], [1]Universitat Jaume I, Spain

Abstract: Recent studies have revealed that the generalist predator Euseius stipulatus (Athias-Henriot) (Acari: Mesostigmata: Phytoseiidae) can feed on citrus cell-sap while triggering plant defense responses similar to those elicited by one of its potential preys, Tetranychus urticae Koch (Acari: Prostigmata: Tetranychidae). Changes in the jasmonic acid, the salycilic acid, and the flavonoids defensive pathways occurred. Changes were also observed in the plant volatile blends induced by E. stipulatus, which did not prevent T. urticae, from choosing E. stipulatus-infested plants. Interestingly, another phytoseiid, Neoseiulus californicus McGregor (Acari: Mesostigmata: Phytoseiidae), which co-occurs in citrus with E. stipulatus but cannot feed on plant cell-sap, can induce similar defense responses. Changes in the volatile blends produced by plants infested with N. californicus were also observed and were repellent for the shared prey, T. urticae. The results obtained so far demonstrate that plant defense responses triggered by phytoseiids are species-specific, depend on plant genotype, and may be also triggered by activities different from plant-feeding. Studies aimed at understanding the mechanisms behind these responses could pave the way for the development of new sustainable and efficient tools to protect our crops.

Illuminating the unknown insect diversity – the GBOL III: Dark Taxa project

Authors: Jaume Santiago, Zoologischen Forschungsmuseums Alexander Koenig, Germany

Abstract: For the overall goal of species discovery, shedding light on „Dark Taxa“ is pivotal. Taxonomy delimits species and is a crucial component in this context. Modern integrative taxonomy needs morphology, DNA barcodes, genomes, life histories, and new researchers that continue tackling the overall goal with a deep understanding of organisms, methods, evolution, and species concepts.

GBOL III: Dark Taxa is a taxonomy and a DNA barcoding initiative funded by the German Federal Ministry of Education and Science (BMBF), the first of its kind, focusing solely on the understudied part of biodiversity.

After 10 years of study by professional and citizen scientists in previous project phases, about half of the animal species occurring in Germany are covered within the DNA Barcode libraries of the German Barcode of Life (GBOL). Even diverse groups like Coleoptera or Lepidoptera are well represented. Yet, considering the estimated number of species in Germany, only about 25% of Hymenoptera and about 33% of Diptera are covered in the GBOL barcode library, i.e., these abundant and megadiverse insect orders pose the largest Dark Taxa problems and are studied in GBOL III: Dark Taxa. This includes characterizing species, creating reference DNA barcodes, and training a new generation of taxonomists.

Fungal diseases in insect rearing for food and feed

Authors: Jensen Annette Bruun[1] and Lecocq Antoine[1], [1]University of Copenhagen

Abstract: Food security is one of the great challenge of the future. Insect production has been recognized as a sustainable solution and many new mass rearing facilities have been established worldwide in recent years. Insects, like all biological production systems, are challenged by pathogens and when thousands of insects are reared in high densities epidemics can develop. Therefore, management and prevention of existing and emerging insect diseases is urgently needed. The insect pathogenic fungi Metharizhium and Beauveria have for decades been used as biological control agents towards pest insects. These fungi have a broad host range and can infect insects produced for food and feed. We will show examples of our research with fungal infection in Acheta domesticus, Hermetia illucens and Tenebrio molitor. Acheta domesticus are relative resistant to infection by Metharizhium and Beauveria, but could be a trigger of the potent AdDV virus. Hermetia illucens larvae are highly resistant to fungal infection, whereas adults are susceptible to Beauveria resulting high mortality and decreased egg production. Tenebrio molitor are susceptible to fungal infection and certain probiotic bacteria has proven to increase survival and growth but also boost the insects immune response helping them to fight off Metharizium infections.

Effects of cold acclimation on predation and predator fitness

Authors: Jensen Kim, Aarhus University, Department of Animal Science, Denmark

Abstract: Biological control is well established and functional in greenhouses, but relatively little used in the outdoor environment. In the temperate zone, temperatures are often low especially in early spring when biological control agents should be released to prevent pest establishment. Furthermore, since the pest has not yet established, food is scarce and predators may starve. In a series of experiments using the soil predatory mite Gaeolaelaps aculeifer, we tested whether acclimation to cold would improve predator performance under cold conditions. This species is used in biological control against a range of soil-dwelling pests and occurs naturally in both southern and northern Europe. Our results showed that G. aculeifer had higher tolerance to severe cold following cold acclimation. Furthermore, starvation tolerance was improved. In contrast, the kill rate of prey and predator egg production were reduced following cold exposure. This was the case both when prey were the flour moth Ephestia kuehniella and the springtails Folsomia candida and Protaphorura fimata, the latter of which is a pest in lettuce and other crops. In the experiment on springtails, a significant interaction between prey species and test temperature showed that low temperature reduced kill rate and reproduction on fast prey (F. candida) more than on slow prey (P. fimata). Importantly, the negative impact of cold pre-exposure on kill rate and reproduction was also significantly higher when preying on the slow springtail than on the faster springtail. This indicates that the fast springtail was increasingly harder to catch relative to the slow springtail at lower temperature, but also following lower pre-exposure temperature of the predator. In contrast, prey thermal pre-exposure did not significantly affect predator kill rate nor reproduction, indicating that the ability of prey to escape was not reduced after exposure to low temperature. Our results show that cold acclimation positively affects predator robustness by increasing severe cold- and starvation tolerance and thus survival under challenging conditions such as expected in early spring. However, predator impact via individual kill rate and population growth were reduced following cold acclimation. Followup experiments further showed that a winter of constant mild cold (10°C) reduced predation and reproduction less than a temperate winter including down to 0.8°C exposure, and that the higher starvation tolerance following cold exposure was caused by larger lipid accumulation during cold but not by reduced metabolism following cold exposure. Based on our experiments, we recommend cold acclimating G. aculeifer for prevention of pest establishment in early spring where robust predators are advantageous to improve survival until the pest appears. However, if the pest is already established in the crop we recommend using standard, non-acclimated predators that are more voracious and have higher potential population growth.

Entomopathogenic fungi-mediated biological control of Spodoptera frugiperda

Authors: Jeon Insoo[2], Kim Jae Su[2], Im Yeram[2], Park Yulim[2], Jeong Yujin[1], Song Gahyeon[2], Kim Jong Cheol[1], KIm Kijung[1], Park Soeun[1], [1]1Department of Agricultural Biology, Jeonbuk National University, Korea, [2]Jeonbuk University, South Korea

Abstract: Fall armyworm, Spodoptera frugiperda is an invasive polyphagous pest derived from America. It has been annually invading Korea during summer since it was firstly reported in 2019. Biological control is one of the strategies to eradicate this serious lepidopteran insect. This study aims to assess the potential of entomopathogenic fungi as biological control agents against S. frugiperda. Ninety-three isolates of entomopathogenic fungi were selected to investigate their insecticidal activities against second instar larvae of S. frugiperda. Of the isolates, thirty-four isolates showed 100% mortality at 8 days after treatments in laboratory conditions. The productivity and thermotolerance of conidia cultured on 1/4 SDA were evaluated to figure out the potential for field application. About ten isolates were determined to have high virulence against S. frugiperda and reasonable fungal production. Of the ten isolates, two-isolate showed the virulence of 83.3% mortality to pupae at soil treatment test. Another two-isolate caused 93.3% and 86.7% of larval mortality. Herein, we evaluated the virulence of entomopathogenic fungi against different stages of S. frugiperda including larva and pupae. The results indicated that entomopathogenic fungi would be practical biological control agents for the management of S. frugiperda.

Production of Beauveria bassiana JEF-350 blastospores with high thermotolerance through liquid culture

Authors: Jeong Yujin

Abstract: Compared to fungal solid culture, liquid culture reduces production time and is easy to prevent contamination. However, it has been reported blastospores are generally unstable to external environments such as heat. In this study, the characteristics of Beauveria bassiana JEF-350 from different culture media were investigated to produce heat-resistant propagules. After liquid cultures of JEF-350 at SDB, SSYP, and YPG media for seven days, the productivity and thermotolerance of JEF-350 blastospores were investigated. Solid cultures at the same media served as controls. The blastospore productivity was the highest in SSYP-liquid medium (6.4×10^7 blastospore/㎠), conidia productivity was the highest in SSYP-agar medium (27.1×10^7 conidia/㎠). As a result of heat exposure of JEF-350 cultured in each medium to 45°C for 60 minutes, blastospores produced in SSYP-liquid medium showed the highest germination rate (22.6%) after being incubated on 1/4SDA for 18 hours. From a virulence test against T. palmi in laboratory conditions, the mortality of T. palmi on all treatments showed more than 95% in day 7 after fungal treatment. In conclusion, JEF-350 blastospores produced in SSYP-liquid medium were excellent in productivity, thermotolerance, and insecticidal activity against T. palmi. SSYP liquid medium was considered an excellent substrate to produce B. bassiana JEF-350.

Development of Push-Pull strategies for biting insect control

Authors: Jerry Zhu Junwei, USDA-ARS, AMRU Lincoln, Nebraska, United States

Abstract: Stable flies are one of the most important arthropod pests of livestock. With changing climate and agronomic practices, they expand their roles as pests and disease vectors as well. Their infestation reduces livestock productivity, annoy companion animals, and interfere with recreational activities.

Volatiles associated with cattle including dimethyl trisulfide, butanoic acid, p-cresol, skatole and especially 1-octen-3-ol have been reported previously to be attractive to stable fly adults. Recently, new compounds, such as phenol, p-cresol and m-cresol, from cattle manure slurry, have been identified and demonstrated with enhanced attraction in the field. Furthermore, stable fly outbreaks in crop residues including pineapple, cabbage, and sugarcane have also been reported. Volatiles released from those stable fly favorable larval development habitats are identified with different chemical profiles compared with livestock associated substrates, which indicates that stable fly use additional attractants associated with their development environments for host and habitat location.

Plant-based repellent compounds have been widely used against blood sucking insects in veterinary and public health fields. However, one of the biggest shortcomings of plant-based repellents are short-lived in their effectiveness. Therefore, it is necessary to discover and explore more resources of plant origins with extended longevity in repellency. In the last 10 years, we have discovered several long-lasting repellent compounds from coconut oil that can provide repellency lasting up to 2 weeks against several types of blood-sucking insects. Over 90% of repellency/feeding deterrence have been demonstrated against biting flies including stable flies and horn flies, ticks, mosquitoes, cockroaches and bed bugs. Some of these compounds' derivatives also act as strong bio pesticide that inhibit stable fly larval growth and deters female oviposition. In some cases, the strength of repellency from these natural repellent products is even stronger than the golden standard, universal insect repellent, DEET (N,N-Diethyl-3-methyl-benzamide).

In this presentation, I will report the results from several studies related to our primary project on "How to use the attractant- or repellent-based semiochemicals to develop an economically- and environmentally sound strategy for biting insect control, particularly against stable flies. I will also introduce several of our recent technology transfers with industry partners in developing novel technologies for stable fly infestation reduction and animal well-being via Push-Pull strategies.

Bioactivity of Smoke Waters towards Bactrocera oleae (Rossi) (Diptera: Tephritidae) adults.

Authors: Jesu Giovanni[2], Vinale Francesco[3], Salvatore Germinara Giacinto[1], Bonanomi Giuliano[2], Pistillo Marco[1] and Laudonia Stefania[2], [1]University of Foggia, Italy - Department: Sciences of Agriculture, Food and Environment, Italy, [2]University of Naples "Federico II", Italy - Department of Agriculture, Italy, [3]University of Naples "Federico II", Italy - Department of Veterinary Medicine and Animal Productions, Italy

Abstract: Biochar is a recent deeply studied material due to the opportunity to reuse raw materials. Smoke-Waters (SWs) obtained during the Biochar production process are currently sold since they have been shown to promote seed germination. In this study, effects of SWs obtained from 5 different materials: alfalfa, cellulose, maize, wood (Quercus ilex L.), and olive mill waste, each obtained at both 300° and 500°C were investigated. The SWs have been tested in two separate mixtures for their toxic and olfactory effects on the adult of the olive fruit fly (OFF), Bactrocera oleae (Rossi) (Diptera, Tephritidae). The first mixture (OLI) was made of olive mill waste 300° and 500°C SWs in equal parts, for the second one (MIX) we used equal parts of all the other remaining SWs.Bioassays to assess the toxicity of OLI and MIX on B.oleae were performed according to testing for oral and contact exposure. Ingestion assays were evaluated by adding a standard amount (200 µl) of MIX or OLI to a 0.6 g sucrose (10%) diet used to feed OFF adults. After 14 days, different degrees of toxicity by ingestion were recorded among the mixtures tested. In particular, MIX occurred the most toxic with a mean mortality of 35,42% (ds 26,68) on females. With subsequent oviposition tests on olives, there was recorded also a reduced number of punctures and an increase in those that were sterile for females treated with the MIX. No toxic effects were detected by contact, assessed by topical application of 0.5 µl on the thorax of adult insects (n = 30) and by checking mortality 24 and 48 hours later. EAG tests showed that the antennal olfactory systems of male and female OFF are able to perceive, in a dose-dependent manner, volatile compounds present in the different SWs. However, the more toxic (MIX) elicited the strongest EAG responses in both sexes. Interestingly, the same SW mixture exhibited a significant repellent effect towards OFF males and females. On the contrary, OLI was attractive almost as fresh olive. In 2019 preliminary field tests were carried out in two different italian regions with different pedoclimatic conditions during the period of activity of the pest until the harvest of the drupes. Adult catches of B. oleae, by yellow sticky traps activated with pheromones and ammonium salt, were significantly reduced by 85,63% and 82,89% compared to control by the simultaneous application of 3 MIX distributors per plant.

CZ-SK SOUTH LIFE: Optimalization of Natura 2000 sites management delivery in the South Bohemia Region and the territory of South Slovakia (LIFE16 NAT/CZ/000001)

Authors: Ježková Eva, South Bohemia Region, Czech Republic

Abstract: The ongoing threats to habitats and insect species in the 55 Natura 2000 networks sites targeted by this project include the abandonment of traditionally-managed pastures and meadows and their overgrowth with dense vegetation; the spread of invasive species; changes to water regimes in wetland and peat bog habitats caused by drainage; and intensive forest management and the removal of old trees. This transboundary LIFE project (CZ-SK) is improving the conservation status of EU priority woodland and grassland habitats to benefit priority species Osmoderma eremita and raised bog and bog woodland priority habitat for Carabus menetriesi pacholei through actions to improve the hydrological function of bog habitats, restore mowing and grazing regimes on grasslands, and tree-planting and invasive species removal in forests. The project intends to purchase 40 ha of land and enter into long term leases for a further 30 ha of land to increase long term security of some of the conservation actions.

In silico identification of neuropeptides and functional study of Adipokinetic hormones in termites

Authors: Jiang Shixiong[1], Marco Heather G, Scheich Nina, He Shulin, Gäde Gerd and McMahon Dino Peter, [1]Bundesanstalt für Materialforschung und –prüfung (BAM), Germany

Abstract: Termites are a diverse group of social insects. As with other insect groups, they possess different neuropeptide classes for regulating various physiological processes. To date, only two neuropeptidomes have been characterized in termites. Here, we aimed to carry out a comparative analysis of neuropeptides across the major termite lineages, including solitary cockroaches and subsocial wood roaches. We characterized the major classes of neuropeptides across these lineages, focusing particularly on a comparative molecular analysis of adipokinetic hormones (AKH) and their receptors (AKHR). Molecular evolutionary analyses and evidence of post-translational modifications (PTMs) of AKHRs are also discussed. We then examine the functional role of termite AKHs by measuring the mobilization of carbohydrates and lipids in the hemolymph of Reticulitermes flavipes following experimental injection with synthesized peptides. Finally, we explore interactions between AKH activity and host immunity by testing the effects of AKHR downregulation (dsRNA injection) on resistance to pathogen challenge.

Our study provides important information concerning the diversity of termite neuropeptides as well as the metabolic role of AKH and its intersection with host immune function. In addition to providing a fresh perspective on the feasibility of using AKHs as potential candidates for biorational pest control agents against invasive termites and cockroaches.

Production of recombinant human angiogenin using hyper-enhanced baculovirus expression system

Authors: Ji Ho Young[1], Woo Soo Dong[1], Im Jin Woong[1] and Kim Hyun Soo[1], [1]Chungbuk National University, Republic of Korea

Abstract: Human angiogenin is a single-chain basic protein consisting of 123 amino acids, belonging to the superfamily of RNase A, and has angiogenesis-inducing activity. Due to these characteristics, it can be applied to the treatment of diseases requiring new blood vessels, and the social necessity is expected to be high in the development of therapeutic substances and various fields. However, there are few reports on the production of recombinant human angiogenin in eukaryotes. In this study, recombinant human angiogenin was produced in insect cells and its activity was evaluated using a newly constructed hyper-enhanced baculovirus expression system and various expression-enhancing fusion partners. As a result, the production potential of human angiogenin in insect cells was confirmed, and the expression level increased by the fusion partner was observed. The activity of recombinant angiogenin, including RNase activity, was also evaluated.

Selection of entomopathogenic fungi against the green peach aphid, Myzus persicae, through simultaneous evaluation of virulence and environmental stability

Authors: Ji Ho Young[1], Lee Jin Yong[1], Woo Ra Mi[1], Kim Hyun Soo[1] and Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: The green peach aphid, Myzus persicae, is an economically important pest for agricultural and horticultural crops because this aphid causes direct damage by feeding on plant nutrients and indirect damage by transmitting many virus vectors. Control of this pest relies almost exclusively on the application of chemical insecticides. Unfortunately, the green peach aphid has developed multiple resistance to many chemical insecticides. Therefore, this study was conducted to select an entomopathogenic fungus effective against the green peach aphid as a new biological control agent. In order to select entomopathogenic fungi effective in controlling the green peach aphid, the virulence and environmental stability of conidia were evaluated for various fungal strains. For the first selected 20 fungal isolates, the most efficient isolates were selected through additional evaluation of thermal stability and UV stability of conidia. High environmental stability is expected to further increase the possibility of commercialization of the selected entomopathogenic fungi.

Juvenile hormone antagonistic activity of actinobacteria and their insecticidal activity against Plutella xylostella

Authors: Ji Kim Hyun[4], Park Min Gu[5], Hwan Park Dong[2], Young Choi Jae[2], Young Kim Jun[4], Wang Minghui[1] and Ho Je Yeon[3], [1]Department of Agricultural Biotechnology, College of Agriculture & Life Science, Seoul National University, China, [2]Department of Agricultural Biotechnology, College of Agriculture & Life Science, Seoul National University, Seoul 08826, Republic of Korea, South Korea, [3]Department of Agricultural Biotechnology, College of Agriculture & Life Science, Seoul National University, Seoul 08826, Republic of Korea. Research Institute f, [4]Department of Agricultural Biotechnology, College of Agriculture and Life Science, Seoul National University, South Korea, [5]Seoul National University, South Korea

Abstract: agricultural pests causes serious damage to crops and economical losses. chemical insecticides were widely used to control pests. However, due to their toxicity to the environment and the development of insect resistance. Insect growth regulators are friendly alternatives to traditional chemical insecticides because of their specification to target insects and low toxicity to non target organisms. However, juvenile hormone agonists causes increased economic damage to crops because of their status quo effect. Recently, novel IGR compounds with juvenile hormone antagonist activity which can effectively control agricultural pests was discovered.

In this study, to identify novel IGR compounds from actinobacteria, culture media of 1,904 actinobacteria isolated from Korean soil samples were discovered for their juvenile hormone (JH)-based IGR activities. Among them, 4 isolates showed insecticidal activity with Juvenile hormone antagonist activity. Identification and characterization of these actinobacteria was performed.

Natural selection has driven the recurrent loss of an immunity gene that protects Drosophila against a common natural parasite

Authors: Jiggins Francis[1], Arunkumar Ramesh[1], Leitao Alexandre[1] and Day Jon[1], [1]University of Cambridge, United Kingdom

Abstract: Parasitoid wasps are common natural enemies of Drosophila melanogaster, and yet most genotypes in nature are susceptible to infection. We have identified a gene that encodes a lectin that is expressed in the fat body and localises to the surface of the parasitoid egg before the attachment of hemocytes. When we mutated this gene, the flies became susceptible to infection. In natural populations multiple alleles of this gene contain deletions to cis-regulatory elements that reduce expression or premature stop codons, and in southern Africa natural selection has driven these loss of function mutations to high frequency. We conclude that in some populations there is a selective advantage to losing an important component of the anti-parasitoid immune system.

The evolution of parasitoid resistance in Drosophila

Authors: Jiggins Frank[1], Leitao Alex[1], Ramesh Arunkumar[2] and Day Jon[1], [1]University of Cambridge, United Kingdom

Abstract: Parasitoids are likely the most important natural enemy of Drosophila melanogaster, and there is considerable genetic variation within and between populations in susceptibility to infection. Using the parasitoid Leptopilina boulardi we have investigated how changes to the activation of the cellular immune response can underlie the evolution of parasitoid resistance. Using single cell RNA sequencing of immune cells called hemocytes, we found that genetically resistant populations have constitutively activated cellular immune systems. By partially bypassing the steps of recognition, signalling and cell differentiation, this may allow the parasitoid to be killed more rapidly. A second mechanism of resistance is associated with a cis-regulatory polymorphism upstream of a gene encoding a putative pattern recognition receptor. In resistant genotypes this gene is massively upregulated after infection, and this is associated with a more rapid immune response. We conclude that changes to the recognition of infection and activation of cellular immunity both play key roles during the evolution of resistance.

Unique peptidic agonists of a juvenile hormone receptor with species-specific effects on insect development and reproduction

Authors: Jindra Marek[2], Tumova Sarka[2], Milacek Matej[5], Muthu Magesh[3], Tuma Roman[5], Snajdr Ivan[4], Novotna Adela[4], Jedlicka Pavel[4], Bittova Lenka[1], Majer Pavel[4] and Sedlak David[3], [1]Biology Center, CAS, [2]Biology Centre CAS, Czech Republic, [3]CZ-OPENSCREEN, Institute of Molecular Genetics, CAS, [4]Institute of Organic Chemistry and Biochemistry, CAS, [5]University of South Bohemia

Abstract: Juvenile hormones (JHs) act through a receptor complex consisting of methoprene-tolerant (Met) and taiman (Tai) proteins to induce transcription of genes including Kr-h1. Among diverse synthetic JH mimics (juvenoids), peptidic juvenoids stand out as highly potent yet uniquely selective to a specific family of true bugs. Their mode of action is unknown. Here we demonstrate that, like established JH receptor agonists, peptidic juvenoids induce expression of Kr-h1 and act upon Met to halt metamorphosis in the linden bug, Pyrrhocoris apterus. Peptidic juvenoids induce dimerization between Met and Tai proteins from P. apterus but, consistent with their selectivity, not from other insects such as the beetle, Tribolium castaneum. Our models for the ligand-binding pockets of Met orthologs from P. apterus and T. castaneum suggest a structural basis for the selective action of peptidic juvenoids. We synthesized >100 new derivatives, many of which acted at sub-nanomolar range and outperformed existing juvenoids including fenoxycarb. Importantly, their potency in inducing Met-Tai interaction correlated with the biological activities in live bugs. Our data establish peptidic juvenoids as highly effective and species-selective JH receptor agonists.

Supported by grant 20-05151X (Czech Science Foundation) and project LM2018130 (MEYS) to the National Infrastructure for Chemical Biology CZ-OPENSCREEN.

Development of novel pest controlling strategies targeting dietary sterol absorption

Authors: Jing Xiangfeng[2] and Zheng Jin-Cheng[1], [1]Guizhou University of Traditional Chinese Medicine, China, [2]Northwest A&F University, China

Abstract: Cholesterol exists as the major sterol in animals including insects. It is essential because it is not only one of the structural components in the cellular membrane but also serves as signaling molecules in eukaryotic cells. Moreover, it is the precursor to the molting hormones. However, unlike mammals, insects cannot synthesize cholesterol because of the loss of the biosynthesis genes. Therefore, dietary sterol uptake is critical for insect survival and growth. Insects and mammals seem to share the conserved dietary sterol uptake mechanism. We identified insect orthologs to the key factors of the NPC1L1-flotillin complex involved in sterol uptake in mammals by comparative genomic analyses. We investigated the function of these orthologs, i.e., NPC1b and flotillin, in a lepidopteran pest, Helicoverpa armigera. First, we confirmed that the insect cannot grow and did not eat much if dietary cholesterol supply was reduced. We then used CRISPR/Cas9 technology to investigate the functions of these genes. Compared to the wild-type insects, the CRISPR/Cas9-edited mutant larvae seemed to have problems in acquiring dietary cholesterol and NPC1b mutants died in the early stage. NPC1b was mainly expressed in the midgut verified by gene expression analyses and in-situ hybridization analyses, indicating that the midgut was the major region for dietary sterol absorption. NPC1b expression was especially upregulated during early larval instars but dropped in the following instars. This variation may be associated with the sterol nutritional status. Interestingly, the substrate binding regions of NPC1b proteins, NPC1b_NTD, are relatively conserved among lepidopteran insects but highly divergent from bees-derived sequences. Therefore, NPC1b and other factors involved in dietary sterol uptake can be promising targets for the development of novel pest-management approaches to control economically significant lepidopteran pests with little off-target effect on bees and sterol-autotrophic mammals.

Review of the subfamily Hypenodinae (Lepidoptera: Erebidae) in Korea

Authors: Ji-Young Lee[1] and Bong-Kyu Byun[1], [1]Hannam University, South Korea

Abstract: The aim of this study was to review of the subfamily Hypenodinae in Korea. This group has small sized moth with wingspan 5.5-12mm, belonging to the family Erebidae. They are known as distributed only in the Holartic region, including temperate zone of eastern Asia (Fibiger, 2011). However, the subfamily Hypenodinae of Korea has been poorly studied to date, including the larval information, host plants and so forth. In this study, totally 13 species of 7 genera under 2 tribes were recognized from Korea. Among them, 2 subspecies are described as new to sciences from Korea. All the known species are redescribed with their available information, including images of adults and genitalia of all species and key to the species.

UCE phylogenomics to elucidate the evolution of wing coloration patterns in the geometrid tribe Palyadini (Ennominae)

Authors: Joele Alves de Moraes Flavia Rossina[1], Martis Dias Filho Manoel[3], Garzón-Orduña Ivonne J.[2], [1]Taxonomic Collection of the Department of Ecology and Evolutionary Biology (DCBU), Department of Ecology and Evolutionary Biology (DEBE), Federal University of, Brazil, [3]Universidade Federal de São Carlos (UFSCar), [2]Universidad Nacional Autónoma de Mexico (UNAM)

Abstract: The evolution and development of butterfly wing color patterns have been extensively studied across multiple fields in Biology. In contrast, the evolution of wing color patterns in “moths'' has been traditionally less explored. In this ongoing study, we are investigating the evolution of wing color patterns in the geometrid tribe Palyadini, a group that is characterized by having various wing color patterns formed by metallic scales. For this, we generated a phylogenetic hypothesis based on ultraconserved elements (UCEs) and using a wide taxon sampling that includes the six genera belonging to the tribe and multiple outgroups. We use this cladogram to identify patterns of character change of multiple color elements such the presence and absence of eyespots on the dorsal surface of the hindwing. The preliminary results of this study represent a window to the sparse knowledge about wing color evolution outside Papilionoidea.

Temporal variation in spatial genetic structure during population outbreaks: distinguishing among different potential drivers of spatial synchrony

Authors: Johns Robert[5], Cusson Michel[3], Larroque Jeremy[1], Lumley Lisa[6], M.A. James Patrick[2], C. Levesque Roger[4], Renaut Sebastien[1] and Legault Simon[1], [1]Department of Biological Sciences, University of Montreal, Canada, [2]Faculty of Architecture, Landscape, and Design (Forestry), University of Toronto, Canada, [3]Laurentian Forestry Centre, Natural Resources Canada, Quebec City, QC, Canada, [4]Laval University, Canada, [5]Natural Resources Canada, Canadian Forest Service, Fredericton, New Brunswick, Canada, [6]Royal Alberta Museum, Edmonton AB, Canada

Abstract: Spatial synchrony is a common characteristic of spatio-temporal population dynamics across many taxa. While it is known that both dispersal and spatially autocorrelated environmental variation (i.e., the Moran effect) can synchronize populations, the relative contributions of each, and how they interact, is generally unknown. Distinguishing these mechanisms and their effects on synchrony can help us to better understand spatial population dynamics, design conservation and management strategies, and predict climate change impacts. Population genetic data can be used to tease apart these two processes as the spatio-temporal genetic patterns they create are expected to be different. A challenge, however, is that genetic data are often collected at a single point in time, which may introduce context-specific bias. Spatio-temporal sampling strategies can be used to reduce bias and to improve our characterization of the drivers of spatial synchrony. Using spatio-temporal analyses of genotypic data, our objective was to identify the relative support for these two mechanisms to the spatial synchrony in population dynamics of the irruptive forest insect pest, the spruce budworm (Choristoneura fumiferana), in Quebec (Canada). AMOVA, cluster analysis, isolation by distance and sPCA were used to characterize spatio-temporal genomic variation using 1370 SBW larvae sampled over four years (2012-2015) and genotyped at 3,562 SNP loci. We found evidence of overall weak spatial genetic structure that decreased from 2012 to 2015 and a genetic diversity homogenization among the sites. We also found genetic evidence of a long-distance dispersal event over > 140 km. These results indicate that dispersal is the key mechanism involved in driving population synchrony of the outbreak. Early intervention management strategies that aim to control source populations have the potential to be effective through limiting dispersal. However, the timing of such interventions relative to outbreak progression is likely to influence their probability of success.

Proviral and antiviral microRNAs impact the outcome of infection with diverse RNA viruses

Authors: Johnson Karyn, School of Biological Sciences The University of Queensland, Australia

Abstract: Insects host a variety of viral infections and can act as vectors of virus disease. The small RNA pathways can be important regulators of the outcome of infection in insect hosts. miRNAs are recognised as widespread regulators of gene expression across many biological functions including antiviral defence and immunity. miRNAs are 22 nucleotide non-coding RNAs that are transcribed from the genome and bind in a sequence-specific manner to the target messenger RNAs. miRNAs act as guides for effector complexes, enabling modulation of gene expression primarily via mRNA decay or translational inhibition. Using the Drosophila model, we have demonstrated that two miRNAs (miR-956-3p and miR-8-5p) can have considerable impact on virus infection, one being proviral and the other antiviral. However, the influence of the vast majority of miRNAs on virus infection remains untested and it is not yet known whether there is generality in the influence miRNAs across diverse viruses. The recent development of genetic tools in Drosophila made the possibility of functional analysis of a large number of miRNAs in whole flies achievable. We conducted an unbiased screen of Drosophila miRNA loss-of-function lines. We challenged the flies with three different virus families: Drosophila C virus (family Dicistroviridae), Flock House virus (family Nodaviridae) or the arbovirus Sindbis virus (family Togaviridae). This study provides answers to questions about the proportion of miRNAs that impact virus infection, and to what extent the impact of the miRNAs is conserved across diverse virus families.

Phylogenomics of the Hemipteroid Insects

Authors: Johnson Kevin, Illinois Natural History Survey, University of Illinois, United States

Abstract: The hemipteroid insect orders (Psocodea, Thysanoptera, and Hemiptera) comprise a diverse assemblage of over 120,000 species with a diversity of feeding habits. New phylogenomic datasets are revealing insights into the evolutionary history of this group at a variety of timescales. At the deepest level, a transcriptome dataset of over 2300 genes for around 200 species provides support for backbone relationships within and among these orders. A sister relationship between Thysanoptera and Hemiptera is strongly supported, while the position of Psocodea remains uncertain. Within Hemiptera, Sternorrhyncha is sister to all remaining suborders, and Coleorrhyncha is sister to Auchenorrhyncha. For small-bodied insects for which transcriptome sequencing is not feasible, whole genome shotgun sequencing approaches can yield gene assemblies to produce similar datasets. Additional uses of these genomic datasets include read-mapping to identify polymorphic sites for population genomic analyses and assembly of bacterial symbiont genomes to uncover repeated replacement of these symbionts and consequences for molecular evolution.

Increased toxicity to honey bees of insecticides, fungicides and adjuvants applied to almonds during bloom

Authors: Johnson Reed[2], Lin Chia-Hua[1] and Walker Emily[3], [2]Department of Entomology, The Ohio State University, United States, [1]Department of Entomology, The Ohio State University, United States, [3]Environmental Sciences Graduate Program, The Ohio State University, United States

Abstract: Beekeepers providing honey bees to pollinate almonds continue to experience unacceptable losses of adult and developing bees, sometimes resulting in colony failure. Many beekeepers attribute these losses to exposure to insecticides, fungicides, spray adjuvants and combinations of all three, that are applied during bloom. Results indicate that particular combinations of fungicides and insecticides, particularly Altacor and Tilt, have the potential to kill adult bees when sprayed directly and larvae when fed contaminated diet. Addition of the adjuvant Dyne-Amic makes this combination more toxic, causing adult mortality at levels below the maximum label rate. The effects observed may explain some of the problems beekeepers are experiencing during and after almond bloom and provide support for recommendations to avoid using insecticides and adjuvants during bloom.

Identification of a potentially novel subclass of insect cys-loop ligand-gated ion channels

Authors: Jones Andrew[1], Mitchell Eleanor[1], Viscarra Franco[2], Goodchild Jim[3], Hawkins Joseph[3] and Bermudez Isabel[1], [1]Oxford Brookes University, United Kingdom, [2]University of Oxford, [3]Syngenta,

Abstract: Introduction: Members of the cys-loop ligand-gated ion channel superfamily, such as nicotinic acetylcholine receptors (nAChRs), are targets of highly effective insecticides. Heterologous expression of these receptors provides useful insights into their functional and pharmacological properties.

Methods: Phylogenetic analysis of insect nAChR gene families has identified the alpha5 subunit in non-Dipteran species (cockroaches, beetles, moths and bees) as being potentially part of a novel sub-group of ion channels. In order to determine their functional and pharmacological properties, the alpha5 subunit from the honey bee, Apis mellifera, was heterologously expressed in Xenopus laevis oocytes, to which was applied two-electrode voltage-clamp electrophysiology.

Results: The A. mellifera alpha5 nAChR subunit expresses robustly in X. laevis oocytes without the need for co-expressing with chaperone proteins. The alpha5 receptor has low sensitivity to acetylcholine with an EC50 of 2.37 mM and is insensitive to the agonist actions of neonicotinoids and the modulatory actions of spinosad. However, serotonin and other biogenic amines, such as dopamine, act as agonists with a considerably lower EC50 in the micro molar range that are also more efficacious than acetylcholine in activating the receptor. Molecular modelling indicates that residues in the complementary binding site may be involved in selectivity towards serotonin.

Discussion: This is the first report of a ligand-gated ion channel activated by biogenic amines from an insect. The study, therefore, highlights a distinct subgroup of ion channel subunits present in certain non-Dipteran insects with unusual pharmacological properties, which may represent targets for the development of novel classes of insecticides.

Baculovirus manipulation of plant defenses and impacts on insect behavior and performance

Authors: Jones Asher[3], Felton Gary W.[1], Mason Charles[2], Shikano Ikkei[4] and Hoover Kelli[2], [1]Department of Entomology Pennsylvania State University, United States, [2]Department of Entomology, Penn State University, United States, [3]Department of Entomology, Penn State University, United States, [4]Department of Plant and Environmental Protection Sciences, University of Hawai'i at Manoa, United States

Abstract: Baculoviruses are arthropod-specific viruses that often target lepidopteran larvae and can be used as biological control for agricultural plant pests. Viral infections cause larval body tissues to liquify and the cadavers release millions of viral occlusion bodies (OBs) and bacteria onto plant surfaces. Healthy larvae ingest OBs which dissolve in the gut, releasing virions that invade midgut cells and establish systemic infections. Interactions between insects and baculoviruses can be modulated by plants. For example, plant defensive compounds including polyphenol oxidase (PPO), peroxidases, and quinones can reduce viral efficacy in the insect midgut. These tritrophic interactions may also function in the opposite direction, whereby baculoviruses manipulate plant defense traits to enhance efficacy or alter host behaviour or performance in a manner that enhances the likelihood of viral transmission.

We explored plant–insect–baculovirus interactions using cabbage looper (Trichoplusia ni) caterpillars, tomato (Solanum lycopersicum), and Autographa californica multiple nucleopolyhedrovirus (AcMNPV). We hypothesized that virus-killed T. ni cadavers (VK) suppress plant defenses and alter behavior and performance of healthy T. ni. We applied water, homogenized VK, or homogenized freeze-killed (FK) cadavers to tomato plants that were undamaged or mechanically damaged. Damaged plants that received water or FK cadavers had significantly higher levels of PPO activity compared to undamaged plants ($F = 4.67$, $P = 0.0007$). However, the induction of PPO was suppressed in the VK treatment. By suppressing the induction of PPO, we hypothesized that AcMNPV increases the attractiveness of plants for oviposition or larval feeding. We present data from neonate choice assays, no-choice performance bioassays, and moth oviposition experiments to examine these hypotheses.

Because VK cadavers contain both OBs and bacteria, we also conducted experiments to explore the roles of these microbes in mediating plant defenses. We found that VK cadavers had significantly more bacterial colony-forming units per mg tissue than FK cadavers ($t = 4.90$, $P < 0.0001$). Using Illumina MiSeq high throughput sequencing, we also compared bacteriomes between VK and FK cadavers to determine how virus infection alters the composition of bacterial communities present in dead insects. To disentangle the role of OBs and bacteria in mediating plant defenses, we will explore plant responses to the application of varying concentrations of purified OBs and bacteria separately.

Our study provides evidence that microbial natural enemies can alter plant traits directly, and highlights the complex roles that bacteria and viruses play in mediating plant–insect interactions.

Getting out of a sticky situation: Peppermint Stick Insects adjusting chemical defensive behaviour relative to predatory threat

Authors: Jones Braxton[1] and Bulbert Matthew[1], [1]Department of Biological Sciences, Macquarie University, Australia

Abstract: Flight initiation is a decision made by prey to deploy defensive tactics during a predator attack. As this predator-prey interaction effects the survival of the prey, there is strong evolution for these defensive strategies. When considering the importance of such a strategy, the timing of when this defence is used in a predator attack is also critical. Accordingly, the ‘flight initiation hypothesis’ describes the ability for prey to choose optimal times to ‘fight or flight’ based on the costs and benefits of either option. This decision-making process relies on the defence strategy being used, where the prey is in relation to its refuge, where the predator is and the speed at which a predator attacks. Whilst this concept is extensively researched among defence strategies, there is no understanding for where chemical defence fits in this hypothesis. By looking into the chemical defence of the Peppermint stick insect (Megacrania batesii), we will use this insect as a model to bring chemical defences into light with flight initiation. Experiments on wild individuals were conducted to examine the relationship between likelihood of spraying relative to distance and slope to refuge. We further considered sex differences, and variation in reproductive preferences of multiple populations (Population 1: sexual, Population 2: asexual). Our presentation will attempt to showcase phasmids as a model taxa for examining the evolution of chemical defences and the genus Megacrania as an excited taxonomic group for examining both dispersal and defensive strategies in Phasmids.

Task allocation by age in Australian native bee colonies

Authors: Jones Lachlan, University of Queensland, Australia

Abstract: In large social insect colonies, effective division of labour is a critical hurdle. Queens of most eusocial species are entirely occupied by laying eggs. The workers, which can number tens of thousands, must therefore coordinate their activities to store food, maintain and defend the colony nest. While many ants rear worker castes of different sizes and morphologies to carry out specific tasks, other insects such as honeybees and stingless bees (Melliponini) progress through each task as they age. Here I present behavioural observations with two species of Australian stingless bee, Tetragonula carbonaria and T. hockingsii. I aimed to define the age range for each distinct behaviour or task carried out by worker bees. I extracted and marked newly emerged adult bees (callows) with coloured paint before releasing them back into wooden observation hives. I then regularly observed activities of marked bees through and observation window and hive entrance tube. While there was substantial overlap in the ages of bees carrying out different behaviours, both bee species progressed similarly through tasks from brood care to food pot and hive structure construction and eventually foraging, with numerous other rarer behaviours.

Abundance decline corresponds with reduced biodiversity in hoverflies, but not in aquatic insects

Authors: Jongejans Eelke, Radboud University, Netherlands

Abstract: Whether declines in insect abundance reflect biodiversity loss is still an open question. We analyse the abundance of hoverflies, at six locations in wet or tall perennial meadows in the German Wahnbachtal in 1989 and 2014, and over multiple years since 1982 in a Dutch forest. We show isometric decline rates between total insect biomass and total hoverfly abundance and a scale-dependent decline in species richness, ranging between −23% over the season to −82% at the daily level. Observed persistence rates were disproportionately lower than expected for species of intermediate abundance, while the rarest species showed decline and appearance rates consistent with random expectation. Contrastingly, aquatic insect communities in the Netherlands showed increasing richness and diversity since 1990, even though abundance declined by -55%. Improved water quality after heavily polluted and eutrophic conditions by the 1980s, can explain much of these patterns. Abundant taxa that tolerate poor water quality declined strongly, while positive indicator taxa were found more often and increased in abundance. This suggests that insect communities can bounce back at least partially when proper management is applied. Adequate target values for pristine communities are lacking though, while water quality is still insufficient in half of the samples.

Effects of intensified agriculture on weed seedbank regulation by seed predators

Authors: Jonsson Mattias[5], Feit Benjamin[5], Daouti Eirini[5], Skuhrovec Jiří, van der Werf Wopke[3], Rennstam Rubbmark Oskar, Carbonne Benjamin, Wallinger Corinna, Traugott Michael , Petit Sandrine, Bohan David A., Neidel Veronika[6], Saska Pavel[4], Foffová Hana[1] and Bommarco Riccardo[2], [1]Crop Research Institute, Czech Republic, [2]Department of Ecology, Swedish University of Agricultural Sciences, Sweden, [3]Department of Plant Sciences, Wageningen University, [4]Functional Diversity group, Crop Research Institute, Czech Republic, [5]Swedish University of Agricultural Sciences, Sweden, [6]University of Innsbruck, Austria

Abstract: Agricultural intensification has markedly increased the productivity of a few commodity crops but taken a heavy toll on the environment by reducing biodiversity and its associated ecosystem services, such as pollination and biological pest control. Weeds are a major constraint to intensified crop production and can cause substantial yield losses. Consequently, farmers have a vested interest in minimising weed load and thus fields are intensively managed. It has been suggested that abundant seed predator communities can reduce the size of annual weed seedbanks but it remains unclear how agricultural intensity impacts weed regulation and service provisioning by the seed predators. Using data derived from a large scale study of 60 cereal fields across Europe, and combing combining molecular gut content analysis with metabolic theory we compute a metric of seed predation strength that links the performance of seed predator communities to the provision of weed regulation. We then investigate how three aspects of agricultural intensity (field management intensity, landscape heterogeneity, and crop rotation simplification) affect weed seedbank regulation via effects on seed availability and seed predation strength. Our results provide compelling evidence that intensive agriculture reduces seed predation strength, which has a positive effect on weed seedbank regulation. Increased field management intensity, crop rotation simplification, and reduced landscape diversity all directly or indirectly reduced seed predation strength with cascading negative effects on weed seedbank regulation.

Effects of elevated CO2 on the life table parameters and population transition of Riptortus pedestris (Fabricius) (Hemiptera: Alydidae)

Authors: Joon Ahn Jeong[1], San Choi Kyoung[1] and Koh Sangwook[1], [1]Research Institute of Climate Change and Agriculture, National Institute of Horticultural and Herbal Science, RDA, South Korea

Abstract: Riptortus pedestris (Fabricius) (Hemiptera: Alydidae) is one of economically important insect pests in soybean field. We investigated the effects of elevated CO2 levels (400, 600, 1000, 1500 and 2000ppm) on the development periods, fecundity and life table parameters of R. pedestris. We collected life table data, log stage structure curves and stage growth rate for R. pedestris using viable eggs and the age-stage, two-sex life table method. R. pedestris developed successfully from the egg to the adult stage in the range of 400~2000ppm. Egg and pre-adult duration of 400ppm were longer than those of other concentrations. Overall female life span was also longest at 400ppm but overall male life span was longest at 600ppm. Although oviposition days and eggs per female were decreased with increasing CO2 concentrations, eggs per oviposition day, net reproductive rate, intrinsic rate of increase and finite rate of increase were increased at the higher CO2 concentrations. We concluded that the R. pedestris population size may be increased within elevating CO2 concentration at atmospheric environment.

The historical role of Madagascar in the diversification of Afrotropical bark and ambrosia beetles

Authors: Jordal Bjarte, University of Bergen, Norway

Abstract: Madagascar is well known for its high endemicity of plants and animals. The origin of the Malagasy fauna is nevertheless poorly known for insects and other arthropod groups. The origin of endemic lineages was likely fostered by rare overseas dispersal, primarily from the African mainland. Due to a shift in the wind and current direction after the island drifted northwards during the Oligocene, it has been argued that colonization from Africa to Madagascar should be older than Miocene age and more recent faunal interchange have occurred from Madagascar to the mainland. Here we show that bark and ambrosia beetles in Madagascar have many different colonization histories. Based on molecular phylogenetic analyses of 11 beetle lineages, we reconstructed the ancestral distribution and approximate age for traversing the Mozambique channel. While a few lineages in Madagascar may be older than 50 Ma, others arrived on this island during the last 10 Ma. The most frequent pattern was colonization of Madagascar in the Paleogene and recent dispersal back to the mainland during the Neogene – in line with biogeographical theory for the area. The recolonization of the mainland generated increased overall diversity and illustrates how the island function as a diversification agent in the Afrotropics.

Potential role of insect growth regulators on Stephanitis pyrioides (Hemiptera: Tingidae)

Authors: Joseph Shimat V., University of Georgia, United States

Abstract: The azalea lace bug, Stephanitis pyrioides (Scott) (Hemiptera: Tingidae), is an important insect pest of azaleas (Rhododendron L. spp.) in the USA. Stephanitis pyrioides feeds on azalea foliage and causes extensive chlorosis, which reduces the aesthetic value and marketability of these plants. Because the use of neonicotinoid insecticides has been dramatically reduced or discontinued, growers and landscape managers are seeking alternative tools or strategies to control this insect. Although insect growth regulators (IGRs) are known for their activity against immature insect stages, their transovarial, ovicidal or nymphicidal activity has not been addressed thoroughly, specifically against S. pyrioides. Thus, a series of experiments was conducted to understand the transovarial, ovicidal or nymphicidal activity of IGRs using novaluron, azadirachtin, pyriproxyfen and buprofezin against S. pyrioides. A low number of S. pyrioides young instars was produced when adults were exposed to topical novaluron compared with non-treated adults. When adults contacted dried residues of novaluron and buprofezin, production of young instars was reduced relative to non-treated controls. When insects exposed to 1.0× and <1.0× doses of novaluron were compared, the number of young instars produced was similar. The number of newly emerged young instars was significantly lower when leaves implanted with eggs were sprayed on both sides with novaluron, azadirachtin and buprofezin compared to nontreated and pyriproxyfen treatments. When IGRs plus adjuvant were applied to the adaxial surface of the leaves, the densities of the newly emerged nymphs were significantly lower under the novaluron treatment compared to the nontreated leaves. However, there was no significant difference in the number of nymphs that emerged in the absence of adjuvant. Furthermore, close monitoring revealed reduced levels of egg hatching in the presence of adjuvant with novaluron compared to its absence. The data show that the survival of S. pyrioides 1st instars was not affected by exposure to dried IGR residues.

Parasitism and predation of Halyomorpha halys egg masses in woodlands, and orchard, vineyard, row, and vegetable crops in the southeastern US

Authors: Joseph Shimat V.[3], Toews Michael[3], Sial Ash[3], Blaauw Brett[3], David Buntin[3], Talamas Elijah[2], Kesheimer Katelyn[1] and Balusu Rammohan[1], [1]Auburn University, United States, [2]Florida Department of Agriculture and Consumer Service, United States, [3]University of Georgia, United States,

Abstract: Reproductive populations of Halyomorpha halys (Stål), are rapidly building in the Piedmont and expanding into Coastal Plains Regions of Georgia and Alabama. Consequently, this study was conducted to evaluate parasitism and predation of H. halys sentinel egg masses by indigenous parasitoids and predators in woodland habitats and orchard, vineyard, row, and vegetable crops alongside these habitats in the southeastern US. Laboratory-reared H. halys egg masses were hung as sentinels on plants for 48-72 h. In the laboratory, retrieved egg masses were examined for predation and held for emergence of adult parasitoids. Of the ten parasitoid species, Anastatus reduvii (Howard), Anastatus mirabilis (Walsh & Riley), Trissolcus brochymenae (Ashmead), and Trissolcus euschisti (Ashmead) were the most prevalent ones in woodland and orchard habitats. Trissolcus edessae Fouts occurred primarily in orchards. Telenomus podisi Ashmead and Ooencyrtus sp. were the predominant species in row crops. Trissolcus basalis (Wollaston) and Gyron obesum Masner were mainly present in vegetables. Trissolcus solocis Johnson and Trissolcus basalis (Wollaston) are new records for H. halys eggs. Gryllidae, Acrididae, and Tettigoniidae fed on eggs in field, and complete chewing damage characteristic of these taxa was detected on retrieved eggs. Some egg masses exhibited incomplete chewing predation characteristic of Coccinellidae, Carabidae, and Dermaptera. Anthocoridae, Geocoridae, and Pentatomidae fed on eggs in the field resulting in stylet sucking predation. Some sentinel eggs exhibited typical puncture sucking predation by Salticidae. Solenopsis invicta Buren removed eggs from egg masses in cotton and soybean. At times, percent parasitism was higher for blueberry compared to other crops except for peach and apple. Percent predation was higher in soybean and cotton than in other crops. Generally, predation was higher than parasitism, and chewing predation was the most prevalent type of predation. In conclusion, native stink bug parasitoids and predators are serving as biological control agents of H. halys in the southeastern USA.

Seasonal occurrence of Drosophila suzukii and pesticide use pattern after its invasion in small fruit crops

Authors: Joshi Neelendra[3], Demchak Kathleen[2] and Biddinger David[1], [1]Entomology, Penn State Fruit Research & Extension Center, Biglerville, PA, USA, [2]Pennsylvania State University, University Park, Pennsylvania, 16802, USA, [3]University of Arkansas, Dept. of Entomology & Plant Pathology

Abstract: Drosophila suzukii (Diptera: Drosophilidae) is a major invasive pest of caneberries (e.g., blackberries and raspberries) and other thin-skinned small fruit crops. In recent years, it has been reported as an economically important fruit pest in many countries. In caneberries, timely detection and management of invasive insect pests like D. suzukii is important to maintain profitability and to avoid fruit export restriction. Invasions by such new pest species in commercial crop production often changes pesticide use patterns and frequency as growers try to control pest populations on their farms. In this study, we examined the seasonal population of D. suzukii and pesticide use patterns before and after D. suzukii invasion in primocane-fruiting raspberry and floricane-fruiting blackberry crop production in Pennsylvania. The result of seasonal monitoring conducted over two years showed higher populations of D. suzukii fruit flies during the period of invasion. Evaluation of crop-specific pesticide programs showed increase in the pesticide use frequency com-pared to the crop season before D. suzukii invasion in the blackberry planting. Similarly, over fivefold increase in pesticide application was recorded in the raspberry planting in the year following invasion. Implications of increased pesticide use patterns in small fruits production will be discussed and presented.

Habitat enhancement strategies for conservation and management of pollinators in tree fruit orchards

Authors: Joshi Neelendra[5], Heller Sarah[4], Leslie Timothy[1], Rajotte Edwin[2] and Biddinger David[3], [5]University of Arkansas, Dept. of Entomology & Plant Pathology, [1]Department of Biology, Long Island University, New York, USA, [2]Department of Entomology, Pennsylvania State University, PA, USA, [3]Entomology, Penn State Fruit Research & Extension Center, Biglerville, PA, USA, [4]Penn State Fruit Research and Extension Center, Biglerville, PA, USA

Abstract: Different species of bees, syrphids, moths and other flower visiting insects provide pollination services and play an important role in production of several types of tree fruit crops. In recent past, decline in pollinators' populations due to multiple interactive factors including lack of floral food resources, nesting habitats, landscape diversity has led researchers to develop viable strategies to conserve their populations in different ecosystems. In multiyear studies, we examined the impact of establishing native floral resource plantings on orchard bee diversity, seasonal occurrence, and community composition in tree fruit production system. We also examined strategies to enhance nesting of tunnel nesting orchard bees and their preferences for different types of artificial nest substrates and different ways to protect them from their natural enemies. Major findings from these studies will be presented and implications of different habitat enhancement strategies for conservation and management of pollinators in tree fruits will be discussed.

The feeding process of an adult dragonfly (Odonata: Anisoptera): Functional morphology and behavioral analysis

Authors: Josten Benedikt[1], Gorb Stanislav N.[1] and Büsse Sebastian[1], [1]Department of Functional Morphology and Biomechanics, Zoological Institute, Kiel

Abstract: Insects have developed specialized mouthparts, which show various adaptations to their respective type of feeding. Dragonflies, for example, are predators showing the carnivorous type of biting-chewing mouthparts. They catch their prey during flight and process the food item while flying or perching. To gain insights into the feeding process of adult Anax imperator LEACH, 1815, we combine results from micro-computed tomography (µCT), confocal laser scanning microscopy (CLSM), morphological movement angle measurements and synchronized high-speed videography. Living specimens of A. imperator were filmed during the feeding process to analyze the movement of every single mouthpart, as well as the concerted movement of all mouthparts. We then combined the obtained results: i) µCT-data, delivering a visualization of the 3D-geometry of each mouthpart including the muscle attachment points; ii) the CLSM-data providing information about the material composition of the cuticle of different mouthparts; iii) the morphological angles of the movements allowing for a quantitative evaluation of the movement range of each mouthpart; and finally iv) the behavioral observations allowing us to evaluate the in vivo movements of the mouthparts and to identify different aspects of feeding behavior. This approach aided in further understanding of the role of individual mouthparts in the feeding process.

Are pitfall traps measuring the tip of the iceberg?

Authors: Jowett Kelly[2], Garrett Dion[4], Milne Alice[3], Senapathi Deepa[1], Storkey Jonathan[3] and Simon Potts Prof.[1], [1]Reading University, United Kingdom, [2]Rothamsted research, Reading university, United Kingdom, [3]Rothamsted research, United Kingdom, [4]Rothamsted Research, United Kingdom

Abstract: With increasing pressures on food systems, and concerns over associated environmental impacts, agricultural land needs to increase yields with less inputs, notably pesticides. In the arsenal of sustainable solutions, natural enemy pest control offers a potentially efficient tool and habitats such as grass margins and beetle banks are used to boost abundance and diversity of beneficial agents such as carabid beetles. Such interventions, however, need to be demonstrated to have economic benefit in order to justify outlay and upkeep.

Carabid beetles are proven predators of many notable crop pests, and have been estimated to reduce weed seed stock by up to 90%. These estimates are based largely on laboratory diet studies and plot level sampling, often using a small set of carabid species that are commonly caught in pitfall traps on farmland. The contribution of soil dwelling carabid larvae are little studied and their contribution seldom considered. This is partly owing to the reliance on pitfall traps that selectively sample surface-active invertebrates.

In our study we addressed these limitations, working towards a more holistic view of ecosystem service delivery by carabids in agricultural landscapes. We measured the response of carabid beetles to experimental margins across a 330 hectare arable farm landscape with multiple crops, in Hertfordshire, England.

We developed novel subterranean traps, based on a design seldom used on carabid beetles. This was run against standard pitfall traps. Trapping was undertaken in crop areas; margin treatments (wildflower/ grass/control); across boundary features; and in adjacent habitats.By sampling the margin, spill-over zone, crop and adjacent habitat, we aim to elucidate the relative influences of landscape and management on carabid community composition- notably incorporating the relative distributions of adults and larvae, and relate this to service provision at the farm scale.

We quantified the difference in response to trapping techniques and trap type in the context of estimates of ecosystem service delivery by carabids. We argue for the value of considering these outcomes of different trap types when designing sampling methodology based on our experience relative to the literature.

Ecologically based IPM package for rice in Cambodia: Results from experiments and adoption study

Authors: Joy Flor Rica[6], Stuart Alexander[4], Asmara Ratna Hadi Buyung[6], Chou Cheythyrith[2], Castilla Nancy[5], Then Rathmuny[3], Khay Sathya[1] and Kumar Virender[5], [1]Cambodian Agricultural Research and Development Institute, Phnom Penh, Cambodia, [2]General Directorate of Agriculture, Toul Kork, Phnom Penh, Cambodia, [3]International Rice Research Institute, IRRI-Cambodia Office, Toul Kork, Phnom Penh, Cambodia, [4]International Rice Research Institute, IRRI-Indonesia Office, Bogor, Indonesia, [5]International Rice Research Institute, Los Banos, Laguna, Philippines, [6]Sustainable Impact Platform, International Rice Research Institute, IRRI-Cambodia Office, 12101 Phnom Penh, Cambodia

Abstract: Cambodia has recently experienced trade setbacks due to pesticide residues in rice. Clamor for safe food is growing in the country; however, the sharp increase in pesticide use is strikingly evident. These provide impetus for reducing reliance on pesticides through Integrated Pest Management (IPM). We present an IPM package that was tested in Cambodia from 2016-2019. We examine how the components of this package performed in the field compared with the current practice of farmers. Also, we explore outcomes in terms of changes in behavior of rice farmers indicating adoption of IPM in the sites where the package was introduced.

A core component was a set of agronomic practices that form the base for a pest-resilient rice ecosystem, termed Basic IPM (BIPM). For insect pest management, BIPM augmented with Beauveria bassiana showed the lowest number of insect pests and defoliator injury, and highest abundance of natural enemies. BIPM only (no insecticide spraying) as well as BIPM augmented with orange oil had significantly better performance for insect pest management than farmer's practice (FP) of 2-3 insecticide sprays per season. For weed management, BIPM augmented with well targeted pre- and post-emergence herbicide spraying resulted in significantly lower weed count and higher crop biomass compared with FP. Furthermore, use of a blast resistant variety showed the best performance for managing leaf blast and neck blast, which are among the top disease constraints in the country. Where use of resistant variety was not possible, biological control is an option. Use of Trichoderma harzianum resulted in significantly lower incidence of neck blast and leaf blast compared with FP. For rodent pests, use of trap barrier system shows significantly lower damage of <2.2% compared with FP (3-18%). Farmers in the experiment sites adopted varied combinations of the IPM package components. Randomly sampled farmers from four province sites in 2016 and 2019 (N=199 paired data) showed significant reduction in insecticide, herbicide and rodenticide spraying.

This IPM package for rice tested in Cambodia showed that practices enabling a pest-resilient ecosystem have better outcomes than current practices of farmers. Introducing these in communities can result in reduced pesticide reliance. Further measures to address constraints in information flow, strengthen policies for production and trade of biological control, and create cost incentives for IPM products can broaden the impacts of IPM in Cambodia.

Plodia interpunctella and Corcyra cephalonica infestation of cricket-based flour

Authors: Jucker Costanza[1], de Milato Silvia[1], Savoldelli Sara[1], Lupi Daniela[1] and Malabusini Serena[2], [1]University of Milan, [2]University of Milan, Italy

Abstract: The continuous population growth is raising the food demand. In this context, the interest in novel food such as insect-based products is increasing. These products could be attacked by stored product pests, including pyralid moths that are among the main pests of food industry.

The present work aims to evaluate whether cricket-based flour (CF) is susceptible to infestation by Plodia interpunctella (Hübner) (Lepidoptera: Pyralidae) and Corcyra cephalonica (Stainton) (Lepidoptera: Pyralidae).

Plodia interpunctella and C. cephalonica were reared separately on CF and on a standard diet (SD) as control. Data collected included survival and performance of emerged adults and the t-test was used to determine the statistically differences.

Results showed the ability of both species to develop on CF. Nevertheless, in both cases the number of emerged adults was significantly lower on CF, compared to SD. Diets also affected the adult dimension and determined a delay in the emergence for adults derived from larvae reared on CF. Moreover, both species showed a lower offspring produced when reared on CF.

Cricket flour has shown to be susceptible to P. interpunctella and C. cephalonica infestation, thus the protection of cricket-food products must be taken into account to avoid stored product moth damage.

The complex effects of the larval environment on Aedes aegypti as vectors

Authors: Juliano Steven A.[1], T. Neale Joseph[1], Chandrasegaran Karthikeyan[1] and G. Evans Katherine[1], [1]Illinois State University, United States

Abstract: Conditions in the aquatic environment of larvae can have profound effects on populations of terrestrial adult insects, and on the traits of individual adults that emerge from the larval environment. For mosquitoes that are important vectors, these effects on adult numbers and traits are both inherently interesting aspects of the ecology of complex life cycles, and important influences on the ability of vector populations to transmit vector-borne pathogens. Detailed studies of the effects of the larval environment of Aedes aegypti reveal major effects of population density of larvae and of mortality due to predation on survival to adulthood, and more subtle effects of density and nonlethal threat of predation on adult traits. These density- and trait- mediated effects are integrated to affect both population rate of change and vectorial capacity of A. aegypti. We present information from field and laboratory experiments on effects of density and predation on the likelihood off overcompensatory responses (=production of more adults with, vs. without, mortality) of A. aegypti in response to mortality of larvae. We also use sensitivity analysis of a demographic model of population growth to assess the relative importance of effects on number of survivors, development time, and size-dependent fecundity for population growth. Finally, we test for nonlethal effects of threat of predation on adult traits of size, longevity, body composition, and blood feeding that are relevant to vectorial capacity. Though both density- and trait-mediated effects can occur, it appears that effects that alter the number of surviving adults have the greatest impact on both population growth and vectorial capacity. Because overcompensation can occur in A. aegypti, simply imposing mortality on larvae is no guarantee of reducing adult production, and therefore no guarantee of reducing A. aegypti populations or vectorial capacity.

Different response of cerambycid and curculionid beetles (Coleoptera) to burned-Pinus densiflora forests in South Korea

Authors: Jung Jong-Kook[1] and Nam Youngwoo[1], [1]Department of Forest Insect Pests and Diseases, National Institute of Forest Science, South Korea

Abstract: We investigated the changes in species richness and abundance of two major saproxylic beetles, such as cerambycid and curculionid beetles, along a fire severities gradient in burned-Pinus densiflora forests. The wildfire was occurred in May 5~6, 2017 and about 86 ha of forests were burned. We classified the study area according to fire severity classes, such as unburned, light, edge of light-moderate, edge of moderate-severe, and severe. For sampling of the beetles, the Lindgren multi-funnel traps were placed in each fire severity classes from March to October in 2018. A total of 34,529 beetles were collected and identified as 87 beetle species. Xyleborinus saxeseni (19,423 individuals) and Xylosandrus germanus (7,216 individuals) were dominant in every burned-pine forests, and they accounted about 77% of all collected beetles. Species richness of curculionid beetles in all fire severity classes were high compared to unburned area, while those of cerambycid beetles in the edge of moderate-severe and severe areas were high compared to others. Among burned areas, however, species compositions of two beetle families were slightly different according to fire severity classes. Some beetle species were selected as potential indicators on burned-Pinus densiflora forests.

Sensitivity of olive fruit fly (Bactrocera oleae (Gmelin)) to insecticides

Authors: Juran Ivan[1], Ančić Mario[2], Grubišić Dinka[1], Pernar Renata[2] and Gotlin Čuljak Tanja[1], [1]University of Zagreb Faculty of Agriculture, Croatia, [2]University of Zagreb Faculty of Forestry and Wood Techhnology

Abstract: To control olive fly, there are studies on the effectiveness of chemical preparations as well as environmentally friendly preparations, but susceptibility tests have not yet been conducted. Infested olive fruits were delivered to the laboratory and placed in climate chambers for cultivation. After the release of the adult forms, an experiment was conducted according to the method of Kakani et al. (2010). Insecticides based on the active ingredients dimethoate and deltamethrin were prepared at dosages of 100%, 50%, and 20%, while water served as a control. Adult flies were anesthetized with CO2 and an insecticide was applied to each individual from the dorsal side using a microapplicator. In 2018, reduced sensitivity to the active ingredient dimethoate was found in only one tested population of olive flies, which originated from the Cres locality, while 71% of the tested population showed reduced sensitivity to the active ingredient deltamethrin. In 2019, as in 2018, only one population (from site Polje) was found to have reduced sensitivity to the active ingredient dimethoate, while the other tested populations were sensitive. Only one test population was sensitive to the active ingredient deltamethrin, while the other tested populations were found to have reduced sensitivity.

Every transcriptome has virus sequences in it

Authors: Jurvansuu Jaana, Ecology and Genetics Research Unit, University of Oulu, Finland

Abstract: Viruses are the most abundant and diverse life form. Insect virology is booming due to the reduced prices of the next generation sequencing. In recent years, about 2000 new insect virus species including new virus orders have been identified. Insects are particularly suitable for virome studies as they are often so small that a whole animal can be analysed at once and so abundant that many individuals can be easily collected and processed. Furthermore, the massive amounts of existing next generation sequencing data in public databases enables directly identification of many more new viruses from multitude of insect species.

However, despite the considerable advances, the basic biology of most insect viruses is still obscure. Next generation sequencing data can provide some information about the virus biology, such as, virus prevalence, virus replication activity, virus genome evolution, and of virus-virus interactions. Yet, in combination with other methods and ecological studies we can further analyse how the viruses affect host fitness, virus seasonality, host anti-virus defenses, and how do viruses transmit among caste, colonies and different species. Examples from our work with the common glow-worm (Lampyris noctiluca), Argentine ants (Linepithema humile), and varied spider species (Arachnida) are discussed.

Aspects of developments in biological control in greenhouse botanical collections

Authors: Kaas Jan Piet, Bio Pre, Netherlands

Abstract: Pest groups and their biological in collection plantings are discussed. An overview of past, present and future of small scale planting- integrated pest management is given. Different interests of governement and non- governemet agencies in the development of new ways of pest control are mentioned.

Pre-application of Metarhizium brunneum for wireworm control in seeded and transplanted crops

Authors: Kabaluk Todd[1], Cory Jenny[3] and Thien Aaron[2], [1]Agriculture and Agri-Food Canada, Canada, [3]Simon Fraser University, Canada, [2]Simon Fraser University, Canada

Abstract: Entomopathogenic fungi, including Metarhizium brunneum, are promising active ingredients for wireworm control in field vegetables, but often do not achieve high efficacy because their slow speed-of-kill still allows the larvae to feed on the crop for weeks after application. In a two year study, pre-plant application of attract-and-kill wireworm control products aimed to achieve an increase in yield and marketability of organic lettuce and turnip in Agassiz, British Columbia, Canada. Pre-plant application of granular products formulated with M. brunneum LRC112 conidia, and containing a CO2 attractant reduced wireworm root tuber damage in turnip by 30% compared to the untreated control in a field highly infested with Agriotes obscurus and A. lineatus, signifying the value of this application strategy.

Horizontal transmission of Metarhizium brunneum conidia between click beetle, Agriotes obscurus, pairs during mating

Authors: Kabaluk Todd[1], Janmaat Alida[2], White Danielle[2] and Zurowski Kari[3], [1]Agriculture and Agri-Food Canada, Canada, [2]Biology Department University of the Fraser Valley Abbotsford, British Columbia, Canada, [3]Department of Biological Sciences Simon Fraser University Burnaby, British Columbia, Canada

Abstract: Due to the subterranean nature of the damaging wireworm larvae, recent efforts have begun to focus on targeting adult click beetles with the fungal entomopathogen, Metarhizium brunneum. In the present study, we examined the transmission of M. brunneum between mating pairs of click beetles. We exposed male or female beetles to conidiated rice granules after which the beetles were paired with an opposite sex unexposed beetle, 2, 24 and 48 hours after initial M. brunneum exposure. Behavioural observations were recorded during each pairing. The time to death of beetles exposed directly to M. brunneum conidia, or indirectly via pairing with a contaminated partner, or contact with the contaminated substrate was compared. In addition, the impact of courtship and mating behaviours on the transmission of conidia between mating pairs will be discussed.

A review of the sterile insect technique against Malaria vectors in South Africa

Authors: Kaiser Maria[3], Munhenga Givemore[2], Brooke Basil[1], [1]Centre for Emerging Zoonotic and Parasitic Diseases, National Institute for Communicable Diseases, National Health Laboratory Service, Johannesburg, South Afric, [2]Wits Research Institute for Malaria, SAMRC Collaborating Centre for Multi-Disciplinary Research on Malaria, School of Pathology, Faculty of Health Sciences, Uni, [3]Wits Research Institute for Malaria, SAMRC Collaborating Centre for Multi-Disciplinary Research on Malaria, School of Pathology, Faculty of Health Sciences, Uni, South Africa

Abstract: Malaria control remains a key priority in South Africa and the country has set an agenda of eliminating local transmission by 2023. The backbone of malaria control is vector control, mainly achieved through indoor residual spraying (IRS) using insecticides. Although this strategy has made significant progress in regressing the number of malaria transmitted cases over the years, low-level transmission continues in the endemic regions of north-eastern Limpopo, the Mpumalanga low-veld and far northern KwaZulu-Natal. The continued residual malaria transmission necessitated investigation of additional vector control interventions to supplement existing strategies. The use of the Sterile Insect Technique (SIT) was proposed. A multi-year plan for testing the feasibility of SIT was developed by a consortium of collaborating parties in 2010. Over the last eight years optimization of key aspects of mosquito SIT applications, including entomological baseline surveys, mating competitiveness studies, population size estimation, irradiation studies, development of sex separation systems and extensive community engagement activities have been carried out culminating in the construction of a mosquito vector mass rearing factory. This development provides a unique opportunity to proceed with the first field demonstration of SIT against African malaria vector. The purpose of this study is to review the experience and knowledge gained in developing the SIT as a complementary malaria vector control tool focusing on the challenges and current status of the project. An insight on the pending pilot sterile release male programme will be given.

Circadian timing adaptations in the intertidal insect Clunio marinus

Authors: Kaiser Tobias S, Max Planck Institute for Evolutionary Biology, Germany

Abstract: The marine midge Clunio marinus (Diptera: Chironomidae) lives in the intertidal zone of the European Atlantic coast. Its life cycle is timed to the tides by circadian and circalunar clocks. As the tides differ along the coastline, C. marinus populations show many local genetic adaptations in circadian and circalunar timing. QTL mapping indicates that these timing adaptations are controlled by few major effect loci.

In order to pinpoint the adaptive timing loci, we sequenced a C. marinus reference genome, assembled it to chromosome-scale and annotated it. Then we sequenced individuals from five populations of C. marinus, which differ in circadian and circalunar timing. Genome-wide we detected timing-associated genes based on the correlation of genetic divergence with timing differences. In one circadian QTL there was a strong evolutionary signature of local adaptation, which pointed to the Ca2+/Calmodulin-dependent protein kinase II (CaMKII) gene.

Subsequent molecular analysis substantiated that adaptation in circadian timing relies on modulating the alternative splicing of CaMKII. CaMKII phosphorylates the CLOCK protein, changing its transcriptional activity. Strains with differences in CaMKII splicing also differ in their endogenous clock period and phase. These findings entail a mechanistic model of how DNA sequence changes translate into adaptive timing phenotypes. We currently test if other population of C. marinus rely on the same mechanism for local adaptation in circadian timing or if new solutions were found in every location along the coastline.

Phylogeny, evolution of termitophily and higher classification of Aphodiinae (Coleoptera: Scarabaeidae)

Authors: Kakizoe Shotaro[1] and Maruyama Munetoshi[2], [1]Kyushu University, Fukuoka, Japan, [2]The Kyushu University Museum, Japan

Abstract: [Introduction]

The subfamily Aphodiinae (sensu lato; proposed in Scholtz and Grebennikov 2005) is composed of 6 subfamilies, 9 tribes, 387 genera, 3732 species, including Aphodiinae Leach, 1815 and its related subfamilies. Some of them are known as "dung beetles," but they occupy various niches, feeding on detritus, dung, carrion, fungi, or living plants, with several groups living with termites or ants (Scholtz and Grebennikov 2005). Therefore, this subfamily is one of the ideal taxa to study the evolution of feeding habits, termitophily, and myrmecophily. However, phylogenetic relationships within the subfamily are poorly understood. Because of the lack of molecular phylogenetic information, higher-level classifications of subfamilies and tribes have been confused among researchers. Therefore, we reconstructed the phylogenetic relationships within Aphodiinae using molecular data.

[Materials and Methods]

We reconstructed the phylogenetic trees using maximum likelihood and Bayesian inference methods for a total of 4,900 bp (4,573 bp after trimming) of 138 OTUs selected from all 6 subfamilies, 9 tribes, and outgroups of Aphodiinae (sensu lato). The following molecular markers were used as sequence information: mitochondrial COI (800 bp), 16S (1040 bp), nuclear 28S Domain 2 (620 bp), 28S Domain 3–6 (560 bp), and 18S (1880 bp). For the outgroups, 3 species were used from Scarabaeinae, which is a sister group of Aphodiinae (Ahrens, Schwarzer and Vogler 2014).

[Result/Conclusion]

Molecular phylogenetic analysis revealed that Aphodiinae (sensu lato) is a monophyletic group and termitophily evolved independently at least twice. Specifically, we suggested that termitophily evolved in the Stereomerini lineage and in the lineage consisting of Termitotroginae, Corythoderini, and Termitoderini. This study clarified that Termitotroginae is monophyletic along with Corythoderini and Termitoderini, and suggested that previous classification that treated Termitotroginae as a subfamily was an exaggeration of the specialized morphology associated with termitophily. Moreover, this result was different from the phylogenetic tree based on morphology in a previous study (Vårdal & Forshage 2010).

With the revelation of these phylogenetic relationships of the higher taxonomic groups of Aphodiinae, including the result that Euparini, Odontolochini, and Aphodiini are polyphyletic, we suggest that the current classification of the subfamily should be revised along with the abovementioned termitophilous groups.

Potential of plant essential oils to control the oilseed rape pest

Authors: Kallavus Triin, Sulg Silva, Kaasik Riina, Sakkool Mariette and Veromann Eve

Abstract: Plant essential oils (EO) contain wide range of active compounds with several biological activities. Their insecticidal activities, as some of them are repellent or toxic for insects, have potential to be used as an alternative to synthetic pesticides. We examined insecticidal efficacy of six plant EOs on the cabbage seed weevil (Ceutorhynchus obstrictus Marsham), one of the main pests of oilseed rape (Brassica napus L).

To determine the effect of EOs on direct mortality of cabbage seed weevil we treated oilseed rape leaf and flower surfaces with six different EOs, with one negative control and one positive control and assessed the mortality of weevils after 3h and 24 h.

The results of the bioassay indicated higher cabbage seed weevil mortality on surfaces treated with various concentrations of Cuminum cyminum L. and Cinnamomum verum J.Presl. EOs, suggesting their potential as complementary or alternative measure to control cabbage seed weevil populations.

The effects of changing land-use on the temporal dynamics of B. tabaci on cassava in Uganda.

Authors: Kalyebi Andrew[4], Hulthen Andrew[1], Jacomb Frances[2], Colvin John[5], Ocitti Patrick[3], DeBarro Paul[1], Macfadyen Sarina[2] and Tek Tay Wee[2], [1]CSIRO Ecosciences Precinct, Dutton Park, Brisbane QLD, 4001, Australia, [2]CSIRO, Clunies Ross St, Acton, ACT 2601, Australia, [3]National Crops Resources Research Institute, Kampala, Uganda, [4]National Crops Resources Research Institute, Kampala, Uganda/Mikocheni Agricultural Research Institute, Dar es Salaam, Tanzania, Uganda, [5]Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, United Kingdom

Abstract: Cassava (Manihot esculenta Crantz) is an important commercial and food security crop in many countries in Africa. However, diseases of cassava (e.g. Cassava mosaic disease, CMD, and Cassava Brown streak disease, CBSD) continue to cause significant yield losses throughout eastern and central Africa. Additionally, populations of species in the cassava whitefly Bemisia tabaci (Hemiptera: Aleyrodidae) cryptic pest complex, that vector both CMD and CBSD, have been increasing in abundance over the past 20 years. We know that insect populations are influenced by a number of factors associated with both cultivated and uncultivated habitats in the landscape surrounding a target field. In smallholder farming landscapes in Uganda, land-use patterns often change due to highly flexible crop rotation plans that are dependent on several other factors such as family, village and regional demand for food and fiber. However, we don't understand how these dynamic land-use decisions impact pest and disease risk. We investigated how a change in land-use across a season around a focal cassava field affects the population dynamics of B. tabaci. Ten sites were planted with two cassava genotypes and the change in B. tabaci abundance monitored over 12 months alongside the change in surrounding land-use. We also determined the B. tabaci species identity commonly found at these sites through sequence characterization of the partial mitochondrial DNA cytochrome oxidase subunit I (mtCOI) gene. Early results identify some of the important landscape factors that lead to high population densities in cassava. The implications of these results for developing landscape manipulation practices to help manage B. tabaci pests in smallholder farming landscapes will be discussed.

A Novel Educational Method for Prevention and Control of Vector-Borne Diseases in the Villages of Bardsir, Kerman Province, Iran

Authors: Kamali Maryam, Department of Medical Entomology and Parasitology, Tarbiat Modares University, Iran

Abstract: Education regarding vector-borne diseases using social media tools can empower rural communities to better identify vectors, and understand diseases and methods of avoiding exposure. We report the results of a quasi-experimental study examining the effectiveness of a novel method of educating individuals through social networks on local insects and ticks of medical importance (mosquitoes, sandflies, ticks, lice, bed bugs, and fleas) which was carried out in 2021, in 12 villages of Bardsir county, a rural community in Kerman Province, Iran. Questionnaires were administered at baseline and following a 4-week educational program offered through a social media app (WhatsApp) on the participants' personal cellphones. Interventions included short educational videos on the insects and ticks of medical importance, that included information on general identification, diseases transmitted by them, and disease prevention methods, distributed through a moderated social media group. Results show a statistically significant increase ($p< 0.01$) in the level of awareness regarding symptoms of diseases transmitted by insects and ticks and prevention methods for these diseases after training. Participants also found the educational material on social media useful and convenient ($P< 0.01$). Social media can be effectively used to increase the level of awareness regarding diseases transmitted by insects and ticks.

Multiple evolution of termitophily in the rove beetle subfamily Aleocharinae

Authors: Kanao Taisuke, Yamagata University, Japan

Abstract: Termitophiles, insects associate with termites during at least one stage of life cycle, are known from 12 insect orders. In termitophilous insects, a remarkably high species diversity, more than 700 termitophilous species, is found in the rove beetle subfamily Aleocharinae. Many of termitophilous rove beetles exhibit specialized body forms, such as physogastry (swollen abdomen with developed membrane area between abdominal segments) and limuloid body shape (resembling a horseshoe crab). Although the host specificity and nature of interaction between termitophiles and host termites vary substantially among termitophilous species or groups, beetles with the specialized body forms generally have species-specific relationships with their host termites and live deep within the host termite nest. Termitophilous species in Aleocharinae are currently classified into 17 tribes, of which 12 tribes are exclusively composed of termitophiles. However, phylogenetic positions of each termitophilous group are not well resolved. To clarify evolutionary history of termitophily in Aleocharinae, robust phylogenetic reconstruction is necessary.

I present the result of molecular phylogenetic analysis as well as a brief summary of taxonomic study. During field surveys in Afrotropical, Neotropical, and Oriental regions, I recognized the species diversity of termitophilous Aleocharinae was quite underestimated. Some of the new species implied polyphyly of the subtribe Termitozyrina in the tribe Lomechusini. I also performed a molecular phylogenetic analysis using six loci of 229 species including termitophilous, myrmecophilous, and free-living species. The results revealed multiple origins of termitophily and convergent evolution of the two specialized body forms of termitophilous species in Aleocharinae. Some termitophilous species were found to form monophyletic groups with myrmecophilous species, which indicates that the beetles experienced dynamic host shifts between termite and ant. Termitophilous species from a single clade were typically associated with termites from a single subfamily, but host switches to different termite subfamilies were also uncovered in several clades. The molecular phylogeny further highlighted systematic problems in Aleocharinae. In addition to the polyphyly of Termitozyrina, this analysis revealed that several termitophilous groups were reconstructed in clades of other termitophilous, myrmecophilous, or free-living groups.

Precision guided Sterile Insect Technique (pgSIT): a novel environmentally friendly technology for insect population suppression

Authors: Kandul Nikolay, UC San Diego, United States

Abstract: Sterile insect technique (SIT) is an environmentally safe and proven technology to suppress wild insect populations. In a classic SIT, sterile males are generated with radiation, sex-sorted to remove females, and released in large numbers into a wild population, where they compete with wild males for female mates. Mating with sterile males results in no progeny and consequently can be used to suppress populations; however, the low fitness of sterile males and inability to adequately sex-sort most insects has limited the application and efficacy of SIT. To overcome these limitations, we developed a novel CRISPR-mediated SIT termed “precision guided SIT” (pgSIT) system. This system is comprised of two separate homozygous lines each carrying Cas9 or double guide RNA (dgRNA). When these lines are crossed in the laboratory, they produce F1 progeny with precise knock outs of two specific genes targets, in this case, one required for female survival and the other for male fertility, resulting in emergence of 100% sterile males from genetically identical F1 eggs. pgSIT mechanistically relies on a dominant genetic technology that enables simultaneous sexing and sterilization, permitting the release of eggs into the environment. To date, we have engineered multiple pgSIT systems in the model organism, Drosophila melanogaster, the crop pest, Drosophila suzukii, and the disease vector, Aedes aegypti, which consistently produce 100% sterile males. Importantly, unlike irradiated sterile males made with a classic SIT, pgSIT generated males in these species are fit and competitive compared to wild type males. Modelling has also predicted that pgSIT will induce greater population suppression over time than can be achieved by current approaches. Taken together, pgSIT may transform our ability to control insect agricultural pests and disease vectors.

Predators’ learning about aposematic prey affects the survival of prey with hidden conspicuous anti-predator defences

Authors: Kang Changku[2], Choi Sei-Woong[1], Hwang Yerin[2] and Kim Yongsu[2], [2]Mokpo National University, South Korea, [1]Mokpo National University

Abstract: Some camouflaged insects have conspicuous hindwings hidden normally. They display them to predators transiently only when their primary defence (camouflage) fails. Such secondary defences are called deimatic displays or flash displays. The conspicuous signals used for deimatic/flash displays resemble those of aposematic signals, thus if predators already learned to avoid aposematic prey, it may benefit the prey that uses deimatic/flash displays. Here, we investigated whether predators’ learning about aposematic prey affects the survival of prey with hidden conspicuous signals. We conducted two separate experiments for deimatic and flash displays using chicks and human subjects as predators respectively. We found that educated predators were more likely to avoid the prey with hidden conspicuous signals than non-educated predators in both deimatic and flash display experiments. This helps explain the pattern we found in 466 macrolepidopteran species: the species with hidden conspicuous signals occur later in seasons than both aposematic and camouflaged species.

Adaptation to cold environments - case studies from a northern malt fly species Drosophila montana

Authors: Kankare Maaria, Dept. of Biological and Environmental Science, University of Jyvaskyla, Finalnd, Finland

Abstract: Drosophila montana from D. virilis species group is one the most cold-tolerant Drosophila species. It is distributed to northern hemisphere and has adapted to live on high latitudes close to, or even above the Arctic Circle in Northern Scandinavia and Alaska. In addition, it has occupied high altitudes (above 3 000 m) on the Rocky Mountains but also warmer areas on the Western coast of North America. Flies of this species can survive up to six months of subzero temperatures in the adult photoperiodic reproductive diapause. This northern fly has been investigated for several decades already, and we have learned many things from its ecology, physiology and genetics. Gene expression studies with microarrays almost a decade ago from diapausing and non-diapausing flies revealed interesting patterns and produced a list of core candidate genes. More lately, we have concentrated more on the genomic level by investigating montana’s cold adaptation across the latitudes and between the sexes. Our latest studies on chromosomal inversions and transposable elements will increase our understanding on how these crucial genomic factors are connected to adaption to variable climatic conditions.

Morphology and significance of antennal sensilla of aphids (Hemiptera, Aphididae)

Authors: Kanturski Mariusz, Faculty of Natural Sciences, University of Silesia in Katowice, Poland

Abstract: Aphids are one of the most economically important groups of bugs and insects due to their great evolutionary success, which they have achieved due to their ecological plasticity, life cycles and polymorphism. Undoubtedly, one of the equally important aspects of this success is the specific sensory organ system on their antennae – setae, rhinaria and rhinariola, which represent various types of sensilla. For several years aphids become a great number of interests in the case of molecular and genomics Research but morphological studies have been neglected. In this presentation, I present comparative scanning electron and light microscopy analyses of antennal sensilla of selected aphid species. Different types of sensilla can be found on aphids antennae, like small multiporous placoid sensilla (primary and secondary rhinaria), large multiporous placoid sensilla (primary rhinaria), sunken coleoconic sensilla (rhinariola and accessory rhinaria) and different types of trichoid sensilla (setae). Besides their morphology and ultrastructure, I will try to show their significance in taxonomy and the phylogeny of particular groups.

Phylogenetic reconstruction of Tuberolachnini and Lachninae aphids (Insecta: Hemiptera)

Authors: Kanturski Mariusz, Faculty of Natural Sciences, University of Silesia in Katowice, Poland

Abstract: Lachninae aphids (Aphididae: Lachninae) are one of the most interesting and consist of so far five tribes and Tuberolachnini seems to be especially interesting group in morphologically and biologically diverse with Pyrolachnus, considered to be rather poorly known. So far only one representative – P. imbricatus nipponicus have been known from Japan and characterized by unique features. We tested the current tribal system of Lachninae including the largest number of Pyrolachnus as well as another poorly known genus Sinolachnus based on four genes. Our phylogenetic analyses inferred that Tuberolachnini is not a monophyletic tribe by separation of Pyrolachnus imbricatus nipponicus and Sinolachnus sp. from the core Tuberolachnini (e.g. Nippolachnus, Pyrolachnus and Tuberolachnus). Detailed morphological investigations (including lignt and scanning electron microscopy) strongly supported our molecular phylogeny. We present and discuss the morphological characters of viviparous and bisexual generations of P. imbricatus nipponicus and related Tuberolachnini genera.

Dissecting overwintering mechanism of Asian tiger mosquito, Aedes albopictus

Authors: Kanuka Hirotaka[1], Takayanagi Sakino[2], Okamoto Naoki[3] and Yamanaka Naoki[3], [1]Department of Tropical Medicine, Center for Medical Entomology, The Jikei University School of Medicine, Japan, [2]The Jikei University School of Medicine, Japan, [3]University of California, Riverside, United States

Abstract: Aedes albopictus (Ae. albopictus) is one of Aedes mosquito species and also known as Asian tiger mosquito. Ae. albopictus is originally a native species to Southeast Asia. This mosquito species, however, is rapidly expanding its distribution throughout the world and now selected as one of species of the 100 of the World's Worst Invasive Alien Species by International Union for Conservation of Nature and Natural Resources (IUCN). The spread of Ae. albopictus is emerging problem because Ae. albopictus mosquitoes are effective vectors of severe human diseases such as Dengue, Chikungunya, and Zika fever. Therefore, the vector control of this invasive species is currently needed to develop.

The reason why Ae. albopictus could be established in temperate to subarctic zones is that eggs of Ae. albopictus are able to survive in a diapause state during winter. In tropic zone, Ae. albopictus repeats their life cycle throughout the year. On the other hand, in temperate zone, such as Japan, when adult females of this species are exposed to short daylength and low temperature in late autumn, they lay diapause eggs. In diapause eggs, development is paused in the stage of pharate first instar larva. The arrest of hatching behavior is maintained until early summer and the pharate larvae show strong resistance to coldness, drying, and starvation. Interestingly, only temperate strain can form diapause eggs but tropic strain never forms them even if females are reared under the late autumn condition.

To reveal the genetic mechanisms of preparation and maintenance of diapause in Ae. albopictus, we focused on two strains, tropic strain and temperate strain. We confirmed that Kuala Lumpur strain and Hiroshima strain shows the difference in hatching rate when adult females were reared under the short daylength and low temperature. And furthermore, we compared temporal and comprehensive gene expression between eggs from tropic strain and diapause eggs from temperate strain using RNA-seq to identify genes involved in diapause mechanism. Our results showed several candidate genes involved in environmental resistance and maintenance of diapause state. Then, we produced deletion mutants in Ae. albopictus using CRISPR/Cas9 system to estimate the function of these genes. Here, we would like to discuss about the molecular basis that enables Ae. albopictus to overwinter, along with ongoing experimental results.

Spatio-temporal distribution of Cydia pomonella L. (Lepidoptera: Tortricidae) populations in local and regional scale

Authors: Karimzadeh Roghaiyeh[3], Feizizadeh Bakhtiar[1], Shayestehmehr Hakimeh[2] and Iranipour Shahzad[2], [3]Department of Plant Protection, Faculty of Agriculture, University of Tabrizm Iran, [1]2Department of Remote Sensing & GIS, Faculty of Planning and Environmental Sciences, University of Tabriz, Iran, [2]Department of Plant Protection, Faculty of Agriculture, University of Tabriz, Iran

Abstract: Detailed information about pest population trends in spatial and temporal dimensions is essential for integrated management programs. In this study the spatio-temporal distribution of codling moth, Cydia pomonella L. (Lepidoptera: Tortricidae) was investigated by integrating spatial analysis by distance indices (SADIE) and geographic information system (GIS). Also, the correlation of population oscillations with elevation, weather condition, and chemical treatments was evaluated. This study was conducted during three growing seasons, 2017, 2018, and 2019 in an agricultural landscape (258 km2) located in Ahar County, East Azarbaijan Province of Iran. The activity of codling moth adult males was monitored using delta-shaped traps baited with sex pheromone of the insect (PH-227-1RR, Russell IPM, UK) in two spatial scales. So that 45 traps were placed within a 12 ha orchard, set between 50-200 m apart, and 30 traps over the entire study area set between 500-7000 m apart. Results of spatial analysis indicated that there was an aggregated spatial distribution for adult males both in local and regional scales. Also, the association index of SADIE and the maps generated confirmed the stability of this aggregation pattern during the growing season. Negative significant correlation was observed between the codling moth population and the number of frost days. The number of chemical treatments in a year was negatively correlated with codling moth population fluctuations too. But there was no significant correlation between pest populations and elevation. These findings can be used for spatial and temporal forecasting and management of codling moth in local and regional scales.

Interspecific competition among three fruit fly species infesting watermelon and zucchini (Cucurbitaceae)

Authors: Karlsson Miriam Frida[1], Fabrice Gbenonsi Akomavo[3], Onzo Alexis[4], Ferdinand Rodolphe Layode Babatounde[2], Totin Félicien[2] and Mama Sambo Sahadatou[2], [1]-International Institute of Tropical Agriculture (IITA) -Department of Plant Protection Biology, Swedish University of Agricultural Sciences (SLU), SE-230 53 Al, Sweden, [2]International Institute of Tropical Agriculture (IITA-Benin), Benin, [3]International institute of Tropical Agricuture (IITA-Benin), Benin, [4]University of Parakou, Benin,

Abstract: Interspecific competition occur among arthropod pest species that share hosts, thereby, influencing their population dynamics. In sub-Saharan Africa, the native fruit fly species Dacus vertebratus (Bezzi) and Dacus ciliatus (Loew) (Diptera: Tephritidae) and the exotic Zeugodacus cucurbitae (Coquillett), are concurrent pests in the same host fruits, hence competition among them is likely to occur. We explored interspecific competition among these three fruit fly species on zucchini (Cucurbita pepo L.) and watermelon (Citrullus lanatus Thunb) (Cucurbitaceae) to improve our understanding of the interaction between the species and their capacity to coexist. We exposed the vegetable fruits to different densities of fruit fly species and studied their behavioural activities, evaluating the extrinsic competition. To assess intrinsic competition and understand the effect of co-occurrence inside the fruits, eggs of the three fruit flies were pairwise inoculated into the same fruits. Results showed that the behaviour on the fruits differed between the species, and that the interspecific competition affected their developmental time and larval survival in both watermelon and zucchini. Zeugodacus cucurbitae were more aggressive than the other species and managed to oviposit more frequent. Emergence was reduced for D. ciliatus and D. vertebratus when inoculated together with Z. cucurbitae in watermelon but not in zucchini. Physical confrontations were more common in zucchini than in watermelon and were more frequently won by Z. cucurbitae than D. vertebratus and D. ciliatus. Interspecific competition information obtained about behavioural differences and interaction effects, providing background for explaining the present fruit fly guild on certain Cucurbitaceae fruits in West Africa.

Estimation of mutation role rate of nutritional genes in Blattabacterium endosymbionts of Periplaneta americana

Authors: Kashimoto Rio[3], Yukihiro Kinjo[2] and Bourguignon Thomas[1], [3]Okinawa Institute of Science and Technology, Japan, [2]Okinawa Institute of Science and Technology Graduate University, Japan, [1]Okinawa Institute of Science & Technology Graduate University, Japan

Abstract: Cockroaches are associated with Blattabacterium, an intracellular endosymbiotic bacterium that has been transmitted from mother to offspring for >235 Million years. The large population and low nutrient environment has lead to constant gene acquisition with loss and recombination from free living state. This process has led organisms to transition from a short history with host to a long history, such as Blattabacterium. The genomes of Blattabacterium strains sequenced to date vary between 590kbp to 640 kbp. In this study, we sequenced 8 Blattabacterium genomes from Periplaneta americana specimens maintained in colonies in four universities over the last 20 years. Because the origin and the timing of separation among samples is known, we were able to measure the mutation rate in Blattabacterium symbiont. Altogether, we detected several mutations that occurred over an evolutionary period of 20 years. This mutation rate is lower than that estimated for Buchnera, the endosymbionts of aphids. Our results therefore suggest that Blattabacterium evolve slowly in comparison with other endosymbionts.

Species Composotion of Phlebotomines (Diptera: Psychodidae: Phlebotominae) as Vectors of Disease Agents in South Western Iran

Authors: Kassiri Hamid[1] and Farhadi Nezhad Reza[2], [1]Department of Medical Entomology, School of Health, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran, [2]Infectious and Tropical Diseases Research Center, Health Research Institute, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran

Abstract: Introduction and Objectives: Sandflies are the main vectors of Leishmania) a neglected tropical pathogen), Bartonella bacilliformis, and some arboviruses. Cutaneous Leishmaniasis (CL) is one of the most prevalent types of leishmaniasis in Iran. The objective of this study was to determine the faunistic, sex ratio, seasonal activity, physiological status and relative abundance of sandflies as vectors of Leishmaniasis in Iran.

Materials and Methods: This descriptive cross- sectional study was carried out in Abadan county, Khuzestan province, during 2015-2016. Totally 10 villages and 1 city were selected in order to Phlebotomine sandflies collection. Sandflies were captured by using the sticky paper traps. Traps were installed before sunset in internal and external places and were collected the next day before sunrise. Females were considered to determine abdominal condition and recorded as unfed, blood-fed, semi-gravid and gravid. Sandflies were mounted on a slide containing a drop of puri's mediumand and were identified using the diagnostic keys of sandflies.

Results: During this study, 6173 phlebotomine sandflies were caught and identified. A collection including 13 species (2 species of Phlebotomus and 11 species of Sergentomyia) was identified as the sand fly fauna in the County. Species of P. papatasi (45.64%), P.alexandri (31.31%) and S. sintoni (15.9%) were in the first to third order in terms of relative abundance. Four species, including S.tiberiadis, S. clydei, S.antennata and S. christophersi are reported for the first time in Abadan.The sex ratio of the sandflies of genus Phlebotomus and Sergentomyia were 362.4 and 92.2 males per 100 females, respectively. The sex ratio of Phlebotomine species was 249.1. The analysis of physiological status of sandflies in outdoors and indoors revealed 61.2% and 71.1% unfed, 2.9% and 4.8% blood-fed, 26.7% and 17.7% semi-gravid, 9.2% and 6.4% gravid, respectively. The population size of sandflies was diverse, as it showed two activity peaks, one in July and the other in September.

Conclusions: Phlebotomus papatasi and P. alexandri respectively play the role of primary and secondary vectors of CL in Khuzestan Province, due to their high abundance, attendance in whole the monthly activities and attendance in whole regions affected with CL. Knowledge about peak activity times and faunistic of sandflies, can be useful in developing strategies and planning programs to control the sandflies and CL.

The Present Status of Cutaneous Leishmaniasis in a Focus in South-West of Iran

Authors: Kassiri Hamid[2], Edalat Hamideh[3] and Khairandish Sedigheh[1], [2]Department of Medical Entomology, School of Health, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran, [3]Department of Medical Entomology and Vector Control, School of Health, Tehran University of Medical Sciences, Tehran, Iran, [1]Bushehr University of Medical Sciences, Bushehr, Iran

Abstract: Introduction and Objectives: Cutaneous Leishmaniasis (CL) is caused by protozoa of the genus Leishmania and can be transmitted by sand fly bites. It is an important health problem in many parts of Iran as well in Dasht-e-Azadegan County, Khuzestan Province. To identify the epidemiologic status of CL with emphasis on trend of its incidence rate in Dasht-e-Azadegan County.

Materials and Methods: This investigation was a descriptive and analytical study. A total of 1093 cases were considered for the study who were reffered to the health centre during the duration of four years (2014-2017). Giemsa staining was used for preparing the expanded smear. Epidemiologic characteristics and clinical information of CL cases were collected by the means of a checklist and analysed by means of chi-square and t-tests. The p-values <0.05 were considered as statistically significant.

Results: Most cases were in the age group of below 10 years. Highest disease frequency was observed in students (30.1%). The majority (57.8%) had one lesion. The hand was most commonly involved (38.9%). About 73.8% of patients used topical injection along with cryotherapy for treatment. In over half of the cases (92.4%), the wound size was less than or equal to one centimetre. There was a significant difference between the residential areas, age groups, genders, occupation, month of reporting, lesion sites on the body and number of ulcers with the prevalence of active lesions.

Conclusion: Cutaneous leishmaniasis is considered as an important health problem in this county. So it is necessary to take certain measures for controlling the disease and reducing its incidence.

Descriptive- Analytical Evaluation of Scorpion Sting Incidence in Masjed-Soleyman County, Southwestern Iran

Authors: Kassiri Hamid[2], Khodkar Iman[3] and Yousefi Mnsour[1], [2]Department of Medical Entomology, School of Health, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran, [3]Student Research Committee, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran, [1]Communicable Diseases Department, Masjed-Soleyman County Health Center, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran

Abstract: Introduction and Objectives: Scorpions are dangerous for humans due to having deadly and toxic sting. Scorpion sting is a major public health challenge in many countries. The south and southwest of Iran with about 95% species of scorpions are the most heavily occupied regions in the country. Khuzestan Province is highlighted for its scorpions and scorpionism amongst the provinces of Iran. Khuzestan with 19 species of scorpions is one of the most important regions in terms of scorpionism problem in the southwestern Iran. Therefore, this study was conducted with the aim of survey epidemiology of scorpion sting in Masjed-Soleyman County from 2015 till 2017.

Materials and Methods: This research is a descriptive - analytical study. All the scorpionism cases who were referred to the 22-Bahman Hospital of Masjed-Soleyman during the study period were included in this research. The required information was extracted from the patients' recorded data in the hospital. Information for each case were recorded in a special checklist and imported into the computer for statistical analysis. Epidemiologic and demographic data were analyzed using the software SPSS-20. Descriptive statistics, including frequency and percentage were used for data analysis. The Chi square test (X2) and the T test were used to compare variables. P- values of 0.05 or less were considered statistically significant.

Results: Out of 11685 cases of scorpionism, 5894 cases were women (50.5 %) and 5791 cases were men (49.5%). Most cases (25% and 24.3%) were in the age groups between 10- 24 and 25-34 years old, respectively ($P<0.01$). Scorpion sting cases took place throughout the year, however the highest frequency happened in May (1637, 14%) ($P<0.05$). Moreover, results showed that the highest rate of scorpion stings cases occurred in summer (36.5%) followed by spring (35.4%) ($P<0.05$). The place of residence was rural district in 3551 (30.3%) patients and the urban in 8134 (69.7%) ($P<0.05$). Among 11685 cases of scorpion sting, 4538 (38.8%) were found on hand, and 3956 (33.8%) on leg. About 31.3% of scorpion cases did not receive any the antiscorpion venom vaccine. The rest of the stung patients received the antiscorpion venom vaccine within 6 hours after the sting. No cases were exposed to multiple stings. Nocturnal and diurnal stings accounted for 78.2% and 21.8% of stings, respectively ($P<0.05$). All scorpion sting cases have gotten better throughout the study and one death (a five- year- old girl, stinged by Androctonus cradssicauda from the leg in 2015) have been reported.

Conclusions: Scorpionism information are able to guide responsible persons to reduce the cases of scorpion sting. Considering that the highest percentage of scorpion stings have been reported in urban regions accordingly, training prevention methods of scorpion sting to urban people and also development and improving human dwellings can greatly reduce the scorpion sting.

Does the little mean a lot? Bacterial endosymbiotic microbiome of aphids of the genus Dysaphis Börner, 1931

Authors: Kaszyca-Taszakowska Natalia[2] and Depa Łukasz[1], [2]University of Silesia, Poland, [1]University of Silesia

Abstract: Ant-aphid mutualism is a phenomenon widely researched for more than a century, being the subject of interest mostly of ecologists but also aphidologists, myrmecologists and researchers dealing with pest management. The primary symbiont of most aphids is a bacterium Buchnera aphidicola, belonging to a subdivision of the Proteobacteria. In addition to the primary symbiont some aphids also harbor other prokaryotic intercellular symbionts – secondary or facultative symbionts. It is proven that endosymbiotic bacteria may protect aphids against a fungal pathogen or make aphids resistant to parasitism. The aim of our research was to analyze the symbiotic composition in aphids of the genus Dysaphis, together with ecological analysis for aphids from primary and secondary hosts and the degree of relationship with ants (Lasius niger); colonies regularly visited by ants and without ants were examined. For this purpose we investigated a few Dysaphis species feeding on Sorbus, Malus, Crataegus, Pastinaca, Heracleum, Valeriana and Ranunculus using the NGS (Next-Generation Sequencing) method and discovered symbiotic bacterias including groups of primary (Buchnera aphidicola) and secondary symbionts (Serratia, Pelomonas, Wolbachia, Regiella and others.).

This work was supported by the PRELUDIUM grant number 2018/29/N/NZ8/00360 from the National Science Center, Poland to Natalia Kaszyca-Taszakowska.

Effectiveness of a novel window screening technology for malaria control in insecticide resistant areas of north-eastern Tanzania: Study design for a two-armed cluster randomized trial

Authors: Kathet Subam[3], Mwingira Victor[2], Tungu Patrick K[2], Magogo Frank[2], Meri Seppo[1], Kisinza William N[2] and Khattab Ayman[4], [1]Helsinki University Central Hospital, Helsinki, Finland, [2]National Institute for Medical Research, Amani Medical Research Centre, Tanzania, [3]TRIMM, Faculty of Medicine, University of Helsinki, [4]TRIMM, Faculty of Medicine, University of Helsinki, Finland

Abstract: In a growing scenario of insecticide resistance, the demand for a sustainable insecticide free malaria control tool is higher than ever. We have been working on a novel strategy focusing on blocking mosquito-host contact to reduce malaria by using a state of the art screened (3D screens) window double screen traps (WDST) developed in Finland. In Phase I laboratory studies, one 3D prototype captured 92% of the mosquitoes in a double screen setup. Phase II semi-field trials in Muheza, Tanzania (2017) found that 3D-WDST were quite effective in capturing (up to 80%) mosquitoes compared to the ones collected in the control setup. In the next step of evaluation (Phase III), we set up two-armed trial in Muheza that will compare houses with 3D-WDST (Treatment) combined with insecticide treated nets (ITNs) and against houses with ITNs only (control).

Phase III evaluation initiated with a baseline cross sectional (CS) study in June 2019. Twenty settlements were selected initially based on household (HH) density and accessibility and were subjected to malaria screening, mosquito density and insecticide resistance (IR) assessment. Based on the entomological, epidemiological and IR profile, 14 clusters with higher malaria prevalence and IR were selected for the study and randomized into control (7 clusters; 458 household) and treatment arms (7 clusters; 443 HH). Both arms were observed for 52 weeks (until May 2021) in which epidemiological and entomological data collection were conducted (every 10 weeks). Sociological studies for community feedback is in progress with dissemination plans in July 2022.

Gustatory polymorphism drives adaptive shifts in food and mating preferences

Authors: Katsumata Ayako[1], Schal Coby[1], Silverman Jules[1], [1]Department of Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States

Abstract: Shifts in food or host preferences in insects, accompanied by changes in the peripheral gustatory system, offer some of the best examples of adaptive behavioral evolution. A remarkable example is the German cockroach, a major indoor pest with a highly diverse omnivorous diet. Strong and persistent selection pressure with toxic baits has induced rapid evolution of behavioral resistance in multiple cockroach populations. While typical cockroaches detect and accept the sugar glucose as a feeding-stimulant via information processing by peripheral gustatory receptor neurons (GRNs) in the mouthparts, behaviorally resistant cockroaches avoid eating glucose-containing toxic baits by processing glucose as a bitter tastant via different GRNs which particularly respond to various deterrents. This glucose-averse (GA) trait is heritable, and controlled by a single major gene that follows Mendelian inheritance patterns. Neuroanatomical observations of GRN projections from the mouthparts to the central nervous system showed no differences in GRN projection between wild-type (WT) and GA cockroaches. The results indicate that qualitative changes of the ligand binding sites on bitter-GRNs contribute to glucose-aversion. Importantly, because GA cockroaches consume less glucose-containing diet, this trait is maladaptive in bait-free environments, as GA cockroaches must seek glucose-free foods. However, under human-imposed lethal environments, the trait protects individuals that bear the mutation(s).

Additionally, we found that the GA trait drives other behavioral polymorphisms in German cockroach populations, even in bait-free natural environments. During courtship, the female mounts the male and evaluates his quality by tasting a nuptial secretion that he offers on his tergum; the secretion contains glucose-related sugars, which stimulate the female's sugar sensitive-GRNs (sweet taste).This nuptial gift evolved under sexual selection to lure the female and position her for copulation. WT and GA males do not preferentially court WT or GA females. WT females accept both WT and GA males. On the other hand, GA females tend to accept GA males more than WT males after tasting the nuptial secretion. The differential mating success observed in this study suggests that WT and GA males have evolved nuptial secretion components that suit the gustatory preferences of the respective females in their population. Our model is that as WT males increase the amount of glucose-related sugars in their nuptial secretion in response to WT female preferences, nuptial feeding by GA females on the nuptial secretion of WT males is interrupted by the taste of glucose. Thus, the reversed modal specificity of glucose causes GA females to sense the nuptial gift components as deterrents, impeding the completion of the courtship sequence. Consequently, WT and GA cockroaches show assortative mating that would impact population dynamics and the frequency of the GA trait.

Evolution of morphological diversity in ant mandibles

Authors: Katzke Julian[1] and Economo Evan P.[1], [1]Okinawa Institute of Science and Technology Graduate University, Japan

Abstract: Along with the radiation of species, ant mandibles diversified to perform a broad repertoire of functions carried out by even more variable forms. Some evolved to fulfill specific tasks, while all are used to forage and manipulate nest and colony. Shapes range from short and stout to long and curved with many states in between. However, it is unclear whether the array of forms is the result of random diversification patterns or whether they are tied to predictor variables. Here, I show how diet relates to shape diversity and whether more diverse ant lineages also have a broader range of mandible shapes. I quantify mandible shape with geometric morphometric methods based on 3D micro-CT segmentations of 200 genera considering different worker polymorphisms. Initial results suggest that variations of the standard "triangular mandible" are prevalent in most ant lifestyles, found in all subfamilies. However, specialized predatorial, elongated mandibles arose in most lineages. Only rarely, shapes are restricted to certain lineages and even in species-poor clades, extreme shapes occur. In the future, I aim to investigate whether evolutionary patterns in mandible shape are also reflected by the mandible musculature and how mandible performance, head and mandible shape relate to each other.

Increasing surveillance of invasive species at Hawaii's ports of entry through inter-agency collaboration

Authors: Kaufman Leyla, Hawaii Invasive Species Council (HISC) Pacific Cooperative Studies Unit (PCSU), University of Hawaii, United States

Abstract: This presentation will describe the Mamalu Poepoe program, a five-year pilot program funded by the Department of Transportation (DOT) to increase surveillance of priority target species at six main Hawaii airports. The program brings together different state agencies with related goals surrounding the protection of airport infrastructure and users and the presence of invasive species, including the Hawaii Department of Transportation (HDOT), Hawaii Department of Agriculture (HDOA), Hawaii Department of Health (HDOH), the University of Hawaii (UH) and the Department of Land and Natural Resources (DLNR). Monitoring targets under this program include mosquitoes (in the genera Aedes, Culex and Anopheles), invasive ants (including the little fire ant, Wasmannia auropunctata, and the red imported fire ant, Solenopsis invicta) the Coconut Rhinoceros Beetle (CRB, Oryctes rhinoceros), and Africanized honeybees (Apis mellifera scutellata). The program aims to foster coordination and communication among the partner agencies, improve the State's capability to prevent invasive species introductions through systematic monitoring efforts, and increase the security of Hawaii's people, natural resources, food supply and economy.

While monitoring efforts for the above species existed prior to the implementation of Mamalu Poepoe, the program enhances those monitoring efforts through research, additional capacity, and strategic guidance. The program funds multiple research groups at UH. There are several studies testing efficacy of various mosquito traps across different trapping parameters, as well as an economic analysis. This presentation will provide information about the current program progress, future efforts, and how this program fits in the overall biosecurity program.

Probabilistic risk assessment, generalist natural enemies and realized risk

Authors: Kaufman Leyla[1] and WRIGHT MARK[2], [1]Hawaii Invasive Species Council (HISC) Pacific Cooperative Studies Unit (PCSU), University of Hawaii, United States, [2]University of Hawaii at Manoa Honolulu, Hawaii, United States

Abstract: Typically, arthropod biological control employs relatively specialized natural enemies, to avoid potential non-target impacts in release environments. There is interest in the using more generalist species in certain circumstances, and there may be ways to use them that reduce non-target risks, yet provide effective suppression of certain pests. This paper will briefly review probabilistic risk assessment (PRA) relevant to biological control agents and consider ways that the approach can be used to reduce potential negative environmental impacts of generalists. We have analyzed historic natural history and retrospective non-target impacts studies and show that probabilistic methods have the potential to provide accurate predictions of likely non-target impacts. Actual impacts, or realized prey or host ranges of natural enemies outside of quarantine environments can be very different to what may be observed under highly artificial conditions. Many generalist natural enemies used under very controlled circumstances such as greenhouses may be maladapted to persisting outside those environments. PRA provides an option for forecasting outcomes of such applications. Also, relative generalists may be specialized in a new environment, depending on regional and local species pools. Adopting PRA could increase the number of natural enemies considered for release despite being oligophagous and typically considered inappropriate options.

Urban Landscapes in Paradise: Identifying and Managing Pests in Hawaii's Urban Landscapes

Authors: Kaufman Leyla[1], Kaufman Andy[2], [1]Hawaii Invasive Species Council (HISC) Pacific Cooperative Studies Unit (PCSU), University of Hawaii, United States, [2]University of Hawaii, United States

Abstract: The Hawaiian Island's are one of the world's most popular vacation destinations with approximately 7 million visitors a year. Along with the many visitors to Hawaii the state has a permanent population of around 1.2 million. One of the most significant features that make Hawaii such a popular travel destination and place to live is the aesthetic beauty of the natural and urban landscape. In addition to people, many insects find Hawaii a desirable destination to live and raise their young. Hawaii is the most isolated landmass in the world, yet is considered the invasive species capital of the world. It is estimated that to eradicate current invasive species and to understand the risks, it would cost approximately 50 million dollars a year. Currently, funding to battle invasive species is only 10-15% ($4 million dollars) of needed levels with an additional 6% being contributed by federal sources. Considering the elevated costs, particularly in the depressed economy, there needs to be a concerted effort dedicated to securing funding sources to enable proper urban landscape management. This funding is needed to combat the onslaught of new urban landscape pests, as well as concentrating on identifying, management and prevention. In order to address the overall issue of urban landscape pests, this presentation provides methodologies in understanding the barriers and opportunities for identifying and then managing the current and future establishment of invasive pets to protect Hawaii's urban landscapes.

Looking for the invisible? A meta-analysis and critical review of remote sensing approaches to timely detect bark beetle infestations

Authors: Kautz Markus[1] and Adler Petra[1], [1]Forest Research Institute Baden-Wurttemberg, Germany

Abstract: Despite rapid technical advances in remote sensing and the urgent demand due to increasing outbreak intensities over recent decades, an approach that can reliably detect bark beetle infestations in time for its sanitation is still missing. Do we long for the unattainable – or will promises soon to be met? We employed an in-depth review and meta-analysis on recent advances, challenges and limitations for remotely-sensed early (or so-called ´green-attack´) infestation detection regarding the European spruce bark beetle – Norway spruce system. We screened and analyzed recent research (2000-2021) on satellite-, airborne-, UAV- and terrestrial-based sensor systems. Among all studies (n=21), satellite imagery and multispectral data were most frequently investigated. Major methodological drawbacks include small sample size, low observation frequency and missing ground-truth verification of bark beetle infestation status. Accuracy metrics revealed an insufficient reliability for the timely detection of infested trees, i.e. user accuracy <80% in all studies. Most promising spectral bands for early detection were within the short wave infrared spectrum – however, the variability of ´promising´ spectral ranges or indices was also high among the studies. Cloud cover analyses we examined across Europe suggest further limitations for the operational use of satellite imagery for supporting a timely infestation detection.

Repellency as an ultimate countermeasure for Aedes mosquito control

Authors: Kawada Hitoshi[1], Minakawa Noboru[1] and Morimoto Yasue[1], [1]Institute of Tropical Medicine, Nagasaki University, Japan

Abstract: N, N-Diethyl-m-toluamide (Deet) and Icaridin are representative mosquito repellents used for human protection from mosquito biting. Almost 100 % protection lasts at least several hours by direct treatment of the repellents on human skin. Pyrethroids are the predominant insecticides used for malaria and dengue vector control and have been the only class of insecticides used for LLINs. Pyrethroids have unique modes of action such as fast knockdown, excito-repellency, spatial-repellency, and disruption of blood feeding motivation. Space spray, fumigation, residual treatment on the wall, impregnation into plastic materials and fabrics, etc. are major delivering measures for pyrethroids.

Use of the repellency of mosquito repellents and pyrethroids might be biorational, since such repellency will not induce the development of any physiological resistance since they do not kill the affected insects or reduce the chance of contact to the insecticides and causes low selection pressure on insect populations. However, little is known about the modes of action, sensing organs, and the relationship between insecticide resistance and repellency.

The aim of this study is to investigate the difference in the repellency of Deet, Icaridin, Permethrin, and Metofluthrin against Aedes aegypti and Ae. albopictus by using the attractive blood feeding apparatus. Relationship between pyrethroid resistance and repellency is also discussed.

Eight simple actions that individuals can take to save insects from global declines

Authors: Kawahara Akito, Florida Museum of Natural History, United States

Abstract: Insects constitute the majority of known animal species and are ubiquitous across terrestrial ecosystems, playing key ecological roles. As prey, they are critical to the survival of countless other species, including the majority of bats, birds, and freshwater fishes. As herbivores, predators, and parasites, they are major determinants of innumerable plants and animals. The majority of flowering plants, the dominant component of most terrestrial ecosystems, depend on insects for pollination and hence reproduction. As consumers of waste products, insects are essential to the recycling of nutrients. Humans and their agriculture rely heavily on such "ecosystem services" provided by insects. Even as insects gain recognition as essential members of ecosystems, a concern has arisen that their diversity and abundance may be in global decline. There is every reason to suspect that such forces, combined with human population growth and urbanization, are leading to declines among insects and many other organisms. To help individuals broaden participation in the conservation of insects and to promote the adoption of behaviors and habits expected to mitigate insect declines, we propose eight simple actions, most with immediate impact, that many people can undertake on their own, regardless of background, occupation, or geographic location.

Phylogenomics and the evolutionary timing and pattern of butterflies and moths

Authors: Kawahara Akito[7], Plotkin David[7], Espeland Marianne[1], Meusemann Karen[1], Toussaint Emmanuel[8], Donath Alexander[1], Gimnich France[1], Frandsen Paul[6], Zwick Andreas[5], dos Reis Mario[9], Barber Jesse[2], Peters Ralph[1], Liu Shanlin[4], Zhou Xin[3] and Mayer Christoph[1], [1]Alexander Koenig Zoological Research Museum, [2]Boise State University, [3]China Agricultural University, China, [4]China National GeneBank, BGI-Shenzhen, [5]Commonwealth Scientific and Industrial Research Organisation, Australia, [6]Department of Plant and Wildlife Sciences, Brigham Young Univ., Provo, UT, USA , United States, [7]Florida Museum of Natural History, United States, [8]Natural History Museum of Geneva, [9]Queen Mary University of London

Abstract: Lepidoptera are one of the major super-radiations of insects, comprising nearly 160,000 described extant species. They have been central to the development of coevolutionary hypotheses, such as butterflies with flowering plants and moths' evolutionary arms race with echolocating bats, but these hypotheses have not been rigorously tested. We inferred a comprehensive phylogeny of Lepidoptera, using the largest dataset assembled for the order (2,098 genes from transcriptomes of 186 species, representing nearly all superfamilies), and dated it with carefully evaluated fossils. The oldest members of the Lepidoptera crown group appeared in the Late Carboniferous (-300 Ma) and fed on nonvascular land plants. Lepidoptera evolved the tube-like proboscis in the Middle Triassic (-241 Ma), which allowed them to acquire nectar from flowering plants. This morphological innovation, along with other traits, likely promoted the extraordinary diversification of superfamily-level lepidopteran crown groups. The ancestor of butterflies was likely nocturnal, and our results indicate that butterflies became day-flying in the Late Cretaceous (-98 Ma). Moth hearing organs arose multiple times before the bat-moth evolutionary arms race, perhaps initially detecting a wide range of sound frequencies before being co-opted to specifically detect bat sonar. Our talk may also include new, unpublished data and results.

The impact of temperature stress on the octopaminergic system of honeybee flight muscles

Authors: Kaya-Zeeb Sinan David, Zoology II, University of Würzburg, Germany

Abstract: Once environmental conditions change drastically, species must decide whether they relocate to new habitats or adapt. The latter requires physiological plasticity. The Western honeybee (Apis mellifera) represents a eusocial insect species that is able to adapt to changing conditions. Their thermoregulatory capabilities allow them to withstand extreme conditions and contribute to their almost worldwide distribution. In this context, the workerbee flight muscles are of special importance. These organs are primarily used during foraging flights. Flight muscles are of central importance for thermoregulation, as their activity enables both cooling and warming. The latter is realized by muscle shivering (thermogenesis) and is important for winter survival, breeding and defense.

We showed that workerbee thermogenesis relies on octopamine signaling. This monoamine activates β octopamine receptors and the subsequent intracellular cascade boosts glycolysis in the flight muscles. Now that we understand this molecular mechanism, we further investigate the flexibility of this system. Here, we will analyze certain aspects while applying short and long term temperature stress. Both phenomena occur naturally, but extreme weather events are expected to increase substantially due to global anthropogenic impact. First results indicate functionality of the flight muscles is maintained under these conditions and any breakdown could have dramatic consequences.

Trehalose metabolism during parasitoid infection in Drosophila.

Authors: Kazek Michalina, University of South Bohemia in Ceské Budějovice, Czech Republic

Abstract: Trehalose is a nonreducing disaccharide that is present in many organisms. In insects, it usually occurs in much higher concentration than glucose. Trehalose can be rapidly cleaved to two glucose molecules by the trehalase enzyme. In Drosophila, two versions of trehalase exist, cytoplasmic and secreted. The secreted version is used to maintain circulating glucose at a stable level and appears to be part of systemic regulation of carbohydrate metabolism. Nevertheless, the physiological role of trehalose during the immune response after parasitoid infection remains largely unclear. Gene expression analysis shows that hemocytes increase expression of both trehalose transporter and cytoplasmic trehalase. Knocking down trehalose transporter and trehalase enzyme, specifically in hemocytes, significantly decreases number of lamellocytes. We also observed that hemocytes prefer trehalose as an energy source during infection. Experiments with 13C-labeled trehalose and glucose show that hemocytes, during parasitoid infection, increase the uptake of trehalose, which is partially metabolized by glycolysis but mainly by the pentose phosphate pathway. Overall, the metabolism of trehalose after activation of immune cells ensures balance and sufficient energy supply, which is important during immune activation and makes the immune system privileged within organism.

High throughput data acquisition and deep learning for insect ecoinformatics

Authors: Keasar Chen[3], Gerovichev Alexander[2], Sadeh Achiad[4], Winter Vlad[2], Bar Massada Avi[1] and Keasar Tamar[1], [1]Department of Biology, University of Haifa – Oranim, Tivon, Israel, [2]Department of Computer Science, Ben-Gurion University of the Negev, Beersheba, [3]Department of Computer Science, Ben-Gurion University of the Negev, Israel, [4]Department of Evolutionary and Environmental Biology, University of Haifa, Israel

Abstract: Insect ecoinformatics is scientifically important and highly applicable, as insects are abundant, speciose, and involved in many ecosystem functions. Yet, insect databases are mostly focused on a small number of pest species, as data acquisition is labor-intensive and requires taxonomical expertise. We describe a high throughput cost-effective approach for monitoring flying insects as an enabling step toward "big data" entomology. We combine "high tech" deep learning with "low tech" sticky traps that sample flying insects. As a proof of concept, we considered three insect invaders of Israel's forests: two hemipteran pests of eucalypts and a parasitoid wasp that attacks one of them. Our deep learning software identifies the three species in images of sticky traps from Eucalyptus forests. This task is difficult as the insects are small and stick to the traps in random poses. The deep learning model discriminated the three focal organisms from one another, and from irrelevant objects (e.g., other insects), with high precision. We used the model to compare the abundances of these species among six sites and validated the results by manual counting. We aim at building an ecoinformatics repository for trap images and generating data-driven models of the populations' dynamics and morphological traits.

Pollinator behavior drives sexual specializations in the hermaphrodite flowers of a heterodichogamous tree

Authors: Keasar Tamar[5], Shapira Idan[3], Tel-Zur Noemi[1], Reisman-Berman Orna[2], Lev-Yadun Simcha[4], Zurgil Udi[1] and Lebber Yochai[6], [1]Ben Gurion University, Israel, [2]Ben Gurion University, the Open University, Israel, [3]Megiddo Biosphere Reserve, Israel, [4]University of Haifa - Oranim, Israel, [5]University of Haifa - Oranim, Israel, Israel, [6]University of Haifa, Israel

Abstract: Dioecy, the specialization of individuals into either male-only or female-only sexual function, has multiple evolutionary origins in plants. One proposed ancestral mating system is heterodichogamy, two morphs of cross-fertilizing hermaphrodite flowers that differ in their timing of flowering. Previous research suggested that small specializations in these morphs' functional genders could facilitate their evolution into separate sexes. We tested the possible role of pollinators in driving such specializations. Ziziphus spina-christi is an insect-pollinated heterodichogamous tree with self-incompatible flowers and two sympatric flowering morphs. We compared the flower development patterns, floral food rewards, pollinator visits and fruit production between the two morphs. Male-phase flowers of Z. spina-christi's "Early" and "Late" morphs open before dawn and around noon, respectively, and transition into female-phase 7-8 hours later. Flowers of both morphs contain similar nectar and pollen rewards, and receive visits by flies (their ancestral pollinators) at similar rates, mostly during the morning. Consequently, the Early morph functions largely as pollen donor. The Late morph, functioning as female in the morning, produces more fruit. We developed an evolutionary probabilistic model, inspired by Z. spina-christi's reproductive system, to test whether pollinator visit patterns could potentially play a role in an evolutionary transition from heterodichogamy towards dioecy. The model predicts that reproductive incompatibility within flowering morphs promotes their evolution into different sexes. Furthermore, the pollinators' morning activity drives the Early and Late morphs' specialization into male and female functions, respectively. Thus, while not required for transitioning from heterodichogamy to dioecy, pollinator-mediated selection is expected to influence which sexual specialization evolves in each of the flowering morphs.

Trait change in different insect species from urban and rural habitats, tracked through museum vouchers from the last 100 years.

Authors: Keinath Silvia[2], Hölker Franz[1], Mayer Frieder[2], Frisch Johannes[3], Müller Johannes[2] and Rödel Mark-Oliver[2], [1]Leibniz-Institute of Freshwater Ecology and Inland Fisheries. Berlin-Brandenburg Institute of Advanced Biodiversity Research, Germany, [2]Museum für Naturkunde, Berlin Leibniz Institute for Evolution and Biodiversity Science. Berlin-Brandenburg Institute of Advanced Biodiversity Research, Germany, [3]Museum für Naturkunde, Berlin Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Increasing human environmental impact leads to rapid transitions from near natural to novel ecosystems. This results in the disappearance of many native species and the invasion of non-native species in such transformed ecosystems. However, some species persist throughout environmental transitions. Mostly it is unclear which adaptations enable these species to persist, whilst others disappear. Furthermore, we usually do not know if these species persist unchanged or adapt to the new conditions. Due to the comparatively long timeframe, during which these transitions occur, direct observations of potential ecological adaptations, such as behavioral and physiological changes, are not possible. However, some insights can be gained from preserved museum vouchers and their morphological traits, the latter can be used as a proxy for a species' ecological and physiological modifications during the transition of an ecosystem. These historical datasets might be completed with recent samples to cover the entire spatio-temporal gradients across environmental transitions. In our study, we investigated morphological trait change in two ground beetle species, one moth and one bumblebee in the Berlin (urban) / Brandenburg (rural) region of north-eastern Germany, collected over 125 years in different habitats, differently influenced by humans.

Classical biological control of Spodoptera frugiperda in Africa and Asia using parasitoids from the Americas

Authors: Kenis Marc, CABI Delemont, Switzerland

Abstract: Since its recent arrival in Africa and Asia, the fall armyworm, Spodoptera frugiperda, has become a major pest of maize and other cereals throughout the two continents, threatening the livelihood of millions of smallholder farmers. So far, emergency responses have consisted mainly in the use of chemical insecticides and more sustainable management methods, such as biological control, are urgently needed. Spodoptera frugiperda could potentially be controlled in Africa and Asia by the introduction of a natural enemy from its area of origin, the Americas, a method named classical biological control. However, in contrast to many other invasive pests, S. frugiperda is also a pest in its area of origin, suggesting that natural enemies alone may not be able to control it. Nevertheless, even a partial control leading to a reduction of yield losses and pesticide use would have, at continental scale, a tremendous effect on food security, health and the economy. The main criteria for the selection of American natural enemies are their efficiency as control agent and their specificity for the target pest. All known predators of S. frugiperda in the Americas are highly polyphagous. Egg parasitism is usually low and the main egg parasitoid, Telenomus remus, is already present in Africa. In contrast, some larval parasitoids could be considered for introduction. In the Americas, larvae are attacked by a large complex of parasitoids and, in areas with no or limited insecticide applications, parasitism rates can be high. Some of the main parasitoids, such as the ichneumonid Eiphosoma laphygmae, are known nearly exclusively from S. frugiperda whereas, for others, specific biotypes or cryptic species cannot be excluded. Some of these species are presently being studied in various quarantine laboratories. At the same time, the parasitoid complex in Africa and Asia has to be investigated to assess potential competitive interactions with introduced parasitoids.

Invasion of the giant pine scale in Australia – first steps towards its biological control

Authors: Kenis Marc[1], Avtzis Dimitrios[3], Andreadi Anneliza[4], Lefoe Greg[5], Eleftheriadou Nikoleta[4], Shaw Richard[2], Lubanga Umar[5] and Markoudi Vassiliki[4], [1]CABI Delemont, Switzerland, Switzerland, [2]CABI Surrey, United Kingdom, [3]Forest Research Institute - Hellenic Agricultural Organization Demeter, Greece, [4]Forest Research Institute Hellenic Agricultural Organization Demeter, Greece, [5]Invertebrate & Weed Sciences, Agriculture Victoria Research Department of Jobs, Precincts and Regions Victoria, Australia

Abstract: In its native range in Greece and Turkey, the giant pine scale (GPS) Marchalina hellenica (Hemiptera, Margarodidae) has always been considered a rather beneficial insect as it provides honey dew to support pine honey production and has rarely been observed to cause tree mortality. However, very soon after its first detection in Australia in 2014, GPS showed its pest potential by spreading rapidly and causing serious damage to a novel host; the economically important plantation tree Pinus radiata. A preliminary survey of the natural enemy complex of GPS in Greece revealed a broad spectrum of species that influence GPS populations; among the species identified, the predatory fly Neoleucopis kartliana (Diptera, Chamaemyiidae) was recorded at every GPS population studied in Northern Greece. Since N. kartliana also exhibited a predation rate that reached up to 50% in some cases, this predatory fly was quickly selected as having the most potential as a biological control agent against GPS. The first attempts to bring N. kartliana into laboratory rearing have shown that this species responds adequately to the controlled environment conditions; nevertheless, there are still many aspects of the fly's biology, ecology and host-range to be studied before N. kartliana can be introduced to control the invasive GPS in Australia.

Potential for classical biological control of Drosophila suzukii using parasitoids from Asia

Authors: Kenis Marc[1], Seehausen Lukas[2], [1]CABI Delemont, Switzerland, [2]CABI, Switzerland

Abstract: The invasive spotted wing Drosophila, Drosophila suzukii, has become a major pest of many fruit crops worldwide. Various methods have been developed to control the pest in conventional and organic systems. However, because of the wide host range of the fly and the high number of generations per year, crops are constantly reinvaded from neighbouring habitats, which complicates management strategies. Classical biological control through the introduction of parasitoids from the native region of D. suzukii in East Asia could provide an area-wide control of the pest. Surveys were carried out in China and Japan to identify the most abundant and most specific parasitoid species in the native range of D. suzukii. These surveys and subsequent research in quarantine in Europe showed that the most abundant and most specific parasitoid is a figitid wasp, Ganaspis cf. brasiliensis. However, cross-mating experiments between populations, molecular studies and behavioural tests revealed the existence of two sibling species, both occurring sympatrically in China and Japan. In specificity tests, one of these species (G1) showed a higher level of specificity than the other (G3). However, studies also revealed that the specificity was not only related to the host species but also to the substrate in which the host larva occurred. Indeed, G1 populations successfully attacked and developed in Drosophila spp. in fresh fruits but not when larvae were offered in fruit-based diets or rotten fruits, In contrast, G3 populations attacked equally well larvae in fresh and rotten fruits and in fruit-based diets. Since, in Asia, G1 is only found in Drosophila spp. in fresh fruits and, in Europe, only D. suzukii attacks fresh, undamaged fruits, G1 should be considered for release in Europe. More generally, this study illustrates the importance of considering the occurrence of biotypes or sibling species varying in host specificity and other traits when selecting agents for classical biological control.

The associational resistance hypothesis in practice: Are mixed Buxus stands more resistant to the box tree moth Cydalima perspectalis (Lepidoptera: Crambidae) than pure stands?

Authors: Kenis Marc[1], Seehausen Lukas[3], Castagneyrol Bastien[4] and Nacambo Saidou[2], [1]CABI Delemont, Switzerland, [2]CABI, Switzerland, [3]CABI, Switzerland, [4]Inra, France

Abstract: Theory and empirical studies provide evidence of associational resistance to native pests and pathogens in mixed forests when compared pure forests, but there is a lack of data for exotic or invasive species. Based on recent reviews, tree species diversity would be more likely to facilitate alien species establishment at the regional scale (more potential host resources) but based on theoretical studies, mixed forests would reduce the development (at the local scale) and spread (landscape scale) of alien pest or pathogen populations (the “invasion paradox”).

The main idea underlying the associational resistance hypothesis in this context is that non-native pests are often introduced without their co-evolved natural enemies (natural enemy hypothesis), however, mixed forests favour a more diverse community of indigenous natural enemies and if these are generalist enough to spill over onto introduced species, they might be useful to provide a certain resistance of forests to the pests.

Within the framework of the European project on HOlistic Management of Emerging forest pests and Diseases (HOMED) the objectives of this research are to compare mixed and pure natural European box tree (Buxus sempervirens, Buxaceae) stands in terms of defoliation by the invasive box tree moth Cydalima perspectalis (Lepidoptera: Crambidae) and mortality of the pest through predation and parasitism by indigenous parasitoids and predators.

The first year of fieldwork revealed defoliation levels of close to 100% in pure and mixed stands in several locations, showcasing the severe effect of the box tree moth on natural Buxus stands. Parasitism rates and predation were generally low, making it difficult to determine differences between box tree densities. A second year of experiments in additional sites will help to clarify if there is an associational resistance of mixed box tree stands against C. perspectalis.

The Power of Peptides in Crop Protection

Authors: Kennedy Robert, Vestaron Corporation

Abstract: We describe here commercialization of the first peptide for crop protection against insects with a novel IRAC neuromuscular mode of action. We also disclose a pipeline of peptide products each with a path to two additional independent IRAC neuromuscular modes of action.

The role of native, perennial nightshades in shaping the transmission of Candidatus Liberibacter solanacearum by Bactericera cockerelli in California

Authors: Kenney Jaimie[2], Mauck Kerry[1], [2]University of California, Riverside, United States, [1]University of California, Riverside

Abstract: Psyllid-transmitted bacteria in the genus ‘Candidatus’ Liberibacter pose a growing threat to agricultural production around the globe. However, our understanding of the ecological and biological factors facilitating the emergence and spread of these virulent pathogens in crop plants is still relatively limited. This is due in large part to a lack of research on the natural history of both Ca. Liberibacter and psyllid vectors outside of agroecosystems. We are addressing this critical knowledge gap by studying the genetic diversity and biology of Ca. Liberibacter solanacearum (CLso) and its vector, the native potato psyllid (Bactericera cockerelli), in natural plant communities in California. To accomplish this goal, we screened native, perennial nightshades growing in southern California ecological reserves for both CLso and potato psyllids. We complemented this work with controlled, psyllid-feeding transmission assays to investigate the effects of CLso infection on the health of California native nightshades. The results of this work demonstrate the importance of understanding the genetic diversity and ecology of crop pathogens and their insect vectors beyond the borders of agriculture, in order to accurately infer the origins of insect-transmitted crop diseases and improve their management.

Through Northern Europe to Western Siberia; genetic approach in reconstruction of invasion pathway of Ips amitinus Eich. 1872 (Coleoptera: Curculionidae, Scolytinae)

Authors: Kerchev Ivan[2], Ilinsky Yury[1], Bykov Roman[1] and Mandelshtam Mikhail[3], [1]Institute of Cytology and Genetics SB RAS, Russia, [2]Institute of Monitoring of Climatic and Ecological Systems SB RAS, [3]St. Petersburg State Forest Technical University named after S.M. Kirov

Abstract: Ips amitinus is a Central European Highlands origin species which has been considered a secondary pest associated with several species of spruces and pines (Pfeffer, 1995). In last decades, the range of I. amitinus rapidly expanded into Northern Europe (Økland et al., 2019), and fether in Karelia, Leningrad and Arkhangelsk regions in Russia (Mandelshtam, 1999; Voolma et al., 2004; Mandelshtam, Musolin, 2016).

In 2019 it was registered for the first time in Western Siberia, there it became new aggressive pest for Pinus sibirica. The secondary area covers 31.2 thousand km^2 with a tendency for rapid eastward expansion (Kerchev et al., 2019; 2021).

Here we study genetic diversity of I. amitinus collected from native range: Austria, Switzerland, Bulgaria, and from second range: Finland and Russia namely Kaliningrad, Leningrad regions, and West Siberian populations. The analysis revealed that European native populations have high variation of mtDNA haplotypes whereas the populations from secondary range were monomorphic, i.e. observed the founder effect. We conclude that initially there was an invasion into Northern Europe, which became a donor region for the subsequent invasion in Siberia.

This research was supported by the RFBR (grant: 20-04-00587).

Ecological consequences of a shifted phenology in the pine processionary moth

Authors: Kerdelhue Carole[8], Branco Manuela[5], Paiva Maria Rosa[1], Rossi Jean-Pierre[7], Burban Christian[6], Santos Helena[4], Godefroid Martin[2], Gautier Mathieu[2], Leblois Raphaël[2] and Rocha Susana[3], [1]1CENSE, DCEA, FCT NOVA, Universidade Nova de Lisboa, Caparica, Portugal, Portugal, [2]CBGP, INRA Montpellier, France, [3]Forest Research Center (CEF), School of Agricultural (ISA), University of Lisbon, Portugal, [4]Forest Research Center (CEF), School of Agricultural (ISA), University of Lisbon, Portugal DCEA, FCT, New University of Lisbon, Portugal, [5]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [6]UMR BIOGECO, INRA Bordeaux, France, [7]UMR CBGP, INRA Montpellier, France, [8]UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France

Abstract: The pine processionary moth Thaumetopoea pityocampa is a pine defoliator with one year life cycle. Typically, mating and egg laying occurs during summer months whereas larval development takes place during winter in gregarious silk nests. Gradual changes in phenology are observed for this species, in particular with earlier flight periods at higher latitudes and altitudes, probably due to adaptation to climate gradients. Here, however, we document an abrupt change in a unique population, possibly caused by mutations in one or more genes regulating life cycle events. In this unique shifted population, the adults mate in the spring and the larvae develop through summer. Such abrupt changes can either cause an eco-evolutionary dead-end, or on the contrary bring ecological opportunities, such as escape from natural enemies, or adaptations to climate change. Here, we report the ecological consequences of the phenological shift for this particular population of the pine processionary moth. Our observations demonstrated ecological implications of the shifted life cycle and ongoing adaptations. Changes in the thermal biology, climatic niche, phenotypic morphological traits, fecundity and egg mortality are evidenced. Feeding constraints imposed by season and host plant physiology are also observed. Finally, the shifted phenology may impose higher risks for human health. Altogether our results show a comprehensive understanding of the implications of phenological changes in the ecology and success of this pine defoliator.

From phenological variability to allochrony: a case study on the pine processionary moth

Authors: Kerdelhue Carole[6], Branco Manuela[1], Rossi Jean-Pierre[5], Buradino Maurane[2], Mesmin Xavier[2], Burban Christian[4] and Martin Jean-Claude[3], [1]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [2]INRAE, France, [3]UEFM, INRA PACA, Avignon, France, [4]UMR BIOGECO, INRA Bordeaux, France, [5]UMR CBGP, INRA Montpellier, France, [6]UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France

Abstract: In temperate species, phenological variability, i.e. the timing of the various stages of the life cycle, can allow adaptation to the local environmental conditions. In particular, insect diapause or quiescence is a classical way of avoiding harsh winter or extreme hot summer conditions.

The pine processionary moth Thaumetopoea pityocampa (Lep., Notodontidae) is a conifer-defoliating species that is found in the Western Mediterranean regions and is currently expanding northwards. It generally has a one-year life cycle, and its phenology is known to gradually vary over its distribution range. Sexual reproduction occurs in summer, and the 5 larval stages usually span from late summer to late winter. When larval development is complete, the caterpillars move from their host tree to their underground pupation site in a typical head-to-tail procession. The pupae enter an obligate diapause, and adult emergence occurs the following summer. As larval development depends on temperature, there is a strong variability in procession date and in diapause duration. Moreover, a fraction of the population may enter prolonged diapause and emerge only a year or more later. Adult emergence and reproduction tend to occur later (in August or September) in warm regions such as the southern part of its range, while it occurs much earlier (June or early July) in northern areas or at high altitude. This pattern is thought to allow the individuals to adapt to the major climatic risk in each region by avoiding extreme heat waves in the South and optimizing resistance to early frost in the North. These general observations suggest that early-reproducing individuals would be counter-selected in the southern part of its range. Nonetheless, a unique population with a shifted life cycle occurs in Portugal and reproduces in spring, and unexpectedly currently shows high population size locally.

To better understand the fine-tuning of phenology in this species, we will document results obtained under two contrasting situations. First, we will report original data based on a historical time series (1970 – 1985) showing how phenology (time of procession and time of adult emergence) varies in space and time over an altitudinal cline in Southern France. The results suggest that local climatic conditions strongly affect the timing of sexual reproduction in this species, but that between-year variations could correspond to different mechanisms than between-site variations. They also show how duration of pupal diapause allows the synchronisation of adult emergence in spite of a very strong variation in the timing of procession. Second, we will present an overview of results concerning the shifted Portuguese population and propose hypotheses concerning its apparent paradoxical success. We will show that the SP probably arose from a sudden phenotypic mutation and experiences allochronic differentiation. We will discuss its fate in front of the current climate change.

Past, present and future potential geographical distribution of Xylosandrus crassiusculus in Europe

Authors: Kerdelhué Carole[3], Rossi Jean-Pierre[3], Urvois Teddy[1], Auger-Rozenberg Marie-Anne[2], Roques Alain[2], [1]INRAE URZF & UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France, [2]INRAE, URZF, Orleans, France, [3]UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France

Abstract: Biological invasions constitute one of the main threats to biodiversity. A better understanding of invasive species' biology, ecology and invasion history is necessary to better anticipate and possibly prevent future bark beetles invasions. Species distribution modelling (SDM) is an increasingly important tool to study and forecast biological invasion, helping us determine which areas are suitable for a species to establish. Hence, this tool helps focus prevention, detection and conservation efforts.

Xylosandrus crassiusculus is a successful worldwide invasive ambrosia beetle originating from Southeastern Asia. Storer et al. (2017) showed that X. crassiusculus comprises two genetically divergent clusters, both invasive in various areas.

We assigned specimens from X. crassiusculus' invasive and native area to each genetic cluster and assessed the two clusters' niche overlap. We found that the two clusters had significantly different climatic niches, and thus we performed species distribution modelling on each cluster separately, using the Maxent algorithm. The resulting models were also projected in Europe according to past and future climate datasets. The future projections were performed for two periods, 2041-2070 and 2071-2100, using 3 Shared Socioeconomic Pathways (scenarios of projected socioeconomic global changes up to 2100) and 5 Global Circulation Models (numerical models accounting for the various components of influencing climate).

Our results showed that both genetic clusters could expand their distributions in each continent, and Cluster 1 could establish in Europe, where it is still absent.

Climate change is expected to shift both clusters' range in Europe, decreasing habitat suitability in Southern Europe and increasing it towards Northeastern Europe in 2071-2100. The newly suitable areas would include new points of entry such as major harbours in northern Europe, in regions that are currently climatically unsuitable.

Most of Southern and Western Europe was predicted as already suitable for both clusters in the early XXth century. This suggests that the recent colonisation of Europe by Cluster 2 is not due to a recent change in climate suitability but probably to an increase in propagule pressure via international trade.

Pine processionary moths: promises from genomic developments

Authors: Kerdelhué Carole[1] and Perrier Charles[1], [1]UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France

Abstract: The pine processionary moth (PPM) Thaumetopoea pityocampa occurs in the Western part of the Mediterranean Basin. In the last two decades, phylogeographical and population genetic studies have allowed to address evolutionary questions and to partially decipher its geographical structure at different spatial scales. Neutral markers specifically developed for this species were for example used to study its Quaternary history and localize the glacial refugia; to study a case of allochronic differentiation and show how a phenological shift can isolate populations; and identify long-distance dispersal events.

We were recently able to develop genomic resources in this species. We could assemble a high-quality genome that was automatically annotated. Gene prediction was further proposed using transcriptomic data. The results suggest that the PPM genome is composed of 49 pairs of autosomes and one pair of sexual chromosomes. We will discuss how population genomic studies will now be developed based on individual re-sequencing and will open possibilities to question both neutral structure, demographic histories and adaptive evolution. This resource will also allow to study introgression events at fine scale and to explore the genomic evolution of the T. pityocampa / T. wilkinsoni species complex.

Description of a new mite species (Storchia oryzaus) Stigmaeidae: Acari from Pakistan

Authors: Kkhan Bilal[2], Bashir Muhammad[4], Afzal Muhammad[1] and Ghaffar Abdul[3], [1](Vice Chancellor) Baba Guru Nanak University, Nankana Sahib, Punjab, Pakistan., [2]Associate Professor Department of Entomology University of Agriculture, Faisalabad. 38000 Punjab, Pakistan, Pakistan, [3]Ayub Agricultural Research Institute, AARI, Faisalabad, Pakistan, [4]University of Agriculture, FSD, Pakistan

Abstract: Experiment was managed to find the predatory mite fauna of family Stigmaeidae (Acari) from Punjab, Pakistan. The holotype adult female (male unknown) of genus Storchia was collected from urban cultivated area of city Gujranwala from rice crop (Oryza sativa) and described here. Eighteen (18) paratypes were collected, among which 12 with same collection data and 6 from another locality of Faisalabad. The description, figures, measurements and discussion of this new species is given here in this manuscript. The collected samples were placed in Acarology Research Laboratory, Department of Entomology, University of Agriculture, Faisalabad, Pakistan.

Climate-adapted push-pull technology: A conservation agriculture technology for food security and environmental sustainability in Africa

Authors: Khan Zeyaur[4], Midega Charles[2], Pittchar Jimmy[3] and Pickett John[1], [1]Cardiff University, United Kingdom, [2]icipe - International Centre of Insect Physiology and Ecology, Kenya, [3]International Centre of Insect Physiology and Ecology (icipe), Kenya, [4]Mbita campus, Int. Centre of Insect Physiology and Ecology, Mbita, Kenya

Abstract: Poor yields of cereal crops caused by constraints such as stemborer and fall armyworm pests, parasitic Striga weeds and degraded soils are responsible for the chronic food insecurity in Africa--a situation that is worsening with climate change and human population growth. Push-pull, a climate-adapted conservation agricultural innovation based on companion cropping, effectively addresses these constraints resulting in substantial grain yield increases without the use of any external inorganic inputs. Push-pull involves intercropping cereal crops with moth repellent forage legume, e.g. Desmodium (push), and planting attractive fodder grasses e.g. Napier grass or Brachiaria as a border crop (pull). Desmodium is also effective in suppressing Striga weed while improving soil fertility by fixing nitrogen and improving soil organic matter and biodiversity of arthropods. Both companion plants are valuable fodder plants thus allowing integration of crop and livestock production which diversifies farmers' income sources. Drought-tolerant companion plants are identified and incorporated into the technology,are extending the benefits to drier areas and ensuring its long-term sustainability in view of climate change. The technology provides an opportunity to improve food security, stimulate economic growth, and alleviate poverty in Africa while making agriculture more resilient to climate change.

A little egg lay on a maize leaf… did the plant scream for help?

Authors: Khan Zeyaur[7], Bruce Toby[6], Tamiru Amanuel[2], Midega Charles[2], Odeny Damaris[3], Sobhy Islam[5], Pickett John[1] and Paliwal Rajneesh[4], [1]Cardiff University, United Kingdom, [2]icipe - International Centre of Insect Physiology and Ecology, Kenya, [3]ICRISAT - International Crops Research Institute for the Semi-Arid Tropics, Kenya, [4]IITA - International Institute of Tropical Agriculture, Nigeria, [5]Keele University, United Kingdom, [6]Keele University, United Kingdom, [7]Mbita campus, Int. Centre of Insect Physiology and Ecology, Mbita, Kenya

Abstract: Herbivore induced plant volatiles (HIPVs) are often emitted when chewing herbivores start biting a plant and these volatiles can function as recruiting signals for predator and parasitoid "bodyguards" in indirect plant defence. Furthermore, it has become apparent that some plants can respond to herbivory at an earlier stage when an egg is laid on a leaf. Our collaborative research, with icipe in Kenya, has revealed that certain maize landraces emit HIPVs in response to stemborer, Chilo partellus, oviposition. We initially found that the two commercially available hybrid maize genotypes tested did not have this trait, whereas, it was widespread in a number of farmer preferred landraces. However, those landraces were not genetically uniform and lacked the yield potential of commercial maize plants. To allow a better understanding of the maize genetics underpinning egg induced HIPV emission, we conducted a genome wide association study (GWAS) of 146 maize genotypes comprising of landraces, inbred lines and commercial hybrids. Plants were phenotyped in bioassays measuring parasitic wasp (Cotesia sesamiae) attraction to volatiles collected from plants exposed to stemborer (C. partellus) eggs. Genotyping-by-sequencing was used to generate maize germplasm SNP data for GWAS. The egg induced parasitoid attraction trait was more common in landraces than in improved inbred lines and hybrids but it did exist in improved germplasm. GWAS identified 101 marker-trait associations (MTAs), some of which were adjacent to genes involved in the JA-defence pathway (opr7, aos1, 2, 3), terpene biosynthesis (fps3, tps2, 3, 4, 5, 7, 9, 10), benzoxazinone synthesis (bx7, 9) and known resistance genes (e.g. maize insect resistance 1, mir1). Intriguingly, there was also association with a transmembrane protein kinase that may function as a receptor for the egg elicitor. We identified maize genomic regions associated with indirect defence and this provides a valuable resource for future studies on tritrophic interactions in maize. The markers identified may facilitate selection of indirect defence by maize breeders. We are also conducting research on maize responses to Spodoptera frugiperda, which has recently invaded Africa, and have found that genotypes that respond to C. partellus eggs with HIPV emission do not necessarily do the same when exposed to S. frugiperda eggs.

Soil-mediated Associational Resistance to an Herbivore due to a novel maize cropping system

Authors: Khan Zeyaur[7], Poveda Katja[1], Mutyambai Daniel[1], Kessler Andre[1], Midega Charles[6], Bass Ethan[1] and Luttermoser Tim[1], [1]Entomology Department, Cornell University, Ithaca, New York, United States, [6]icipe - International Centre of Insect Physiology and Ecology, Kenya, [7]Mbita campus, Int. Centre of Insect Physiology and Ecology, Mbita, Kenya

Abstract: Plants can alter structure, nutrients and chemistry of the soil they grow in. These soil changes can positively or negatively influence the growth and metabolism of other plants that co-occur or grow later in the conditioned soil. In this study we investigated the effect of emergent soil properties as a result of push-pull cropping technology on plant defences. Push-pull technology is a pest management strategy that involves attracting cereal stemborers with trap plants; Napier grass (pull) whilst driving them away from the main crop using a repellent intercrop; Desmodium (push). The system has been shown to have ecological and socio-economic emergent properties that go far beyond the effects of efficient insect pest control. Chemicals released by intercrop roots induce abortive germination of the parasitic Striga weed, providing very effective control of this noxious weed. The companion plants provide high value animal fodder, facilitating milk production. Furthermore, soil fertility is improved through nitrogen fixation and increased soil organic matter by the intercrop and soil degradation is prevented as the intercrop acts as a cover crop. We hypothesised that the emergent improved soil quality affected secondary plant metabolites. Maize plants were grown in soil collected from push-pull and non-push pull monoculture fields in the screen house. Volatile organic compounds were collected from 3-week old maize plants through headspace sampling and plant tissue was preserved in 50%methanol. Coupled Gas Chromatography-Mass Spectrometry and HPLC was used for chemical analysis. Volatile analysis showed that maize plants grown in soil from push-pull fields emitted higher amounts defence volatiles. HPLC analysis revealed increase in secondary non-volatile defence metabolites in maize grown in push-pull soil. These results show that push-pull cropping system-associated changes in soil quality affect plant metabolism and increase maize crop metabolite production with effects on plants' direct and indirect defences against herbivores.

Physiological function of immune mediators in ticks

Authors: Kim Donghun[2] and Jo You Myung[1], [1]College of Veterinary Medicine and Bio-safety Research Centre, Chonbuk National University, South Korea, [2]Department of Applied Biology, Kyungpook National University, South Korea

Abstract: Ticks are obligatory ectoparasites of many animals including human and transmit numerous pathogens such as viruses (SFTS) and bacteria (Lyme disease). During blood feeding, tick salivary secretion is critical for successful tick feeding. Tick saliva containing various bioactive molecules such as immune mediators play a critical role for inhibition of host hemostasis and suppression of host immune system. Limited studies had been conducted to understand the functions of immune mediator in physiological events from hard ticks. Comparative transcriptomic analysis between unfed and partially engorged female ticks revealed that various genes related to the production of immune mediators were differentially expressed. Reverse genetics using RNA interference targeting differentially expressed genes and classic physiological study using pharmacological agents inhibiting or rescuing the production of immune mediator were applied to understand the physiological function of immune mediators in various physiological events such as reproduction and salivation. The understanding of physiological function of immune mediators in tick physiology will provide an insight to the development of novel methods to control tick-borne disease and suppress hard tick population.

Evaluation of the effect of fusion expression of P10 protein to increase productivity of recombinant protein in baculovirus expression system

Authors: Kim Hyun Soo[1], Choi Cheol June[1], Lee Jin Yong[1] and Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: The baculovirus expression system (BES) is widely used in the protein production industry, but in order to increase the usefulness of the system, it is necessary to further maximize the productivity of the target recombinant protein. There have been reports of various fusion partners for expression enhancement, but there has been no report on the effect of fusion expression of baculovirus P10 protein mass-produced in the nucleus and cytoplasm after virus infection. Based on the characteristic that the P10 protein exists in a stable large matrix form in cells, it was evaluated whether the productivity of the target protein could be increased when expressed in fusion. As a result, it was confirmed that the expression of P10 fusion can increase the production of recombinant protein, and different expression levels were shown according to the P10 fusion regions. These results showed the potential of the P10 protein as a fusion partner to increase the production of the target protein in BES.

Selection of entomopathogenic fungi with acaricidal activity and high environmental stability against the bulb mite Rhizoglyphus robini

Authors: Kim Hyun Soo[1], Lee Jin Yong[1], Woo Ra Mi[1] and Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: Bulb mites (Rhizoglyphus robini) have recently become a serious problem because of the continuous use of acaricides, which has resulted in resistance among bulb mite populations. Here, we report the results of screening pathogenic fungi for the control of R. robini. The initial screen was performed using 342 isolates of entomopathogenic fungi from soils. As a result, the most effective 11 isolates were selected through comparing the virulence against the bulb mite. In addition to the virulence, thermotolerance and UV-B tolerance of the 11 isolates were further evaluated and compared. Finally, based on all of the above results, three isolates of Metarhizium anisopliae were confirmed to be the most effective for controlling bulb mites, and they can be considered as promising biological control agents against bulb mites.

Colonization of Beauveria bassiana ERL836 on the Monochamus alternatus-infested pine tree logs

Authors: Kim Jae Su[2], Park So Eun[1] and Kim JongCheol[1], [2]Jeonbuk National University, South Korea, [1]Jeonbuk National University

Abstract: Monochamus alternatus is a major forest pest that causes pine wilt disease in pine trees by mediating pine wilt nematodes. The use of chemicals causes pollution of forest ecosystems and toxicity to users. Alternatively entomopathogenic fungi could be considered to control pine sawyer beetle in an eco-friendly way. In this study, a commercialized entomopathogenic fungus, Beauveria bassiana ERL836 strain was used to control the target pest. We investigated the potential of B. bassiana ERL836 to control M. alternatus: the insecticidal activity of ERL836 against M. alternatus adults, the possibility of colonization on pine tree bark, the control effeciency against M. alternatus by fungal pre-treatment on semi-field and field conditions. On the pine trees logs which were pre-treated with the ERL836 fungal suspension in a semi-field condition, the M. alternatus adults were infected and finally dead by the fungus. At the same environmental conditions, a fungal wettable powder (WP) was directly treated on the beetle-infested pine tree logs and it showed a high insecticidal activity, similar to a fungal suspension treatment. Finally in field conditions, the fungal powder treatment showed a high insecticidal activity against M. alternatus.

Establishment and characterization of novel transgenic insect cell line for virus quantification

Authors: Kim Kyu Seek, Chungbuk National University, Republic of Korea

Abstract: The baculovirus expression system is widely used for the production of useful proteins through the generation of recombinant viruses. Therefore, although the virus quantification process is essential for research and industrial purpose, virus quantification has a problem that requires a long time and high skill. To improve this problem, a novel transgenic Sf9 cell line capable of convenient and rapid virus quantification was established. The transgenic Sf9 cells showed a higher cell proliferation rate and virus susceptibility comparing to parent Sf9 cells. In addition, convenient and rapid quantification was possible due to EGFP expression. In particular, it showed high convenience for mechanical quantification using a fluorescence spectrophotometer. The newly established transformed cell line will be able to further increase the utility of the baculovirus expression system by increasing the convenience of virus quantification and shortening the time.

Selection of optimal grain media for mass production of entomopathogenic fungus against the two-spotted spider mite, Tetranychus urticae

Authors: Kim Kyu Seek[1], Woo Ra Mi[1], Lee Jin Yong[1], Kim Hyun Soo[1] and Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: The two-spotted spider mite, Tetranychus urticae, is the most important spider mite in the family Tetranychidae because it can infest more than 200 host plants, including vegetables, fruit crops, food crops and ornamentals. This study was carried out to select the optimal grain medium for mass production of conidia of the entomopathogenic fungus Beauveria bassiana 331R with high acaricidal virulence against the two-spotted spider mite. As a result of comparative evaluation of production and virulence of conidia according to the medium, characteristics of conidia were different depending on the produced medium. Millet or rice medium showed the highest conidia production, environmental stability, and acaricidal virulence. These results showed that various characteristics including virulence of entomopathogenic fungi are possible through adjustment of the production environment.

Year-round trap capture of the spotted-wing drosophila, Drosophila suzukii (Diptera: Drosophilidae), in Korean strawberry greenhouses

Authors: Kim Iksoo[1], Lee Keon Hee[1], Park Jeong Sun[1], Kim Min Jee[1], Ju Hwang Eun[1], Seong Jeong Jun[1], Ra Jeong Na[1] and Yeon Jeong Su[1], [1]Department of Applied Biology, College of Agriculture & Life Sciences, Chonnam National University, South Korea, South Korea

Abstract: Korean greenhouse strawberries are mostly cultivated from October to May, which includes the cold winter season. During this time, the population size of the spotted-wing drosophila (SWD), Drosophila suzukii Matsumura (Diptera: Drosophilidae), is expected to decrease in the wild, and is also expected to decrease inside the greenhouses, as long as SWD are not already present inside. Field surveys of SWD have been extensively carried out for field-grown agricultural fruits, but no study has been conducted for greenhouse fruits, such as strawberries. Furthermore, strawberries have been shown to serve as one of the most preferred egg-depositing media for SWD. In this study, SWD capture patterns were examined inside and outside of the greenhouse blocks, and in the nearby woodlands in a southwestern locality of Korea using selected traps and attractants for nearly 19 months—in addition to several greenhouse blocks—during the strawberry cultivating periods. The highest capture period was observed from October to mid-December in woodland areas, with a mean capture number per trap of 100–600 individuals. However, capture number subsequently and sharply decreased up to mid-April, resulting in mostly zero-captures or low captures (= 10). During this period, a zero-capture period was observed inside the greenhouse that lasted for nearly three months (late December to late February), while the captures outside the greenhouses were mostly zero or = 5 individuals. An incubation of the fallen strawberries from inside the greenhouses during December to May showed no emergence of SWD adults, supporting the results of trap capture from inside the greenhouses. Taken together, the occurrence of SWD in the strawberry greenhouses is likely to be highly dependent on that of the nearby woodlands. Furthermore, captures were highest in the woodland areas, followed by captures outside the greenhouse and inside the greenhouses. Thus, a sharp winter drop in captures and the subsequent zero- or low-capture periods that were present up to mid-April in the woodland areas were likely responsible for the observed zero-capture periods inside the greenhouses.

Comparison of wild-caught and commercially purchased Orius majusculus

Authors: Kim Jensen, Saltholmsgade, Denmark

Abstract: We find that wild O. majusculus are larger than commercially produces individuals. However, we found no difference in consumption capacity.

Rice grasshopper artificial feeds development

Authors: Kim SeongYeon[2], kim doik[2], kim hohyuk[2], Koo Huiyeon[1], Kim Hyunjin[2], Kim Jisoo[2], Kim Jungeun[2] and Lee yubeom[2], [1]Jellanamdo Agricultural Research and Extension Services, South Korea, [2]Jellanamdo agricultural research and extension services. insect&sericultural research institute, South Korea,

Abstract: A rice grasshopper has been recognized as a pest damaging crops. However, grasshoppers are raised and then are mixed with flies, mealworm beetles, and grasshopper insect powders to be distributed on the market as feeds for livestock of fish in China and Thailand. Rice grasshoppers are effective to tetanus, asthma and pertussis, and help prevent blood pressure, cholesterol and brain and heart disease. A technique has been established to mass produce rice grasshoppers in Korea all the year round. However, there are some disadvantages in which food plants for rice grasshoppers should be cut and provided. The artificial feeds are developed to compensate for such disadvantages. Corns and hybrid sorghum are used as summer crops, and wheats and IRG are used as winter crops. The growth period is short and their growth is excellent. Whole wheat flour and whole rice powders are used as the source of carbohydrates. Soybeans are used as the source of protein. The mortality rate of fish is low. Thus, these raw materials are mixed to prepare the artificial feeds.

Solid artificial feeds consist of whole wheat flour + whole rice powder + fish + soybeans and are given to 2nd ~ 3rd larvae. When the artificial feeds were provided, the survival rate was 87.9 % (control group 89.1 %) and individual weight of rice grasshoppers was 0.76 g (control group 0.74 g). There was no statistically significant difference.

Novel locomotion mechanisms and leg micro-structures in the world largest semi-aquatic insect, the giant water strider (Gigantometra gigas), as adaptations to its heavy body.

Authors: Kim Woojoo, Seoul National University, South Korea

Abstract: Semiaquatic insects are good organisms to study animals' ability to walk and jump on the water surface with their different types of locomotion and various micro-morphological structures on legs. Their adult body mass varies from about 1 mg to about 500 mg. They use different types of locomotion and developed morphology adapted to locomotion in their species-specific habitats. Researchers mostly focused on a relatively small number of species of medium-body sizes (~8-30mg body weight) from the Palearctic region. It has been recently established that these "typical" water striders use surface-tension-dominated locomotion and are able to control their leg's movements to prevent water surface breaking. We studied mechanisms used for locomotion by the large-bodied water strider from SE Asia: the giant water strider (Gigantometra gigas). We found that, like the "typical" Palearctic species, the giant water striders use near vertical jumps as antipredatory responses. However, their jumps are powered not only by legs' interactions with the water surface, but also by upward drag force created by air-wrapped midlegs moving downward in the water after the surface is broken. Unlike the "typical" waters striders, who use their middle legs symmetrically to thrust themselves forward, the giant water striders use asymmetric gait: an individual extends one midleg forward pointing towards the direction of movement while the second midleg provides power by rowing with counter-movements from the opposite hind leg providing additional thrust. The forward pointing midleg supports their body on the water surface while front legs are lifted and do not touch the surface. This asymmetrical gait results in the insect's forward movement in the direction diagonal to the body axis. The hair structures on legs of G. gigas were also different than those in other water striders. Midlegs' setae in G. gigas are relatively longer than in Aquarius paludum, (after correction for leg size), and they are extended from leg surface at a steeper slope that in A. paludum. This results in an increased functional diameter of a leg, which may be useful to create force in and on the water during jumps and rowing. Finally, the specialized leaf-shaped setae on the ventral side of the hind leg tarsi and tibia were more pronounced and complex than in other species. Those leaf-shaped setae formed a long unified beam structure and contributed to a smooth outline facing water on the ventral side. We hypothesize that these special hair structures of G. gigas are adaptations to novel locomotion mechanisms and are related to the species extreme body size.

Biosynthesis and immunity of epoxyeicosatrienoic acids in a lepidopteran insect, Spodoptera exigua

Authors: Kim Yonggyun, Andong National University, South Korea

Abstract: Eicosanoids mediate both cellular and humoral immune responses in insects. Epoxyeicosatrienoic acids (EETs) are a group of eicosanoids containing epoxide formed by epoxygenase (EPX) activity of cytochrome P450 (CYP). Although EETs have been considered to mediate immune responses in some insects, their synthetic machinery was little understood in insects. This study monitored EETs in a lepidopteran insect, Spodoptera exigua, immunized with bacteria and found all four EETs (5,6-EET, 8,9-EET, 11,12-EET, and 14,15-EET) from larval fat body at 247?1,736 pg/g levels. Then to predict EPXs, 140 CYPs were collected from S. exigua transcriptomes and compared with human EPXs. Four CYPs (SeEPX1-SeEPX4) sharing homologies with human EPXs were chosen and assessed in subsequent expression and functional analyses. All four EPXs were expressed in all development stages. In larval stage, all four EPXs were expressed in immune-associated tissues such as fat body and hemocytes. Furthermore, their expression levels were highly enhanced by bacterial challenge in different tissues. RNA interference (RNAi) using gene-specific double stranded RNA injection suppressed their expression levels by more than 55%. RNAi treatments interfered with hemocyte-spreading behavior and nodule formation upon bacterial challenge except RNAi treatment against SeEPX2. All four EETs stimulated cellular immune response measured by nodule formation in S. exigua. The suppressed immune responses by the RNAi treatments against three SeEPXs were rescued by the addition of 8,9-EET. However, other three EETs gave their specific rescue effect depending on SeEPX types under RNAi. In humoral immune response, all four RNAi treatments suppressed expression of antimicrobial peptide genes. This study reports the presence of all four EETs in larval fat body of S. exigua and suggests that four SeEPXs are associated with immune responses mediated by EETs.

Characterization of the first insect prostaglandin (PGE2) receptor: MansePGE2R is expressed in oenocytoids and lipotheicoic acid (LTA) increases transcript expression

Authors: Kim Yonggyun[2], Pietrantonio Patricia[5], Lee Dae-Weon[3], Kwon Hyeogsun[4], Bajracharya Prati[4], Kumar Sunil[1], Calkins Travis[4] and Yang Yunlong[4], [1]Andong National University, South Korea, [2]Andong National University, South Korea, South Korea, [3]Texas A&M University Department of Entomology. Current Kyungsun University, Busan, Korea, United States, [4]Texas A&M University, Department of Entomology, United States, [5]Texas A&M University, United States

Abstract: In arthropods, eicosanoids derived from the oxygenated metabolism of arachidonic acid are significant in mediating immune responses. However, the lack of information about insect eicosanoid receptors is an obstacle to completely decipher immune mechanisms underlying both eicosanoid downstream signal cascades and their relationship to immune pathogen-associated molecular patterns (PAMPs). We cloned and sequenced a G protein-coupled receptor (MW 46.16 kDa) from the model lepidopteran, Manduca sexta (Sphingidae). The receptor shares similarity of amino acid motifs to human prostaglandin E2 (PGE2) receptors, and Bayesian phylogenetic analysis supports its classification as a prostaglandin receptor. In agreement, the recombinant receptor was activated by PGE2 resulting in intracellular cAMP increase, and therefore designated MansePGE2R. Expression of MansePGE2R in Sf9 cells in which the endogenous orthologous receptor had been silenced showed similar cAMP increase upon PGE2 challenge. Receptor transcript expression was identified in various tissues in larvae and female adults, including Malpighian tubules, fat body, gut and hemocytes, and in larvae silk glands and female ovaries. In addition to the cDNA cloned that encodes the functional receptor, an mRNA was found featuring the poly-A tail but lacking the predicted transmembrane (TM) regions 2 and 3, suggesting the possibility that internally deleted receptor proteins exist in insects. These shorter transcripts (1.3 kb) were detected in laid eggs and in female tissues (ovaries, Malpighian tubules and fat body), in addition to the complete 1.5kb transcript present in the same. Immunocytochemistry and in situ hybridization revealed that among hemocytes, the receptor was exclusively localized in the oenocytoids. Larval immune challenges injecting bacterial components showed that lipoteichoic acid (LTA) increased MansePGE2R expression in hemocytes. In contrast, injection of lipopolysaccharide (LPS) or peptidoglycan did not increase MansePGE2R transcript levels in hemocytes, suggesting the LTA associated increase in receptor transcript is regulated through a distinct pathway. This study provides the first characterization of an eicosanoid receptor in insects, and paves the way for establishing the hierarchy in signaling steps required for establishing insect immune responses to infections.

Diuretic Hormone 44 Signaling Establishes Levels of Female Mating Drive during Reproductive Maturation and the Post-Mating Responses

Authors: Kim Young Joon[1], Kim Do-Hyoung[1] and Jang Yong-Hoon[1], [1]School of Life Sciences, GIST, Republic of Korea, South Korea

Abstract: Female mating motivation or receptivity in the fruit fly Drosophila melanogaster is an excellent model for understanding reversible modulation of a complex behavioral network. Here, we report the neuropeptide diuretic hormone 44 (Dh44) and its receptor Dh44R1 switch female mating motivation by modulating the functional states of pC1, a subset of the brain's doublesex-positive (dsx) neurons that integrate sensory cues from courting males. Activation of Dh44 or Dh44R1 signaling in pC1 makes immature females and mated females receptive to mating. Our evidence suggests that the Dh44-Dh44R1 pathway integrates the SP signal and switches female sexual motivation by reversibly modulating the functional state of the downstream dsx neurons. Dh44 is orthologous to the vertebrate corticotropin-releasing factor (CRF) family of neuropeptides, which is broadly conserved across taxa, suggesting a role for the Dh44/CRF system in female sexual activity in other animal species.

What effect is the invasive Harmonia axyridis having on the structure of native ladybird guilds and their role in the biological control of aphids?

Authors: Kindlmann Pavel[1], Štípková Zuzana[1], [1]Global Change Research Institute CAS, Brno, Institute for Environmental Studies, Faculty of Science, Charles University, Czech Republic

Abstract: The efficiency of biocontrol agents in aphid-ladybird systems is important in determining the success of biological control. Therefore, it has been the subject of many discussions and empirical studies, which attempt to evaluate the extent to which predators are able to suppress their aphid prey. A very interesting situation occurs when a guild of native ladybirds is invaded by a non-native species (Rosenheim 1993; Hentley et al. 2016). Because of strong cannibalism, the numbers of native ladybirds may be diminished by a non-native invasive species of ladybird, which lowers the biocontrol potential of the former. However, the invader also eats aphids and would also increase the biocontrol efficiency of the new ladybird guild. The question then is what prevails: is the final biocontrol efficiency greater or smaller after the invasion?

A nice example of such a situation is the Pan-European invasion of many countries by Harmonia axyridis (Roy et al. 2016). It is seductive to say that this invader in reducing the abundance of the native ladybirds lowers the biocontrol potential of the whole guild (Pell et al. 2008; Brown et al. 2011; Roy et al. 2012). However, do we really have sufficient data to prove this (Kindlmann and Štípková 2019)? In many cases, the statistical analysis of the data purporting to prove a reduction in biocontrol potential is neither sufficient nor correct.

Here we raise a series of points and warn against improper use of statistics and overemphasis of seemingly persuasive data.

Does aphid colony duration cause low numbers of Harmonia axyridis in the Mediterranean?

Authors: Kindlmann Pavel[1], Štípková Zuzana[1], [1]Global Change Research Institute CAS, Brno, Institute for Environmental Studies, Faculty of Science, Charles University, Czech Republic

Abstract: An enormous amount of knowledge is available concerning factors limiting distribution ranges of species settled in their native areas, but much less information is available on factors limiting potential changes in distribution ranges of species that are currently spreading outside of their present range, especially on factors limiting spread of invasive species. However, this information is often quite essential, as it enables prediction of future spatial distribution and local abundances of invasive species and prediction of potential damages they may cause to people and their crops.

Some individuals of the invasive ladybird, Harmonia axyridis (Pallas) (Coleoptera: Coccinellidae), originating from east Palaearctic, escaped from the glasshouses, where they were reared, and spread massively into natural environment, first in North America and subsequently over most of Europe, which has caused a serious concern. Recent observations show that the spread of H. axyridis towards the equator is limited – for example, it is quite rare in the Mediterranean and its northward spread in South America is also quite slow, as if there were some limit in its spread towards equator. Recent literature indicates it is neither climate, nor the distance of the Mediterranean from the original release location in the Netherlands that is causing the limitation. Therefore, we hypothesized that biotic factors may be the cue. We thought the limiting factor can be the duration of prey colony (= population in one patch, usually one plant) that becomes shorter, as one approaches the equator. This may lead to lowering the fitness of the predator and subsequently to its low population densities. We test here, whether the duration of aphid colony is shorter in the Mediterranean, as compared with the Central Europe. Unfortunately, our data do not support this hypothesis. Therefore, the question of the limitation of H. axyridis distribution towards equator still remains open.

Exploring mechanisms of parasitoid diversification through the lens of chemosensory speciation

Authors: King Kendall[1], Johnson Norman[1], Meuti Megan[1], [1]The Ohio State University, United States

Abstract: Insects are the most diverse multi-cellular organisms on the planet. Parasitoid wasps, in particular, have an incredible species richness and are the second most-described group of insects behind Coleoptera. Their astounding diversity has given rise to questions addressing the mechanisms by which host-associated parasitoids diversify. Over time, parasitoid wasps have undergone adaptive radiations that are seemingly correlated with shifts in host-associations, likely a result of evolving chemical receptor proteins that mediate olfaction of unexploited host groups. Therefore, we believe chemosensory speciation drives parasitoid diversification and may inform mechanisms of evolution of olfactory gene families. To address our long-term goals of mapping the olfactory processes responsible for parasitoid host-finding and acceptance, we have annotated odorant binding protein (OBP) sequences in the Trissolcus basalis genome and modeled their 3D structure. OBPs may act as the first filter in odor coding, as they are responsible for transporting ligands from the environment to the olfactory receptors expressed on the surface of sense cells. Variation in OBP and receptor specificity to ligands may contribute to a parasitoid's ability to shift host groups.

The dorsal eye for phototactic flight in an Asian migratory butterfly, Parantica sita

Authors: Kinoshita Michiyo, SOKENDAI, Hayama, Japan

Abstract: The chestnut tiger butterfly Parantica sita shows seasonal long-distance migration among Asian countries. For orientation flight in its migration, Parantica presumably uses visual cues over the sky, such as polarized light, and spectral and intensity gradient (like in monarch butterflies).

The Parantica compound eye consists of three distinct regions: dorsal rim, dorsal and ventral. These three regions are distinguished by anatomical features. Under epi-illumination microscope ommatidial reflection of the dorsal region appears homogeneously yellowish, whereas yellowish and reddish ommatidia are randomly distributed in the ventral region. The reddish ommatidia contain dense red pigment around their rhabdom at their proximal depth. Ommatidial reflection of the dorsal rim region is the same as in the dorsal region; however, the rhabdoms are relatively large and rectangular shaped, compared to the smaller circular shaped rhabdoms in the ommatidia of the other two regions. These regions also differ in the spectral sensitivity. The sensitivity of the dorsal region is relatively higher in the UV wavelength region than that of the ventral region, which may fit to detect light information over the sky.

The dorsal region would be the best placed for extracting directional cues over the sky. To explore the function of the dorsal region, we investigated phototactic flight as an orientation behavior. When we evenly illuminated a small cage with fluorescent tubes and four halogen lamps, a butterfly naturally flew near the ceiling of the cage. When introducing two additional solar lamps at one side of the cage, the butterfly's flight became biased towards these lamps. This phototaxis persisted when the light of the solar lamps was blue-filtered, and greatly reducing the intensity, while the phototaxis disappeared when the light was yellow-filtered. This phototaxis flight basically persisted even when the dorsal rim region (plus some of the dorsal ommatidia) was occluded. This was also the case when the ventral two-thirds of the eye was occluded. However, butterflies with the dorsal one-third of the eye (= dorsal rim + dorsal region) covered did not fly; instead, they perched on the cage wall. These results indicate that phototaxis in Parantica is most likely mediated by the dorsal region and depends on not only illumination intensity but also spectral composition over the cage.

Inbreeding in Scolytinae, and its consequences for invasive species

Authors: Kirkendall Lawrence, University of Bergen, Norway

Abstract: It is now clear that regular inbreeding (usually, brother-sister matings) is a key factor in the success of invasive alien bark and ambrosia beetles. What are the advantages and disadvantages to regular inbreeding? Are inbreeders better colonizers? Do the relationships with nutritional or pathogenic microorganisms differ, for inbreeders vs outbreeders? What are the short- and longterm genetic consequences of inbreeding—for example, can invasive populations of inbreeders evolve as rapidly as invasive populations of outbreeders? How often do regular inbreeders outbreed, and with what consequences? In my talk, I will address these and other questions about the ecology and biodiversity of inbreeding in Scolytinae.

Scaling up digitization in entomology collections - a new approach initiated and enabled by the Museum fuer Naturkunde Berlin, supported by Naturalis Biodiversity Center and realized by Picturae

Authors: Kirschey Lukas[1], Berger Frederik[1], Grigoryeva Elena[1] and Krause Stefanie[1], [1]Museum fuer Naturkunde Berlin, Germany, [1]Museum fuer Naturkunde Berlin

Abstract: Millions of pins in entomology collections carry valuable information in form of labels that have been described and maintained over generations. Digitizing this information is one of the major challenges of this decade in collection digitization. This will enable direct access to the data of the collection event via databases.

Within the project for collection discovery and development at the Berlin Natural History Museum the requirements for standardized and automated high-throughput collection disclosure were defined in 2020-2021. The aim of this first pilot project is to digitally record 500,000 specimens from the Hymenoptera collection. The project is not limited to mere imaging, but also includes conservational preparation as well as the digital recording of the collection data by collection management.

The first prototype for an automated digitization line was extensively tested at the Naturalis Biodiversity Center in Leiden in mid 2021. After successful trial runs, the system was moved to Berlin and put into operation. Further improvements on all levels followed. In May 2022, the system is about to enter regular operation.

This poster presentation intends to explain the decisions behind this ambitious project, to address the challenges and to present the results so far.

Synergistic interactions of bark beetles and wildfire: post-fire outbreak potential of the Douglas-fir beetle (Dendroctonus pseudotsugae) in dry interior forests of British Columbia

Authors: Kitchens Katherine[1], Carroll Allan[2], [1]University of British Columbia Faculty of Forestry Department of Forest and Conservation Sciences, Canada, [2]University of British Columbia, Canada

Abstract: Douglas-fir beetle (Dendroctonus pseudotsugae) is one of the most significant agents of mortality in Douglas-fir forests. Landscape-scale outbreaks are common following widespread disturbance such as wildfire, drought and/or disease. These events increase the availability of defensively compromised host trees and thereby facilitate beetle population increases. As climate change continues to exacerbate stress in conifer forests, there is concern that Douglas-fir beetle outbreaks will increase in size and severity. Following recent record-breaking wildfire seasons in the dry interior forests of northwestern North America, we initiated a study to elucidate the relationship between Douglas-fir beetle and wildfire. We found the outbreak potential of Douglas-fir beetle to be constrained by pre-fire stand characteristics, burn severity, parasitism and competition from other members of the subcortical insect guild. These relationships varied across three large burn complexes in the dry Douglas-fir forests of British Columbia, Canada. Results will be discussed within the context of future management strategies for changing disturbance regimes in a warming environment.

Identification of the gene responsible for the brown egg 4 (b-4) mutant in the silkworm, Bombyx mori

Authors: Kiuchi Takashi[1], Osanai-Futahashi Mizuko[1], Tomihara Kenta[1], Katsuma Susumu[1], Uchiyama Hironobu[3], Satta Katsuya[1] Yoshitake Kazutoshi[1], Yamamoto Kimiko[2] and Yajima Shunsuke[3], [1]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan, [2]Insect Genome Research and Engineering Unit, Division of Applied Genetics, Institute of Agrobiological Science, National Agriculture and Food Research Organization, [3]NODAI Genome Research Center, Tokyo University of Agriculture, Japan

Abstract: Ommochrome pigments are widely distributed in invertebrates and involved in body color patterning, screening pigments of compound eyes, and tryptophan metabolism. In the silkworm, Bombyx mori, ommochrome pigments are accumulated in eggs, compound eyes, and reddish markings of larval epidermis. The brown egg 4 (b-4) is a recessive ommochrome mutant, whose eggs and eyes exhibit reddish-brown color, instead of normal purple and black, respectively. The responsible gene for the b-4 mutant is known to be located at 21.9 cM on chromosome 20. Although the mutant and wild-type eggs have similar ommochrome pigment composition, the total amount of pigments significantly reduces in the mutant eggs. Because the amount of 3-hydroxykynurenine, the ommochrome precursor, of the mutant eggs is comparable to that of wild-type, the gene responsible for the b-4 phenotypes is predicted to be involved in the biosynthetic pathway from 3-hydroxykynurenine to various kinds of ommochrome pigments. To well understand the ommochrome biosynthetic pathway, we attempted to identify the responsible gene for the mutant phenotypes.

We obtained backcross progenies (BC1) by crossing a wild-type strain with a b-4 mutant strain. Using genomic DNAs from 92 of these BC1 individuals, their F1 hybrid parents, a parental wild-type and a b-4 individual, we performed double digest restriction-site associated DNA sequencing (ddRAD-seq) and narrowed down the responsible region for the b-4 locus to approximately 1.1 Mb. Sequencing of cDNAs and genomic DNAs from two b-4 mutant strains revealed that exon skipping was induced in one gene due to an insertion of a transposable element. RNA-seq analysis of another b-4 strain indicated that the same gene has a different transcription start site, which leads to a short open reading frame. These results suggested that the mutations in this gene are the cause of b-4 phenotypes. To test this hypothesis, we performed CRISPR/Cas9-mediated gene knockout targeting the candidate gene. Several generation 0 (G0) adult moths displayed totally or partially reddish-brown compound eyes. Generation 1 (G1) individuals with reddish-brown eggs and eyes were obtained from crosses between G0 adults. Genomic sequencing indicated that the G1 individuals had mutations resulting in frameshifts and premature stop codons in the target gene. Furthermore, the eggs from complementation crosses between a b-4 mutant and the candidate gene knockout also exhibited reddish-brown color which was quite similar to the b-4 mutant eggs, demonstrating that the candidate gene is responsible for the b-4 phenotypes.

Genetic engineering of sex-linked genes in the silkworm, Bombyx mori

Authors: Kiuchi Takashi[1] and Katsuma Susumu[1], [1]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan

Abstract: The silkworm, Bombyx mori, is an economically important domesticated insect, which produces silk as well as recombinant proteins by transgenic or baculoviral technology. To obtain silks and recombinant proteins more efficiently, male- or female-only production system is expected for practical use. We succeeded in identifying both feminizing and masculinizing factors for B. mori (Kiuchi et al., 2014, Nature). In this presentation, we introduce an attempt of silkworm sexual control by genetic engineering of the sex-linked genes.

Distribution of the Japanese beetle, and quarantine and eradication efforts against it

Authors: Klein Michael, The Ohio State University, United States

Abstract: Soon after the Japanese beetle (JB) (Popillia japonica, Newman) was discovered in a New Jersey nursery in 1916, quarantine and eradication programs were started. The eradication effort was abandoned four years later due to “too many beetles”. However, the federal quarantine lasted until the mid-80s, when more states were infested than not. Little was known about P. japonica in its native range in Japan and Russia, and it did not reach pest status because of a lack of turf for larval development, cold temperatures requiring a two year life cycle, and an effective parasitoid. Reports of this species in Korea and China were proven false in the 1990s. In the U.S., the beetle slowly moved out in all directions at a rate of 5-10 miles a year. However, after the national quarantine was eliminated, and a variety of State quarantines put in place, the JB was moved in turf and nursery stock, and infested distant areas more quickly. A national “Harmonization Agreement” protected the three Pacific coast states from nursery shipments, but opened up movement of nursery stock to other uninfested states. This came at a time when there were no insecticides that could eliminate JB larvae in nursery settings. California has the most ambitious JB surveillance and eradication programs, and is the state with the most successful eradications of isolated JB populations. The state deploys two JB traps/mi2 (about 13,000 traps) baited with a “floral lure” and the JB sex attractant (Japonilure). Two beetles in a trap, or beetles in adjacent traps triggers deployment of 50, 25, 5, and 5 traps/ mi2 around the finds. A set eradication program follows the finding of additional beetles. Such programs have been initiated six times between 1961 and 2014, with treatments of Chlordane or imidacloprid for larvae, and primarily carbaryl for adults for 2-4 years, followed by two years of negative trapping at the high density. Acelepyrn is the likely insecticide of choice now for both larvae and adults. Oregon has also had several eradication programs, and just finished the third year of treatment in the only active program in the U.S. Isolated JB populations have also been eradicated in five other western state with treatments of about four years. There are at least six Canadian Provinces with JB infestations, with an eradication/containment effort in only the western most Province. A National Quarantine involving airports and passenger or package carriers remained in existence following the dropping of the nursery program. Package carriers have gone to great expense to keep adult beetles out of their planes, and away from western states. Japanese beetles were discovered on Terceira in the Azores Islands in the mid-80s, but eradication efforts were doomed from the start, and eventually virtually all of the islands became infested. Hopefully, the European community can adapt from past successes and failures to combat the P. japonica infestations now in Italy and Switzerland

Food safety of genetically engineered-insect resistant crops & pesticides

Authors: Kleter Gijs A.[2] and Project team members IUPAC[1], [1]IUPAC, [2]Wageningen Food Safety Research (part of Wageningen University & Research), Netherlands

Abstract: Whereas Bacillus thuringiensis-derived Cry proteins have dominated the scene of crop biotechnology for most of the time since the mid-90s, various other insecticidal agents have started emerging as of lately. A notable development is the introduction of GM crops encoding certain double-stranded RNA (dsRNA) molecules. These may evoke a phenomenon known as “RNA interference”, which eventually leads to the silencing of the gene whose sequence is complementary to the dsRNA. Moreover, applications have appeared for these types of proteins and polynucleotides beyond their expression in GM crops, such as in sprayable formulations with which the protein or dsRNA is sprayed directly onto crop plants that are to be protected. The safety assessment of these active agents expressed in GM crops hosting them is carried out according to the internationally harmonized principles enshrined in FAO/WHO Codex Alimentarius guidelines for recombinant DNA plants. As for the safety of pesticide formulations of proteins and dsRNA, these may be categorized as, for example, biopesticides or other low-risk categories with specific and more specific and risk-proportionate risk assessment requirements than the extensive testing required for mainstream chemical active ingredients and may in some cases also be exempt from action threshold owing to favorable safety profiles.

Development and evaluation of novel spatial repellent delivery devices for the improving adult control strategies of the peridomestic species, Aedes albopictus and Ae. aegypti.

Authors: Kline Dan, USDA/ARS/CMAVE, United States

Abstract: Aedes albopictus and Ae. aegypti are two important invasive species in the United States, which on a worldwide scale transmit several arboviral diseases including dengue, chikungunya, yellow fever and Zika. These mosquitoes are often the dominant species occurring in peridomestic habitats. Even if the threat of imminent disease transmission is lacking their presence causes much annoyance in peridomestic areas, resulting in residents not being able to enjoy performing activities in their yards. Traditional control strategies in the U.S., with heavy reliance on the use of chemical insecticides being delivered by ULV spray trucks is largely ineffective. Therefore, complementary vector control methods are needed to enhance existing control efforts. Several alternative technologies are currently being considered at USDA-ARS, CMAVE, Gainesville, Florida, USA, to improve control of these two species. The use of spatial repellents in the peridomestic environment is one technology being evaluated. Various active ingredients and delivery devices, both active and passive, are being developed and evaluated. Some novel devices target protection of the individual while others target area protection.

Anthropocenic ozone levels can disrupt a fly’s sex communication

Authors: Knaden Markus[1], Jiang Nanji[1] and Hansson Bill S.[1], [1]MaxPlanck Institute for Chemical Ecology, Germany

Abstract: Insect sexual communication often relies upon olfactory signals, the so-called sex pheromones, which can inform about species identity, sex, and mating status of a potential mate. Most insect pheromones, however, contain carbon-carbon double bonds and hence can potentially become degraded by oxidation. Here, we report that the current increased levels of Anthropocenic ozone in the atmosphere oxidize fly pheromones and by that disrupt sex recognition in many drosophilid species.

Invasive host caught up with a native parasitoid: Field data reveal high parasitism of Harmonia axyridis by Dinocampus coccinellae in Central Europe

Authors: Knapp Michal, Department of Ecology, Czech University of Life Sciences Prague, Czech Republic

Abstract: The harlequin ladybird, Harmonia axyridis, is considered to be one of the most invasive insect species worldwide. Its invasion success and extreme speed of range expansion has been partially attributed to weak control of its populations by natural enemies. Previously published data on emergence rates of the hymenopteran parasitoid Dinocampus coccinellae support the enemy release hypothesis: Harmonia axyridis has been consistently less successfully parasitized compared to native ladybird species. In this study, we show that since 2016, i.e. 10 years after its arrival in Central Europe, several populations of H. axyridis in the Czech Republic have a very high prevalence of D. coccinellae parasitism. Dinocampus coccinellae emerged from 46 % of H. axyridis individuals in the most parasitized population. Moreover, H. axyridis was more parasitized than the native Coccinella septempunctata in seven of nine investigated co-occurring populations. The meta-analytically pooled estimate of D. coccinellae emergence rate from H. axyridis across the Czech populations (this study) is thirteen times higher than the pooled estimate for invasive populations of this beetle elsewhere (historical data up to 2016). We hypothesize that some Central European populations of D. coccinellae have evolved to overcome the immune system of H. axyridis, which was previously thought to be responsible for the high larval mortality of D. coccinellae. As parasitism rates are highly variable in time and space, we encourage future research investigating the determinants of parasitoid prevalence in H. axyridis and other large ladybird species on a continental scale.

Winter survival, post-overwintering energy reserves and basic immune parameters in laboratory-reared and field-collected invasive ladybirds

Authors: Knapp Michal[2] and Dobeš Pavel[1], [1]Department of Animal Physiology and Immunology, Institute of Experimental Biology, Faculty of Science, Masaryk University, Brno, Czech Republic, [2]Department of Ecology, Czech University of Life Sciences Prague, Czech Republic

Abstract: The harlequin ladybird, Harmonia axyridis (Pallas, 1773) (Coleoptera, Coccinellidae) is considered one of the most invasive insect species in Europe and North America. H. axyridis has an effective immune system which was proposed to be partly responsible for its successful invasion. High winter survival is another important factor that can explain the successful invasion of H. axyridis in temperate zones. Using two independent studies, we investigated the effects of overwintering temperature on survival, energy reserves, and basic immune parameters for laboratory-reared and field-collected beetles.

In the first study, we investigated the effect of different winter temperature regimes (warm, average, and cold) on the winter performance of H. axyridis. The warm winter regime increased survival rate and body mass loss and reduced post-winter starvation resistance in both laboratory-reared and field-collected beetles compared to the cold winter regime. Winter survival of laboratory-reared beetles was much lower than that of field-collected beetles. Laboratory-reared beetles lost a larger proportion of their body mass and had a reduced post-winter starvation resistance. Pre-overwintering body mass positively affected winter survival and post-winter starvation resistance in both laboratory-reared and field-collected ladybirds. The differences between laboratory and field individuals indicate that quantitative conclusions derived from studies investigating solely laboratory-reared individuals cannot be directly extrapolated to field situations.

In the second study, we investigated the effects of overwintering on selected physiological and immune parameters of H. axyridis. For laboratory-reared beetles we tested effects of three temperature regimes (cold, average and warm winter) on haemocyte concentration. For field-collected beetles we measured also total protein concentration and antimicrobial activity against E. coli, and all parameters (including haemocyte concentration) were measured for innate as well as for E. coli challenged beetles. Concentration of circulating haemocytes for laboratory-reared beetles decreased significantly in the course of winter. Data for field-collected beetles confirmed the result obtained for laboratory-reared beetles, and haemocyte concentration was also marginally affected by immune challenge. Concentration of circulating haemocytes increased in challenged compared to untreated individuals before overwintering but not after overwintering. Total protein concentration in the haemolymph of H. axyridis increased significantly during the overwintering. Females had significantly higher total protein concentration in their haemolymph compared to males. Antimicrobial activity against E. coli did not changed during overwintering and was unaffected by immune challenge. This research was financed by grant IGA 42110/1312/3145 (FES-CULS Prague).

Do field defects support beneficial arthropods and ecosystem services within arable fields?

Authors: Knapp Michal[2], Kadlec Tomáš[1], González Ezequiel[1] and Seidl Miroslav[1], [1]Czech University of Life Sciences Prague, Czech Republic, [2]Department of Ecology, Czech University of Life Sciences Prague, Czech Republic

Abstract: Non-crop habitats within agricultural landscapes can increase biodiversity and provide important ecosystem services in adjacent fields. Field defects are temporary non-crop patches within arable fields where the crop is poorly developed and other plants can emerge. Despite that these defects can be common, their relevance as habitat for insects is unknown. Therefore, we investigated natural field defects as well as artificial field defects created at field edges and field interiors in collaboration with farmers. We found that natural field defects represent suboptimal habitats for carabids compared to field interiors and the boundaries between them. Similarly, ecosystem services provided by carabids (pest predation and weed seed predation), were slightly reduced in field defects. Low plant cover within field defects probably created hostile conditions for carabids preferring microhabitats with high humidity and moderate temperatures. In artificially created defects within oilseed rape (OSR) fields, we investigated diverse arthropod taxa covering various beneficial groups, e.g., parasitoids, predators, pollinators and decomposers. In general, we found a significant interaction between habitat type and sampling period. During late spring (OSR flowering), similar numbers of species and individuals were found in field defects and field interiors (OSR crop). In summer (when OSR was ripe and desiccated), richness and abundance were much higher in field defects than in OSR crops. Only small differences between defects created at field edges and interiors were detected for many groups. Overall, our results indicate that field defects are important habitats that can enhance abundance and species richness of several groups of beneficial arthropods, especially after crop flowering. This study was funded by grant GACR 18-26542S.

The earliest known occurrence of endophytic herbivory, a Pennsylvanian leaf mine and its evolutionary implications

Authors: Knecht Richard[1], Emma Steve, Benner Jacob[2], Pierce Naomi[1] and Ortega-Hernández Javier[1], [12]Harvard University, United States, [2]University of Tennessee, Knoxville

Abstract: Preserved tissue damage on fossil plants provides valuable insights into the evolutionary and ecological history of plant-insect interactions. Leaf mines, traces of insects whose larval stages feed and live primarily within the parenchymal and mesophyll layers of leaves, are well represented in the fossil record, with the oldest examples dating back to the mid-Triassic (Mesozoic). Several Late Paleozoic leaf mines have been proposed but lack enough defining characters (e.g., stepwise increases in mine width, oviposition site, terminal chamber, etc.) to be generally accepted. Herein, we describe a new fossil leaf mine, with clear defining characters, on a Neuropteris pinnule from the Carboniferous (309.5-315.2 myo) of Massachusetts, USA. This leaf mine is coeval to the oldest known holometabolous insect, an exophytic larva, but extends the oldest occurrence of endophytic larvae by ~65 million years. Leaf mining is only found in the insect orders Coleoptera (8 families), Diptera (18 families), Hymenoptera (3 families), and Lepidoptera (34 families). Phylogenetic evidence along with morphological characters of leaf mines observed in modern leaf mines narrows down the possibilities to an early Lepidopteran or Coleopteran trace maker. This fossil may add additional support to earlier claims of leaf mines in other Paleozoic deposits.

Can bumblebees self-medicate? Investigating secondary nectar metabolite-parasite interactions in the lab and in the field

Authors: Koch Hauke, Royal Botanic Gardens, Kew, United Kingdom

Abstract: Bees can receive medicinal benefits from nectar and pollen secondary metabolites against their parasites. However, many open questions regarding the interaction of secondary metabolites and bee parasites in the host remain. I here present research on the effects and internal dynamics of nectar metabolites on the common intestinal trypanosomatid parasite Crithidia bombi in bumblebees (Bombus terrestris). I identify active secondary metabolites in the nectar of three common foraging sources for Bombus terrestris in Europe: linden trees (Tilia sp.), strawberry trees (Arbutus unedo) and ling heather (Calluna vulgaris).The compound callunene in heather nectar leads to the loss of the parasite flagellum (which is needed for motility and attachment), thereby reducing infection probability. I show that chemical modification through glycosylation or deglycosylation of nectar metabolites from Tilia and Arbutus nectar during gut passage can strongly alter antiparasitic activity. This modification can stem from the host or the bumblebee gut microbiome. I close by presenting experimental field data examining if Crithidia infected bees collect nectar or pollen of different secondary metabolite composition, to test their ability to self-medicate under natural conditions.

Current knowledge and future challenges in the world biodiversity and biogeography of Zygentoma

Authors: Koch Markus[3], Smith Graeme[2], Molero Rafael[4] and Mitchell Andrew[1], [1]Australian Museum, Sydney, Australia, [2]Australian Museum, Sydney, Australia, [3]Institute of Evolutionary Biology and Ecology, University of Bonn, Germany, [4]University of Cordoba, Spain

Abstract: The Zygentoma are an ancient and widely distributed hexapod order but are poorly studied. Almost 660 silverfish species have been described in five families. They can be found in a variety of habitats including free-living, especially in dry environments, in soil and deep subterranean habitats as well as living in the nests of ants and termites. A few species are peridomestic pests. The biodiversity and biogeography of the order is reviewed and a preliminary molecular phylogeny is presented. Some of the open questions and challenges facing us are presented, the most obvious being the lack of experienced taxonomists and the large number of countries whose fauna is almost unknown.

Knowing Microcoryphia (Insecta): Proposal of a standardized description of new taxa

Authors: Koch Markus[3], Gaju Miquel[2], Molero Rafael[5], Bach de Roca Carmen[1] and F. Mendes Luis[4], [1]Barcelona, Spain, [2]Department of Zoology, University of Córdoba, Spain, [3]Institute of Evolutionary Biology and Ecology, University of Bonn, Germany, [4]Museu Nacional de História Natural e da Ciência; Universidade de Lisboa; Lisboa, Portugal, [5]University of Cordoba, Spain

Abstract: Jumping bristletails of the order Microcoryphia (= Archaeognatha) are the most basal lineage of the Insecta. More than 550 species have been described thus far, with fossils from the Triassic, and grouped into two families with different geographical distribution, the Machilidae preferably in the Northern Hemisphere and the Meinertellidae in the Southern Hemisphere. Only a few researchers publish regularly on the taxonomy of the jumping bristletails, although their anatomy and phylogeny regularly attract broad interest in the context of insect evolution. The first fairly precise taxonomic descriptions were made by Silvestri in 1905. However, a revision of the early accounts is necessary, since many of the characters used today to delimit species were not contemplated in the original descriptions. Contemporary accounts are likewise rarely complete as they often omit morphometric values or detailed descriptions of some secondary sexual characters. Our contribution calls for a standardization that homogenizes the taxonomic study of the group, so that the species are described, whenever possible, based on characters that allow proper comparisons between the different taxa. This standardization is currently essential for precise estimation of the global species richness and a prerequisite for accurate phylogenetic analyses.

Pollen preference and nutritional components of pollen collected by honeybees (Apis mellifera) in Murang’a county, Kenya

Authors: Koech Sheila[1], Lattorff Michael[3], Karanja Rebecca[2], [1]International Centre of Insect Physiology and Ecology Kenyatta University, Kenya, [2]Kenyatta University, Kenya, [3]University of Nairobi; Martin-Luther-University Halle-Wittenberg

Abstract: Several factors have been linked to honeybee population decline globally. Such include limited floral resources, bee pests and diseases, and agricultural pesticides. However, it is largely because of limited floral resources owing to increased land use and fragmentation, contributing to a nutritional shortage. The aim of this study is to investigate the pollen preferences and nutritional component, as well as the levels of pesticide residues of pollen (corbicular) collected by Apis mellifera in three different landscapes (high, medium, and low vegetation diversity) in Murang’a, Kenya over a period of 12 months. Six farms per landscape containing each two colonies of A. mellifera will be used in this research. Bottom fitting pollen traps will be used to collect pollen samples at each hive entrance. The sampling will be done from November 2019 to October 2020. Pollen loads will be analyzed for abundance and diversity of contributing plant species, but also for crude protein content, proline, lipids, as well as the pesticide residues. The findings of this project will improve the knowledge on what crops to cultivate and conserve, the type of pollen or supplement to feed, and the level of pesticide residue contamination. These findings will help guide the government and stakeholders to develop strategic conservation protocols that preserve or restore A. mellifera foraging habitats.

Beetle assemblage across elevations and indicator functioning in Peninsular Malaysian mountains

Authors: Koivula Matti[3], Abdullah Fauziah[2] and M. Musthafa Muneeb[1], [1]Department of Biosystems Technology, Faculty of Technology, South Eastern University of Sri Lanka, Sri Lanka, [2]Institute of Biological Science, Faculty of Science, University of Malaya, Kuala Lumpur, Malaysia, [3]School of Forest Sciences, University of Eastern Finland, Joensuu, Finland

Abstract: Community composition, their relative shares, and interactions – largely determines biodiversity responses to environmental variation. Communities also vary according to, among other aspects, latitude and altitude (Ashton et al., 2015). This study assesses the indicator functioning and beetle assemblage across elevations at two mountain slopes in Peninsular Malaysia. The beetle sampling was carried out at elevations: 500m, 1000m, 1500m and 1800 m ASL, where pitfall, Malaise and light traps were used to capture the beetles. The statistical analysis were conducted using GLMM, NMDS and IndVal softwares. The collection was resulted in 198 morpho-species of beetles, from 32 families total number of 3052 beetles. Species richness declined with altitude in light and Malaise but not in pitfall, the two mountains differed considerably in pitfall but less so in light or Malaise data. NMDS showed light traps is distinguished at 1,800 m from lower altitudes. Malaise and pitfall traps reflected primarily variation between the two mountains. IndVal, low altitudes had about twice as many indicators as middle or high altitudes. This research found 83 indicator species for different combinations of Method and Altitude. Light and Malaise trap samples shared about half of the abundant species, whereas pitfall trap samples were distinctive in this respect. Our results are applicable to tropical species conservation, as they provide evidence for many species to be adapted to particular altitudes and, more importantly, differences in beetle samples between collecting methods, which in turn calls caution in analysis interpretations. Therefore, conservation efforts should be based on results obtained using multiple sampling and analysis methods.

Development of conditional sterility system in Aedes aegypti males

Authors: Kojin Bianca[3], Luis da Costa da Silva Andre[2], Carvalho Danilo[1], Capurro Margareth[5] and Adelman Zach[4], [1]Department of Parasitology, Institute of Biomedical Sciences, University of São Paulo, Brazil, [2]Florida University, United States, [3]Texas A&M University, Department of Entomology, United States, [4]Texas A&M, United States, [5]University of Sao Paulo, Brazil

Abstract: Dengue, Chikungunya and Zika, currently, are the most noticeable diseases affecting several countries in the tropical and subtropical areas, and due to global warming and globalization, they are now reaching and spreading very fast to areas without a transmission history. Complementary strategies, in order to contribute with the available methods and fight the disease, are under development or evaluation. These strategies comprise methods to reduce the mosquito populations to levels below the transmission threshold. The well established Sterile Insect Technique (SIT) have proven to be an efficient and effective method against fruit-flies and screwworm, by releasing millions of sterile males on the field and promote the population collapse over time. The sterility is reached by exposing insects to an ionizing radiation source, reducing the general fitness of these males as side effect.

This study proposes the establishment of a transgenic construction to promote a conditional sterility only in males. The advantage of this construction is the possibility to promote sterility without irradiating the insect, resulting in a better performance without compromising fitness.

Embryonic microinjection using a pMos-3XP3-DsRed plasmid carrying an effector gene where, males conditionally express the Apoptosis-Inhibitor-Protein (AIP) antagonist, Michelob_x during embryogenesis, resulted in the establishment of transgenic lines dependent of tetracycline to block sterility. Five out of six strains had mRNA expression of Michelob_x detected by RT-PCR, leading to the challenge of these strains with a mating with non-transgenic virgin females and determining their residual fertility. One out of five strains showed significant reduction in the residual fertility in the absence of the antibiotic, while there was no reduction when they were supplied with antibiotic. This strain had a sterility level of approx. 62% under heterozygosis. This encouraging result led us to the development of another approach to a higher impact on male fertility.

Computer modelling of wing rotation in bumblebees

Authors: Kolomenskiy Dmitry[3], Liu Hao[2], Sesterhenn Joern[6], Schneider Kai[1], Ueyama Kohei[2], Xu Ru[5], Onishi Ryo[3], Ravi Sridhar[7], Engels Thomas[6] and Jakobi Timothy[4], [1]Aix-Marseille University, France, [2]Chiba University, Japan, [3]Japan Agency for Marine-Earth Science and Technology, Japan, [4]RMIT University, Australia, [5]Shanghai Jiao Tong University, China, [6]TU Berlin, Germany, [7]University of New South Wales at the Australian Defence Force Academy, Australia

Abstract: During hovering and slow forward flight, flapping wings of insects can produce positive upward force on both upstroke and downstoke. This is achieved by large pitching (feathering angle) rotations at the end of each half-cycle necessary for maintaining positive kinematic angle of attack. Prior experiments with robotic flappers have demonstrated similar kinematic patterns produced by wings with only up and downstroke motion being driven directly and elastic hinge attachment permitting passive pitching rotation. Thus, pitching motion of the wings emerges as a result of fluid-structure interaction. In our study, we evaluated the role of fluid-structure interaction for wing rotation of bumblebees Bombus ignitus. Bumblebee hives (Mini Polblack) provided by Arysta LifeScience ltd were maintained at Chiba University from October 2015 to September 2016. The experimental chamber consisted of the hive and a feeding area connected by a flight tunnel with transparent ceiling. The bees were trained to fly through the tunnel. The flights were recorded with three synchronized high-speed cameras (Phantom SA3, Photron), equipped with CCTV lens (B2514D or B5014A, Pentax) at 2000 fps. We used an open-source software DLTv5 to reconstruct the three-dimensional coordinates of the bees. Morphological models of the wings were constructed on a basis of photographic images. Surface density distribution of the membrane was determined by dissecting the wings and measuring the weight of each part. Micro-CT scans (Shimadzu inspeXio SMX-100CT) were used to measure the vein thickness necessary for calculating their linear density distribution. The moments of inertia were obtained by integration of the vein and the membrane density distributions. Subsequently, using the acquired physiological data, computer simulations of the wing motion were carried out. The bumblebee was represented by three rigid elements: the body and two wings, which moved relative to each other. Time-periodic positional angular motion of the wings was prescribed, while the pitching rotation was found by solving an ordinary differential equation with the aerodynamic pitching moment obtained from numerical solution of the partial differential equations governing the surrounding air flow, see an example visualization in the figure. The values of the hinge stiffness coefficient that minimize the mean squared error between feathering angle in the simulation and the experiment were determined by parametric sweep. The results indicate that the hinged plate model provides a reasonably accurate approximation of real bumblebee wing motion. Considering the normalized hinge stiffness as a material parameter, we conjecture that the same optimal value may be adequate for all flight regimes. This would open the perspective of numerical simulation of complex flight maneuvers using only the wing-tip kinematics as input data, which is much easier to measure in the experiments than the full three-dimensional wing kinematics.

Warming alters indirect effects of wolf spiders on litter-dwelling microbial communities in the Arctic

Authors: Koltz Amanda[3], Koyama Akihiro[2] and Wallenstein Matthew[1], [1]Colorado State University, United States, [2]Michigan State University, United States, [3]Washington University in St. Louis, United States

Abstract: Understanding controls on carbon cycling in the Arctic is critical due to the rapid pace at which this region is warming and its potential feedbacks on the global climate. Despite the importance of the microbial community for driving key soil functions, knowledge of how biotic interactions contribute to microbial community structure and function in this region remains limited. For example, microbial community composition is influenced by the consumer community, which is in turn regulated by litter- and soil-dwelling predators. Wolf spiders are dominant tundra predators that have cascading effects on their detrital prey, decomposition, and soil nitrogen, suggesting that wolf spiders may also influence microbial communities. We tested the effects of wolf spider density and warming on the diversity and composition of litter-dwelling bacterial and fungal communities through a fully factorial mesocosm experiment over two summers in the Alaskan Arctic. We deployed two sets of replicate litter bags at the soil surface and buried in the upper organic horizon and collected the litter bags at the end of the first and second summers. We extracted microbial DNA from subsamples of the litter and prepared Illumina libraries by PCR amplification of bacterial 16S and fungal ITS before processing the sequences via QIIME. After one summer, there were no treatment effects on fungal diversity, but both surface and buried litter in warmed plots had significantly reduced bacterial diversity. After two summers, there were significant interactive effects of wolf spider density and warming on bacterial and fungal diversity. Specifically, under ambient temperature, bacterial diversity increased with increasing spider density, whereas in experimentally warmed plots, higher spider density reduced bacterial diversity both at the soil surface and in buried litter. Treatment effects on fungal diversity varied by location. At the surface, fungal diversity increased with increasing spider density, but this trend was opposite under warming. In buried litter bags, fungal diversity was reduced in low and high spider density treatments compared to the control, whereas under warming, fungal diversity tended to decrease with increasing spider density. There were also interactive effects of wolf spider density and warming on fungal and bacterial community composition after one summer and on the fungal community after two summers. Overall, our results indicate that the effects of wolf spiders on detrital food webs in the Arctic extend to microbial communities but that warming alters these effects. Moreover, these findings suggest that generalist-feeding predators may play an underappreciated role in driving variation in microbial community composition in the Arctic.

The egg-larval parasitoid, Ascogaster reticulata, utilizes ubiquitous volatiles from intact plants to discriminate leaf ages of tea plants

Authors: Komatsuzaki Suguru[1], Piyasaengthong Narisara[1], Matsuyama Shigeru[2] and Kainoh Yooich[1], [1]Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan, [2]University of Tsukuba, Japan

Abstract: The moth, Adoxophyes honmai, causes serious damage to tea plants, one of the most important crops in the world. Ascogaster reticulata is an egg-larval parasitoid, and one of the principal natural enemies of A. honmai. However, modulation of interactions between parasitoids and the host moth by tea plant odor has not been well studied. Previous investigations have shown that A. honmai prefers to oviposit on mature tea leaves (ML) rather than young leaves (YL). Therefore, we hypothesized that A. reticulata locates host egg masses by searching close to ML when host-derived cues are not available. In this study, we investigated leaf age preferences of A. reticulata and identified attractive volatiles from ML.

A dual-choice bioassay using a 4-arm olfactometer was performed to determine leaf age preferences of A. reticulata. Female wasps preferred intact ML odor over YL. Interestingly, they did not discriminate between YL volatiles and control (clean air). Volatiles from ML and YL were collected using the head-space volatile collection method, and were analysed with GC-MS. Quantitatively, YL emitted greater amounts of volatiles than ML.

We identified 10 compounds from YL and 5 compounds from ML. Although 4 compounds (Z)-3-hexenyl acetate (H), (E)-ß-ocimene (O), linalool (L), and DMNT (D) were found in both, methyl salicylate (M) was detected only in ML. Based on these results, the 5 ML volatiles were regarded as candidate attractants. Blends of 4 or 5 compounds were prepared (HOLDM, HOLD, HOLM, HODM, HLDM, and OLDM), ratios of which were adjusted to match those of ML volatiles. Single componuds (H, O, L, D, and M) were also examined. Parasitoid preferences were tested in comparison with solvent controls using an olfactometer. Parasitoids showed positive responses to HOLDM and HOLM, but not to other blends or to single compounds.

Wasps were attracted to volatiles of ML, supporting our hypothesis. The adaptive significance is that by tracking plant volatiles, parasitoids are more likely to encounter host egg masses in the absence of host-derived cues. Parasitoids preferred blends of H, O, L, and M, indicating that wasps detect tea plant ML based on some of their volatile components. Moreover, the attractive blend components are ubiquitous plant volatiles even though proportions of them may change depending on the species. Such non-specific responses to plant species are necessary for host searching by this parasitoid since the host moth is a generalist. On the other hand, parasitoids distinguish between ML and YL of tea plants, the main host plant of their host moth, by detecitng differences in their volatile components. Taken together, A. reticulata utilizes a blend of volatiles from intact plants to efficiently locate potential habitats of its generalist host. In tea fields, A. reticulata can distinguish appropriate leaf age for host location.

Efficacy of different entomopathogenic fungal isolates against the developmental life stages of three key edible insect species

Authors: Komivi Akutse

Abstract: Globally, the interest to produce black soldier fly (Hermetia illucens L.) and crickets (Gryllus bimaculatus and Scapsipedus icipe) in mass for feed and food, respectively, is gaining attention. Despite their economic importance, there is limited information on the risk of entomopathogenic fungi on the BSF (larval and adult stages) and crickets (nymphal and adult stages), which is vital to the production system. This study evaluated new research on the risk and effects of disease-causing pathogens (Beauveria bassiana and Merthizium anisopliae) on the mortality, egg-laying capacity, and sporulation when the insects were subjected to different concentrations of the fungi species. We showed that adult flies and crickets were more susceptible to the biocontrol agent B. bassiana and M. anisopliae, with high mortality (>70%) than the other life stage in high dose treatment. This confirmed the pathogenicity of both fungal pathogens against BSF and crickets, with potential for significant negative consequences for production.

Multifunctional monoterpenes contribute to the establishment of mutual adaption and restriction relationships between host and Ips typographus L.

Authors: Kong Xiang-Bo[1], Liu Fu[1], Fang Jia-Xing[1], Zhang Qing-He[2], Zhang Sufang[1] and Zhang Zhen[1], [1]Key Laboratory of Forest Protection of the National Forestry and Grassland Administration of China, Research Institute of Forest Ecology, Environment and Protec, [2]Sterling International, Inc., Spokane, Washington, United States

Abstract: Host monoterpenes acting as host defense compounds can be exploited by I. typographus as aggregation pheromone precursors and/or kairomones, and by natural enemy such as predators as a synomones for finding their prey. In the current study, the toxicities of three monoterpenes: S-(-)-a-pinene, R-(+)-a-pinene and myrcene as potential bark beetle pheromone precursors were evaluated on I. typographus adults in both contact and fumigation tests. The in vivo productions of volatile metabolites in the hindguts of males and females when topically treated with these three monoterpenes were analyzed by gas chromatography (GC) and GC coupled with mass spectrometer (MS). The behavioral activities of these monoterpenes when combined with the aggregation pheromone of I. typographus were assayed in the field. These three monoterpenes showed significant insecticidal activities on I. typographus with LD50 values being ca. 247-358 µg/beetle in the topical assay and LC50 values being ca. 3.38-4.54 µl/ml in the fumigation assay, which might be the major host tree defense strategy against the beetles with S-(-)-a-pinene being the most significant. In GC/GC-MS analyses, S-(-)-cis-verbneol, (+)/(-)-trans-verbenol, S-(-)-verbenone, (-)-myrtenal, and (-)-myrtenol were detected in the beetle hindguts when topically treated with S-(-)-a-pinene, and the (+)-trans-verbenol, R-(+)-verbenone, and (+)-myrtenol were detected when topically treated with R-(+)-a-pinene. Productions of these volatile metabolites varied significantly in quantities by sexes of the bark beetles and by chirality of a-pinene [S-(-)- vs. R-(+)-]. E-myrcenol, ipsenol, ipsdienol and their derivatives were not detected in the beetle hindguts when topically treated with myrcene at the dosage tested. S-(-)- and R-(+)-a-pinene showed a significantly synergistic effect on the trap catches of I. typographus, while myrcene revealed a significant antagonistic effect when combined with its aggregation pheromone. The plasticity and multi-functionality of these three monoterpenes might be a part of trade-off strategies in the arms race between the host trees and I. typographus. The S-(-)-a-pinene, as the key monoterpene component of the spruce host trees, might participate in a series of olfactory signal transductions in the tritrophic system of spruce trees – I. typographus – predators, whereas R-(+)-a-pinene and myrcene might also play some roles in host tree defense and behavioral regulations of I. typographus and its predator, Thanasimus substriatus. Our results provided a better understanding of the “trade-off” strategies in the relationship between host trees and bark beetles, and further gained an insight into the co-evolutionary and olfactory mechanisms in the tritrophic system. A deep understanding of all the chemical communication signals used by I. typographus may facilitate an optimal control strategy to combat this economically and ecologically important forest insect pest.

The defense protein MLX56: Its unique structure, its unique mode of function, and its application to produce GM plants resistant to various pests belonging to Lepidoptera, Coleoptera, and Thysanoptera

Authors: Konno Kotaro[2], Ueno Chihiro[2], Mitsuhara Ichiro[2], Nakamura Masatoshi[1], Murata Mika[3], Wasano Naoya[4], Shimura Sachiko[2] and Arakawa Toru[2], [1]Genetic Resources Center, NARO, 408-0044 Hokuto, Japan, [2]Institute of Agrobiological Sciences, NARO, 305-8634 Tsukuba, Japan, [3]Institute of Vegetable and Floriculture Science, NARO, 514-2392, Ano, Japan, [4]University of Toyama, 930-8555, Gofuku, Japan

Abstract: The Leaves of mulberry, Morus spp. has long been known as a suitable hostplant of the silkworm, Bombyx mori from the ancient time. Recently, we found that mulberry leaves are toxic to insects other than B. mori because of two types of defensive components in mulberry latex, sugar-mimic alkaloids (1-3) and MLX56 family proteins (MLX56 and its close homolog LA-b) (4). MLX56 is a 56 kDa protein consisting of 394 amino acids with a unique sandwich-like structure composed of an extensin domain (Gum Arabic-like domain) surrounded by two hevein (chitin-binding) domains (4). MLX56 inhibited the growth of Spodoptera litura, Mamestra brassicae, and Eri-silkworms, Samia ricini, in 0.01-0.04% concentrations (4). MLX56 has a unique mode of toxic action (5). MLX56 swells the peritrophic membrane (PM, thin chitin-based membrane existing between midgut epithelium and food materials) of Eri-silkworms fed MLX56 into an extraordinary thick gel-like structure by binding to chitin-framework of PM with hevein domains, and swelling PM with extensin domain (5). The thick swollen PM presumably functions as obstacle to digestive processes by decreasing the permeability of digestive enzymes and nutrients through PM, and thereby inhibits the insect growth (5,6). Interestingly, B. mori is resistant to MLX56 as well as to sugar-mimic alkaloids, suggesting the physiological adaptation in the mulberry specialist, and the involvement of the latex components in the evolution of silkworm-mulberry interactions (1-5). We are attempting to make pest-resistant crops using MLX56 (7,8). Tomato, tobacco, and Arabidopsis, transiently (7) or stably (8) expressing mlx56 gene (MLX56 protein) showed strong resistances to various important pests including Spodoptera litura (7,8), Mamestra brassicae (7), Plutella xylostella (Lepidoptera) (7), Henosepilachna vigintioctopunctata (Coleoptera, ladybirds larvae) (8), and Frankliniella occidentalis (Thysanoptera, thrips) (8) suggesting that MLX56 can be a promising substitute/complement of Bt toxin in making pest-resistant crops in future.

Efficacy of entomopathogenic fungi against Colorado potato beetle (Leptinotarsa decemlineata) under laboratory conditions

Authors: Konopická Jana[2], Bohatá Andrea[3], Skoková Habuštová Oxana[1] and Zemek Rostislav[1], [1]Biology Centre CAS, Institute of Entomology, Ceské Budejovice, Czech Republic, Czech Republic, [2]University of South Bohemia, Faculty of Agriculture, Department of Plant Production, Ceské Budejovice, Czech Republic   Biology Centre CAS, Institute of Entomol, Czech Republic, [3]University of South Bohemia, Faculty of Agriculture, Department of Plant Production, Ceské Budejovice, Czech Republic, Czech Republic

Abstract: The Colorado potato beetle (Leptinotarsa decemlineata) is the most widespread insect pest that causes huge economic losses, especially on potatoes. As a result of the intensive use of insecticides this species has gradually developed resistance to most pesticides and its control is thus currently very difficult. The frequent use of pesticides can have also negative impact on non-target organisms, the environment, and human health. Thereby, the use of biocontrol agents, like entomopathogenic fungi (EPF) is an alternative method for control of this pest. The aim of this study was to assess the efficacy of selected strains of EPF against L. decemlineata adults under laboratory conditions. New EPF strains were isolated from soil samples collected in potato fields in the vicinity of the Czech Republic. Isolation of EPF was performed by a modified method of live traps “Tenebrio bait method” or directly from naturally infected adults of L. decemlineata using selective medium. Fungal species were determined using macroscopic, microscopic, and molecular markers. Totally, 20 strains of EPF isolated from soil samples and 12 strains of Beauveria bassiana isolated from infected adults of L. decemlineata were tested in this study. The highest efficacy against L. decemlineata adults was found in native strains of B. bassiana and the strain of Metarhizium anisopliae (figure) which caused mortality 100 % at the end of the bioassay. The lowest virulence was found in Isaria sp. and Beauveria sp. strains isolated by Tenebrio bait method (ca 80 %). The present study showed that some strains of EPF, especially native strains of B. bassiana and M. anisopliae, might be prospective biocontrol agents against L. decemlineata.

Biologically produced pheromones: Electrophysiological and behavioural responses of Helicoverpa armigera

Authors: Konstantopoulou Maria[1], Raptopoulos Dimitris[2], Koutsoumpeli Eleni[1], [1]Laboratory of Chemical Ecology and Natural Products, Institute of Biosciences & Applications, NCSR “Demokritos”, Athens, Greece, [2]Novagrica Hellas Biological Products & Solutions, TESPA Lefkippos, NCSR “Demokritos”, Athens, Greece

Abstract: The detrimental effects of insecticides to human health and the ecosystem has been since long very well documented and the public concern constitutes a significant leverage to public bodies and the scientific community to seek equally efficient but environmentally safe alternatives for pest control using biological or biotechnological methods. In this context pest management systems based on pheromones present a lucrative solution. As an ever-increasing number of chemical insecticides is withdrawn from the market the need for eco-friendly approaches to pest management based on pheromones, such as mating disruption, mass trapping, etc., offers a great challenge to humans and the environment and has the potential of a multiplier effect on the economy.

Currently pheromones are produced by chemical synthesis through an expensive and polluting process, which constitutes a limiting factor to their widespread use.

OLEFINE project (http://olefine.eu/) will produce pheromones from yeast cells in bioreactors through the development of a novel technology that reduces production costs significantly. Biological production of low-cost pheromones will enable the rapid adoption of pheromone-based pest management products that can be used as effective and non-toxic alternatives to insecticides.

Validation and comparison of the efficacy of the in-yeast-produced pheromones with those chemically synthesised, was performed by electrophysiological methods and field tests on the cotton bollworm, Helicoverpa armigera (Hübner) (Lepidoptera: Noctuidae). Specifically, we evaluated the antennal responses to compounds produced by fermentation constituted mainly of Z11-hexadecenal (major component of the sex pheromone) in comparison to commercially available pheromones.

In addition, by electroantennography coupled with gas chromatography (GC-EAD) we investigated whether any impurities left in biologically synthesised pheromones after purification can be perceived by the insect’s antennae and potentially interfere with its normal behaviour.

Laboratory behavioural bioassays and field test in cotton fields in Greece, confirm the activity of the bio-pheromones. The results obtained indicate that there are no differences between the biologically produced pheromones and those chemically synthesised.

Pheromone production from yeasts is an innovative, market disruptive technology and is expected to have a strong impact on the Plant Protection Products (PPP) Industry.

This project is implemented under the framework of Horizon 2020/NMBP-BIO-2017 OLEFINE (OLEaginous yeast platforms for FINE chemicals), which is funded from the European Union’s Horizon 2020 research and innovation programme.

Entomopathogenic nematodes for the management of the Japanese beetle and other invasive white grub species

Authors: Koppenhöfer Albrecht, Rutgers University, Dept. Entomology, New Brunswick, NJ, United States

Abstract: The larvae of several invasive white grub species are among the most important insect pests of turfgrass and ornamental plants in eastern North America. The Japanese beetle (JB), Popillia japonica, is the most widespread and notorious of these, but species like the oriental beetle (OB), Anomala orientalis, or the European chafer (EC), Rhizotrogus majalis, are regionally more important. White grubs share their natural soil and rhizosphere habitats with entomopathogenic nematodes (EPNs). At least 5 EPN species were originally collected from naturally infected white grubs, and many more have been documented to use white grubs as natural hosts. White grub species differ in their susceptibility to EPNs and the relative virulence of different EPN species also varies among white grub species. Moreover, larval stages of white grubs may also differ in their susceptibility, but the effect varies with white grub and EPN species. Good control (i.e., = 70% in field studies) in turfgrass of JB, has been achieved with the EPNs Steinernema scarabaei (100%), Heterorhabditis bacteriophora (34–97%), and H. zealandica (73–98%). S. scarabaei is the only species that has provided high field control of OB (87–100%) and EC (89%).

EPN efficacy against these pests in ornamental nurseries has been highly variable (0-100%), likely due to factors similar as in turfgrass. However, research has been more limited, and none of the most promising species or strains more recently tested in turfgrass have been tested in nurseries.

EPN persistence beyond a season following application against white grubs has been reported for H. bacteriophora and S. scarabaei. Due to the excellent adaptation of S. scarabaei to white grubs (high virulence, recycling) and outstanding IJ persistence, a single application of this species provided control of OB within 1 month (77–100% at 0.25–2.5 × 109 IJs/ha), provided additional control in the following spring (86–100% at 0.1–2.5 × 109 IJs/ha), and suppressed OB for up to 4 years.

Combining EPNs with other control agents can increase consistency and level of pest control,and lower costs by being able to use reduced rates of chemicals and EPN. Much of the work on combining EPN with other control agents has been conducted in turfgrass with JB and other invasive species. The best studied and most feasible combinations are those of EPNs with the neonicotinoid imidacloprid. Imidacloprid interacted synergistically in combinations of 4 EPN species in third instars of JB and OB. Imidacloprid–H. bacteriophora combinations provided more consistent synergism against third instars but higher control rates against second instars and early third instars using rates as low as 25% and 50% of the full rates for H. bacteriophora and imidacloprid, respectively. Combinations of the anthranilic diamide chlorantraniliprole and H. bacteriophora resulted in mostly synergistic mortality of third–instar JB and OB.

Advances in use of EPNs turfgrass and ornamentals

Authors: Koppenhöfer Albrecht, Rutgers University, Dept. Entomology, New Brunswick, NJ, United States

Abstract: Turfgrass is one of the best studied commodities regarding use of entomopathogenic nematodes (EPNs). Much of the research has been conducted in the USA. The best studied insect groups for EPN use are white grubs, mole crickets, weevils, and lepidopteran larvae.

The efficacy of EPNs against white grub species varies with white grub species and larval stage and EPN species. Good control of Japanese beetle, Popillia japonica, was observed with S. scarabaei (100%), H. bacteriophora (34–97%), and H. zealandica (73–98%). Only S. scarabaei provided high control of the oriental beetle, Anomala orientalis (87–100%), the Asiatic garden beetle, Maladera castanea (71–86%), and the European chafer, Rhizotrogus majalis (89%). Good control of the northern masked chafer, Cyclocephala borealis, was observed with H. zealandica (72–96%), S. scarabaei (84%), and H. bacteriophora (47–83%). EPN persistence beyond a season following application against white grubs has been reported for H. bacteriophora and particularly the scarab-adapted S. scarabaei.

Invasive mole crickets are important turfgrass pests in the southeastern USA and were controlled with broadcast applications of S. scapterisci and S. riobrave (both 75%). The introduction into the USA of the mole cricket adapted S. scapterisci, isolated from mole crickets in Uruguay and Argentina, was the first successful use of an EPN in classical biological control. It is more effective against the southern mole cricket (S. borellii) than against the tawny mole cricket (S. vicinus) and least effective against the short-winged mole cricket (S. abbreviatus); it is most effective against adult mole crickets and is ineffective against small nymphs. S. scapterisci use in more damage sensitive areas has been limited due to competition from insecticides and by the heavy use of nematicides. In pastures, it has been applied using slit injectors in strips covering 12.5% of the area from which it then spreads over several years.

The bluegrass billbug, Sphenophorus parvulus, was effectively controlled with S. carpocapsae (78%) and H. bacteriophora (74%) in the USA. On golf courses in Japan, S. carpocapsae was very effective for control of the hunting billbug, S. venatus vestitus (84%). Control of annual bluegrass weevil, Listronotus maculicollis, larvae on golf courses with S. carpocapsae, S. feltiae, and H. bacteriophora was variable (0-94%). Split applications of S. carpocapsae were more effective and in combination with the neonicotinoid insecticide imidacloprid provide 84-98% control.

Black cutworm, Agrotis ipsilon, larvae are a pest of golf course greens and tees. S. carpocapsae was the best performing EPN (70–90%). Syringing (twice daily small amount of irrigation) provided limited improvement of S. carpocapsae efficacy under warm, sunny conditions, and split application improved efficacy by around 20%.

The secret of a long, fecund life: why can social insect queens live so long?

Authors: Korb Judith[2] and Meusemann Karen[1], [1]Alexander Koenig Zoological Research Museum, [2]University of Freiburg, Germany

Abstract: Social insect queens can have extraordinary lifespans and at the same time produce many offspring whereas their nestmate workers are often short-lived and functionally sterile. This seems to violate the common life history trade-off between fecundity and longevity which predicts a negative association between these traits. Within the research consortium ‘So-Long’, we study different ants, bees and termites, using the non-social fruitfly Drosophila melanogaster as an ‘outgroup’, to obtain insights into common mechanisms and causes underlying the apparent reversals of the trade-off. To do this we performed a canonical set of experiments across taxa and applied standardized analyses (incl. transcriptomes).
At the mechanistic, molecular level our data suggest that network changes associated with the long, fecund lifespan of queens differ across taxa. Yet, all these mechanisms are connected with the TI-J-LiFe genetic network, which includes the TOR (target of rapamycin) and IIS (Insulin/insulin-like growth factor) signalling pathways, juvenile hormone and downstream pathways such as those involved in immune defence or oxidative stress. At the evolutionary ultimate level, our experimental data indicate that sociality is key to explain the long lifespan of queens. They provide evidence for a superorganismal analogy where workers function partly as disposable soma and queens as germline. Overall, our results provide new insights to the question ‘How and why social insect queens can live so long’.

What happens to fruit-feeding butterfly communities and diversities during tropical forest restoration?

Authors: Korkiatupa Eveliina[6], Malinga Geoffrey M.[2], Nyafwono Margaret[1], Akite Perpetra[3], Holm Sille[5] and Valtonen Anu[4], [1]Gulu University, [2]Gulu University, University of Eastern Finland, [3]Makerere University, [4]University of Eastern Finland, Joensuu, Finland, [5]University of Eastern Finland, University of Tartu, [6]University of Eastern Finland, Finland

Abstract: The alarming rate of deforestation of tropical forests has resulted in decline in biodiversity and has compromised ecosystem functioning. The primary aim of forest restoration approaches has been to reinstate the original vegetation. Less emphasis has been placed on other aspects of biodiversity, such as insect communities.

We investigate the recovery patterns of fruit-feeding butterfly communities across a tropical forest restoration project area of Kibale National Park, Uganda. Study sites represent seven restoration areas planted between 1995 and 2011, as well as two primary forest areas. At each study site we used one cylindrical trap baited with fermented banana. The sites were first sampled in 2011-2012 (40 study sites), and the sampling was repeated with five additional study sites in 2020-2021, allowing a direct comparison of how communities and diversities have changed in the nine years.

During the 2011-2012 census we captured a total of 4 588 fruit-feeding butterflies from 67 species, while during the 2020-2021 census 10 015 individuals from 98 species were captured. As a main result, we found that communities in restored forests were becoming more similar to the primary forest communities over time. We conclude that forest restoration also supports the recovery of fruit-feeding butterfly communities

Insect antennae: coupling blood pressure with cuticle deformation to control movement

Authors: Kornev Kostya[1], Donley Griffin[1], Sun Yueming[1], Pass Guenther[2], Adler Peter[1] and Beard Charles[1], [1]Clemson University, USA, [2]University of Vienna, Austria

Abstract: Insect antennae are hollow, blood-filled fibers with complex shape with muscles only in the two basal segments (scape and pedicel). The distal part of antenna, the flagellum, is muscle-free, but the insect can controllably flex, twist, and maneuver it laterally. To explain this behavior, we performed a comparative study of structural and tensile properties of the antennae of Periplaneta americana, Manduca sexta, and Vanessa cardui. These antennae demonstrate a range of distinguishable tensile properties, responding either as brittle fibers (M.sexta) or strain-adaptive fibers that stiffen when stretched (V.cardui and P.americana). Electron microscopy and high-speed imaging of antennal breakup during stretching revealed complex coupling of blood pressure and cuticle deformation. A solid mechanics model was developed to explain this behavior. The model was validated on artificial antennae with no adjustable parameters. The pressure-cuticle coupling can be controlled through changes of the blood pressure of volume in the antennal lumen and resulted in strain-adaptive behavior. In insects that do not fill the antennal lumen, this blood pressure control is lacking, and the antennae react only by muscular activation; their stress-strain curve is similar to that of a hollow fiber such as a cotton fiber.

Does food enrichment by Hermetia illucens larvae affect overwinter survival and spleen size in the brown trout (Salmo trutta)?

Authors: Kortet Raine[1], Korhonen Kanerva[1], Hyvärinen Pekka[2], Yaripour Sareh[1], Heiska Susanne[4] and Niva Teuvo[3], [1]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland, [2]Natural Resources Institute Finland (Luke), Aquatic population dynamics, Paltamo, Finland, [3]Natural Resources Institute Finland (Luke), Natural resources, Oulu, Finland, [4]Natural Resources Institute Finland (Luke), Production systems, Joensuu, Finland

Abstract: Various enriched rearing methods have been promoted as a possible cost-efficient way to produce fish stockings that show increased survival in the wild. We reared brown trout juveniles in enriched and conventional tanks, provided them novel food enrichment (Hermetia illucens larvae), and finally studied their overwinter survival and relative spleen size. We did not find difference in overwintering survival between the trout that received H. illucens food supplementation and the trout that were not food-supplemented. However, the trout reared under early enriched conditions seemed to show higher feeding performance to forage on these novel prey items, and they had also relatively larger spleens than trout reared in conventional environment. Our results suggest that early enriched rearing provides beneficial and long-lasting effects, but that possible beneficial effects of H. illucens food supplementation remain unclear. Enriched rearing can be recommended especially when fish stockings are produced for conservation purposes.

Suitability of different Amaranthaceae and Polygonaceae species as food sources for the sugar beet weevil Asproparthenis punctiventris

Authors: Koschier Elisabeth[1] and Dittmann Lena[1], [1]Institute of Plant Protection, University of Natural Resources and Life Sciences, Vienna, Austria

Abstract: Asproparthenis (Bothynoderes) punctiventris Germar (Coleoptera: Curculionidae) is widely distributed in Eurasia and one of the most important pests of sugar beet. In addition to sugar beet (Beta vulgaris subsp. vulgaris), several Amaranthaceae and Polygonaceae species have previously been described as food sources of the weevil. To find out whether and which plants can maintain or even promote the beetle population outside sugar beet fields, the leaf consumption of A. punctiventris females on sugar beet was compared with different weeds and other plant species. In addition, differences between mated females during oviposition and unmated females during maturation feeding were investigated in the laboratory. Unmated females consumed the greatest amount of leaf mass from B. vulgaris and about a third less from Atriplex species, indicating that these plants have the highest nutritional value for A. punctiventris. Considerably less was fed on Chenopodium spp. and Amaranthus retroflexus. Spinacea oleracea and all Polygonaceae species were hardly or not fed at all. Mated females generally consumed more leaf mass than unmated. Widespread weeds such as Atripex patula and C. album occurring in high densities in sugar beet and other crops could therefore serve as alternative food source in the absence of sugar beet.

Host plant selection and host use in the sugar beet weevil Asproparthenis punctiventris

Authors: Koschier Elisabeth[1], Dittmann Lena[1], [1]Institute of Plant Protection, University of Natural Resources and Life Sciences, Vienna, Austria

Abstract: The sugar beet weevil Asproparthenis (Bothynoderes) punctiventris (Coleoptera: Curculionidae) is one of the most important pests of sugar beet in Eurasia. It is not known which stimuli adult females during maturation feeding use to find the young sugar beet plants or other plants serving as food source after overwintering, and whether the larvae can also develop on plants with a lower nutritional value than sugar beet. The following plants have, in order, a decreasing nutritional value for females: Beta vulgaris subsp. vulgaris, Atriplex hortensis, B. vulgaris subsp. maritima, Amaranthus retroflexus and Chenopodium album. Females were significantly attracted to leaf odours of Beta spp. and responded positively to odours of A. hortensis and A. retroflexus, but not to C. album. The most and heaviest fourth instar larvae developed on sugar beet, while fewer individuals with lesser weight were found on B. vulgaris subsp. maritima and A. hortensis. Very few larvae were able to develop on C. album, and none on A. retroflexus. The analysis of the odour profiles of Beta spp. and A. hortensis could provide information on which plant volatiles act as olfactory attractants for the sugar beet weevil. Such compounds could be integrated into future sustainable control strategies.

Transcriptome analysis of social isolation response in ants Camponotus fellah

Authors: Koto Akiko[1], Privman Eyal, Keller Laurent, Aburatani Sachiyo, Mc Kenzie Sean and WongPui Shan, [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Abstract: Social deprivation can have negative effects on the lives of social animals, including humans, yet little is known about the mechanisms by which social withdrawal affects animal health. In the carpenter ant Camponotus fellah, socially isolated workers have a greatly reduced lifespan relative to ants kept in groups of 10 individuals. By using a tracking system, we found that social isolation resulted in important behavioral changes and greatly increased locomotor activity. The higher activity of single ants and their increased propensity to leave the nest to move along the walls suggested that the increased mortality of isolated ants might stem from an imbalance of energy income and expenditure. This view was supported by the finding that while isolated ants ingested the same amount of food as grouped ants, they retained food in the crop, hence preventing its use as an energy source. Furthermore, we performed the transcriptome analysis to compare the gene expression between grouped and isolated ants that were separated from the mother colony. We found the differential gene expression related with various metabolic process such as nucleotide, fat, or digestion in isolated ants, and the gene expression profile of isolated ants is similar with that of other organisms which show short lifespan in aged or stressed condition. We would like to discuss about the molecular mechanisms how the social environment affects the fitness of ants from the transcriptome analysis.

Comparative Lidar Studies of Mosquito Habitats

Authors: Kouakou Benoit[2], Gbogbo Adolphe[1], Assamoi Doria[1] and Zoueu Jeremie[2], [2]University of San Pedro, [1]National Polytechnic Institute Felix Houphouet Boigny

Abstract: Habitats constitute one of the main components of biodiversity and provide possible indicator of diversity at the species level such as mosquitoes, vector of malaria. Four sites of habitats have been selected to monitor mosquitos' activities with a Scheimpflug lidar during campaign measurement inside the National Polytechnic Institute located in the center of Ivory Coast. We detected more than 2000 mosquitoes per day per site.

Telomerase activity in Bombus terrestris

Authors: Koubová Justina [1] and Capkova Frydrychova Radmila[1], [1]University of South Bohemia Biology centre, Czech Academy of Sciences, Institute of Entomology, Czech Republic

Abstract: The attrition of telomeres, the ends of eukaryote chromosomes, and activity of telomerase, the enzyme that restores telomere length, play a role in the ageing process and act as indicators of biological age. A notable feature of advanced eusocial insects is the longevity of reproductive individuals (queens and kings) compared to those from non-reproductive castes (workers and soldiers) within a given species, with a proposed link towards upregulation of telomerase activity in the somatic tissues of reproductive individuals. Given this, eusocial insects provide excellent model systems for research into ageing.

We tested telomerase activity and measured telomere length in Bombus terrestris. In somatic tissues, telomerase activity was upregulated only in the fat bodies of pre-diapause queens, and this upregulation was linked to heightened DNA synthesis. Telomere length was shorter in old queens compared to that in younger queens or workers. We speculate that (1) the upregulation of telomerase activity, together with DNA synthesis, is the essential step for intensifying metabolic activity in the fat body to build up a sufficient energy reserve prior to diapause, and that (2) the lifespan differences between B. terrestris workers and queens are related to the long diapause period of the queen. A possible relationship between telomere length regulation and TOR, FOXO, and InR as cell signaling components, was tested.

Effects of urbanisation on woody plant losses to insects

Authors: Kozlov Mikhail V., University of Turku, Finland

Abstract: Despite the increasing rate of urbanization, the consequences of this process for biotic interactions remain insufficiently studied. Individual abiotic drivers of global change, which simultaneously affect urban biota, may differently impact plant-feeding invertebrates. In this presentation I briefly summarize the results of two projects, which compared insect herbivory between urban and rural habitats. Our aims were to identify the general pattern of urbanization impact on background insect herbivory, to explore variations in this impact related to characteristics of both urban areas and insect–plant systems, and to uncover the factors governing urbanization impacts on woody plant losses to insects. We also asked whether urbanisation decreased stability (or, more precisely, increased invariability) of plant – herbivore – enemy interactions. The first project compared the foliar damage inflicted on the most common trees by defoliating, leafmining and gall-forming insects in rural and urban habitats associated with 16 European cities. In two of these cities, we also explored quality of birch foliage for herbivorous insects, mortality of leafmining insects due to predators and parasitoids and bird predation on artificial plasticine larvae. On average, the foliage losses to insects were 16.5% lower in urban than in rural habitats. The magnitude of the overall adverse effect of urbanization on herbivory was independent of the latitude of the locality and was similar in all 11 studied tree species, but increased with an increase in the size of the urban area: it was significant in large cities (city population 1–5 million) but not significant in medium-sized and small towns. Quality of birch foliage for herbivorous insects was slightly higher in urban habitats than in rural habitats. At the same time, leafminer mortality due to ants and birds and the bird attack intensity on plasticine larvae were higher in large cities than in rural habitats, which at least partially explained the decline in insect herbivory observed in response to urbanization. The second project, in addition to defoliating, leafmining and gall-forming insects, addressed also sap- and root-feeders, and explored the differences between urban and rural forests during three subsequent years (2017-2019). Already now, our findings suggest that responses of root- and sap-feeding insects to urbanisation may differ from the responses of externally feeding defoliators. We conclude that top-down forces play important role in mediating impacts of urbanization on the background insect herbivory: factors favouring predators may override the positive effects of temperature elevation on plant-feeding insects and thus reduce plant damage.

Effects of climate on insect herbivory, bird attack rate and leaf traits in oak trees revealed by ecologists and school children

Authors: Kozlov Mikhail V.[29], Tack Ayco[21], Branco Manuela[12], Valdés-Correcher Elena[3], Sam Katerina[1], Selikhovkin Andrey[20], Fürjes-Mikó Ágnes[16], Kozel Alexander[2], Galmán Andrea[4], Prinzing Andreas[26], G. Abstract: Latitudinal patterns in plant defenses and insect herbivory are commonly used to infer the impact of climate change on plant-herbivore interactions. However, despite decades of research, no general pattern has emerged yet. This could be because bottom-up and top-down forces that determine herbivory have rarely been studied concomitantly, making previous attempts to understand the effect of large scale climatic variation on insect herbivory unsuccessful.

We used citizen science to investigate the effect of climate on insect herbivory on the pedunculate oak (Quercus robur) across its complete latitudinal range in Europe. We quantified insect herbivory and the occurrence of specialist herbivores as well as leaf traits and attack rates on artificial caterpillars on 261 oak trees surveyed by both professional scientists and school children in 17 European countries. We further tested whether climate driven variability in insect herbivory was determined by joint variation in bottom-up (plant defenses and nutritional quality) and top-down (bird attack rates) forces acting upon herbivores.

Although there was no clear relationship between climate and total herbivory, the proportion of oak leaves with insect galls increased with increasing spring temperature and peaked at intermediate level of spring precipitation; and the proportion of leaves with insect mines peaked at intermediate spring temperature. Among the leaf traits examined, leaf soluble sugar content decreased with increasing precipitation while leaf C:N ratio increased non-linearly with temperature. Leaf defenses and bird attack rates on artificial caterpillars were unrelated to climate. The proportion of leaves with mines was positively related to the concentration of hydrolysable tannins, but neither other traits nor bird attack rates affected insect herbivory.

Our study shows that although insect herbivory on oak leaves, leaf traits and bird attack rates were all highly variable across Europe, they were weakly influenced by climate variation and were not related to each other. These findings urge for further examination of the drivers of insect herbivory on trees.

Does winter cold really limit the dengue vector Aedes aegypti in Europe?

Authors: Kramer Isabelle[1], Müller Ruth[3], Kreß Aljoscha[3], Ahrens Bodo[2], Scherer Christian[3], Groneberg David[3], Klingelhöfer Doris[3], Dhimal Meghnath[4], Phuyal Parbati[3] and Kuch Ulrich[3], [1]Goethe University, Frankfurt am Main, Germany, [2]Institute for Atmospheric and Environmental Sciences, Goethe University, Frankfurt am Main, Germany, [3]Institute of Occupational, Social and Environmental Medicine, Goethe University, Frankfurt am Main, Germany, [4]Nepal Health Research Council, Kathmandu, Nepal

Abstract: The mosquito Aedes aegypti is a potential vector for several arboviruses including dengue virus. The arboviral vector seems to be restricted to their subtropical/tropical habitats and may have difficulties to overwinter and establish permanent populations in Europe. The aim of this study was to clarify if cold winter temperature limits the re-establishment of the dengue vector Ae. aegypti in Europe. At first, we performed a systematic literature review of the cold tolerance of eggs of two major arbovirus mosquito vectors Ae. aegypti and Aedes albopictus. At second, we added experimental data to close knowledge gaps from literature. We conducted a cold tolerance experiment with eggs of non-diapausing subtropic populations of both species (egg exposure to 0°C & -2°C: <8 days; -6°C: <2 days). The meta-analysis of literature data clearly showed the lack of studies testing zero and subzero temperatures of Ae. aegypti in comparison to Ae. albopictus, though those few studies implied a certain cold tolerance in Ae. aegypti eggs. We confirmed the reported cold tolerance of Ae. aegypti eggs experimentally (16.71% hatching after exposure to -2°C for 8 days; 10.3% hatching after exposure to -6°C for 2 days). The bibliometric and experimental data clearly indicate that subtropical populations of both species can survive low and sub-zero temperatures for a short time period, though the success rate to reach adulthood strongly decreases over exposure duration. Three Ae. aegypti adults emerged after a 6-day exposure to -2°C, and one Ae. albopictus adult emerged after a 1-day exposure to - 6°C. Emergence of adults after longer exposure duration did not occur. One may suspect, that Ae. aegypti eggs are likely to overwinter in Southern Europe especially with regard to climate warming.

Seasonal patterns in high-altitude insect movement over Texas revealed by radar

Authors: Krauel Jennifer[3], Dokter Adriaan[1], Farnsworth Andrew[1], Schmid Baptiste[2], Nilsson Cecilia[1], Liechti Felix[2], McCracken Gary[3] and Horton Kyle[1], [1]Cornell Lab of Ornithology, United States, [2]Swiss Ornithological Institute, Switzerland, [3]University of Tennessee, United States

Abstract: Aerial insect migration is widespread and has enormous impacts on terrestrial landscapes. Yet, these vast flows of biomass, involving trillions of individuals globally, are generally not well characterized. In North America some migratory insects are significant agricultural pests and characterizing their movements, particularly cultivated areas, is of great interest. Although numerous factors may govern these movements, including seasonal and geographic variation in species and behaviors, many movements are facilitated by favorable winds and thought to occur in altitudinal layers in which insects can employ these winds to migrate and disperse. We analyzed data from a vertical radar installed over three seasons during 2018 in southern Texas, as well as data from a nearby weather radar, to identify patterns in aerial insect flows. We report distributional patterns of these flows, with discussion of species involved and comparisons with movements of other aerial biota through this airspace.

A Decade of Biological Control: The Success Story of Liloceris cheni in Florida

Authors: Kraus Emily, Florida Department of Agriculture and Consumer Services, United States

Abstract: Florida is home to hundreds of exotic species. Some of these invaders have serious consequences for the native flora and fauna. The air potato vine, Dioscorea bulbifera, is one such plant. The invasive vine eventually reached all 67 counties in Florida as well as counties in five other states. The vine is known for crowding out native species and becoming a major nuisance for landowners. Biological control was considered for this pest as mechanical and chemical controls were labor intensive and costly. The air potato beetle, Liloceris cheni, was selected as a potential agent. The beetle was tested for host specificity against 41 non-target plant species and determined to be sufficiently host specific. Air potato beetle individuals were released into conservation areas in Florida in 2011 and subsequently provided to residents for release on private properties. Since then the beetle has reduced propagule production, vine mass, and overall improved control of the pest vine.

Individuals were collected from both China and Nepal. There was some apprehension that release of the two biotypes would hinder biological control through reduced fecundity of hybrids. Fortunately, this was not an issue as the beetles showed no preference between biotypes and fecundity was promising in all crosses. Concern again arose when biological control of a closely related beetle, Liloceris lillii, using a larval parasitoid was suggested in the northern US. Subsequent investigations revealed the larval parasitoid displayed clear preference for L. lillii and fortunately posed no threat to L. cheni.

Regarding the vine itself, multiple pathogens and arthropods have been found associated with the plant in Florida. It is not surprising that there would be associations as Florida has several native Dioscorea spp. As the vine continues its' spread further north it is likely there will be newly formed interactions with organisms in those areas. In addition to these potential interactions there are several questions which must be answered to predict the efficacy of the beetle in these areas. The beetle's tolerance responses to temperature and ability of the beetle to withstand cold temperatures is of major concern. Additionally, the ability of the beetle to successfully diapause and emerge in sync with the vine is vital to the effective control of the vine. Finally, it must be determined if the beetles will produce self-sustaining populations or if continued rearing efforts be required to promote management via biological control. Several entities have been in collaboration to answer these questions. Preliminary results will be presented.

Bio-rational management of Halyomorpha halys in fruit orchards in Pennsylvania, USA

Authors: Krawczyk Greg[1] and Peterson Hillary[1], [1]The Pennsylvania State University, Department of Entomology, Fruit Research and Extension Center, Biglerville, PA, United States

Abstract: Since the 2010 season, many successful IPM programs in Pennsylvania fruit orchards were disrupted due to the severe outbreaks of the brown marmorated stink bug (BMSB) Halyomorpha halys (Stål) (Hemiptera – Pentatomidae). Broad spectrum insecticides, mainly pyrethroids and some neonicotinoids, were identified as the most effective tools for emergency treatments against BMSB, and consequently wide-spread overuse of such products by farmers was frequently observed. Over a time, research on BMSB monitoring strategies and alternative management methods has helped to decrease the number of insecticide sprays throughout the season. The BMSB monitoring studies which included lure and trap design comparisons, documented the viability of BMSB field monitoring practices for accurate assessment of the actual BMSB pest pressure at least from mid-July until October. During the 2017 - 2019 seasons we also tested insecticide treated nets baited with commercially available BMSB monitoring lures to monitor BMSB populations around commercial apple orchards. Starting from mid-July, the treated nets were placed outside of the apple blocks, with a higher number of nets placed in the direction of potential influx of BMSB from the outside vegetation such as woods. The standard BMSB monitoring sticky or container based traps were used to assess the pest population in the orchards surrounded by the net traps and control blocks. At the peak BMSB activity periods very high numbers of BMSB adults and nymphs, as well as native stink bugs were collected from under the BMSB net traps.

Reduction in the usage of insecticides enhances practical effective biological control of BMSB. During the 2016 and 2017 field seasons we found species of native egg parasitoids attacking BMSB eggs in Pennsylvania from three native genre Anastatus spp., Telenomus spp., and Trissolcus spp. Additionally, populations of the samurai wasp (Trissolcus japonicus Ashmead), a highly successful parasitoid of BMSB in Asia, have been recently found on sticky traps located in and around fruit orchards in Pennsylvania. During the 2018 and 2019 seasons for the first time we also found the samurai wasp attacking sentinel and wild BMSB eggs. With the samurai wasp being widely present in Pennsylvania fruit orchards, this parasitoid has now become an important candidate for potential biological control of BMSB alongside its native “cousins.”

Reductions in the number of insecticide applications combined with BMSB aggregation pheromone baited insecticide nets and potential broad distribution of samurai wasps should lead to a wide utilization of effective alternative BMSB management method(s).

The development and application of novel molecular tools to study prey-predator interactions in arthropod communities

Authors: Krehenwinkel Henrik[2], Kennedy Susan[1], Gillespie Rosemary[4] and Ashley Adams Seira[3], [1]Okinawa Institute of Science and Technology, Japan, Germany, [2]Trier University, Germany, [3]UC Berkeley, United States, [4]University of California, Berkeley, United States

Abstract: Recent developments in DNA sequencing technology have greatly contributed to our understanding of the taxonomic diversity and species interactions in biological communities. This is particularly true for arthropod communities, where interactions are often cryptic and difficult to observe. Molecular gut content analysis using high throughput amplicon sequencing now enables the reconstruction of even rare and elusive prey-predator interactions in unprecedented detail. However, the routine application of high throughput molecular gut content analysis of predatory arthropods still faces significant challenges. A particular issue is the overabundance of predator DNA sequences. Here we highlight two novel molecular tools to enrich prey DNA from DNA extractions of predatory arthropods. The first approach is based on a separation of intact predator DNA and degraded prey DNA, while the second utilizes PCR primers targeting lineage specific SNPs, to prevent predators from amplifying. Using these protocols, we show two exemplary applications in the study of arthropod communities in Hawaiian rainforest ecosystems. We first focus on an adaptive radiation of Hawaiian spiders, in which dietary niche partitioning may have played a critical role in diversification. Different sympatric species of the genus Tetragnatha are not only distinguished by different substrate use and web architecture, but also by clearly distinct and specialized prey niches. Moreover, we show how the invasion success of introduced arthropod taxa on Hawaii may be directly associated with a release from predation by endemic arthropods.

Targeting the molecular basis of pheromone detection in the desert locust Schistocerca gregaria

Authors: Krieger Jürgen[2], Breer Heinz[4], Fleischer Jörg[1], Khosravian Maryam[1], Pregitzer Pablo[4], Lemke René-Sebastian[1] and Jiang Xincong[3], [1]Martin Luther University Halle-Wittenberg, Institute of Biology/Zoology, Department of Animal Physiology, Halle (Saale), Germany, [2]Martin Luther University Halle-Wittenberg, Institute of Biology/Zoology, Department of Animal Physiology, Halle (Saale), Germany, [3]University of Hohenheim, Institute of Physiology, Stuttgart, Germany present adress: Max Planck Institute for Chemical Ecology, Department of Evolutionary Neur, [4]University of Hohenheim, Institute of Physiology, Stuttgart, Germany

Abstract: In insects, pheromone signals are detected by specialized olfactory sensory neurons (OSNs) mainly residing in chemosensory sensilla on the antenna. In moths and Drosophila, these OSNs express pheromone-specific odorant receptors (ORs) and are characterized by the CD36-related “sensory neuron membrane protein 1” (SNMP1) that is supposed to act as a co-receptor involved in the transfer of pheromones to adjacent ORs.

In search for pheromone receptors in the desert locust Schistocerca gregaria, we have analyzed via fluorescent in situ Hybridization a potential co-expression of SNMP1 with a variety of the 119 ORs that we recently identified in this species. For a substantial portion of the ORs tested, this revealed co-expression with SNMP1 in OSNs, suggesting that not only ORs for pheromonal but also ORs for non-pheromonal compounds are co-expressed with SNMP1. To evaluate a possible role of the SNMP1-co-expressed ORs in pheromone detection, we utilized the S. gregaria pheromonal compounds phenylacetonitrile (PAN) and acetophenone in so-called “DREAM-experiments” to assess a subset of the co-expressed ORs for their response to these substances. These approaches indicated that some of these ORs were activated by either PAN or acetophenone.

In order to scrutinize the possibility that SNMP1 is involved in the detection of pheromonal as well as non-pheromonal compounds, we knocked-down its expression by RNAi and are currently analyzing the consequences for the responsiveness of the antenna to PAN and plant volatiles using electroantennogram recordings. The results may shed some new light on the role of SNMP1 in insect olfaction.

Sixty years of wheat germ in insect artificial diets: history, cautionary tales of trade-offs and contamination, and a look ahead

Authors: Krishnan Natraj, Department of Biochemistry, Molecular Biology, Entomology and Plant Pathology, Mississippi State University, United States

Abstract: Insects reared on artificial diets have many uses such as feed for other animals, agents of biological control in sterile insect techniques, food for people, bioreactors for production of pharmaceuticals or recombinant proteins for human medicine and research material in entomology and other biological sciences. Incorporation of wheat germ represented a quantum leap in the development of artificial diets for lepidoptera. Insect biochemist Erma Vanderzant (1920-1999) used wheat germ in a diet for the boll weevil (Anthonomous grandis) in 1959 at the USDA, ARS laboratory at Texas A&M. While this diet showed some promise for rearing the boll weevil, the Vanderzant group achieved remarkable success incorporating wheat germ into an artificial diet for the pink boll worm (Pectinophora gossypiella) a year later. Since then, wheat germ has proven to be a vital component in successful artificial diets of numerous lepidoptera plus some coleoptera and orthoptera. In this presentation, I will review the history of various diet formulations involving wheat germ with a focus on why wheat germ is such a suitable diet component for lepidoptera and the trade-offs one experiences when the percentage wheat germ in a diet is varied. In addition, I will present the cautionary case of the Yamamoto diet for the tobacco hornworm (Manduca sexta), in which the wheat germ was contaminated with the insect growth regulator methoprene. Finally, I will briefly discuss the possible future of wheat germ in insect artificial diets.

Animal Hosts of Tunga penetrans in Uganda

Authors: Kruecken Juergen[2], MUTEBI Francis[4], Waiswa Charles[1], von Samson-Himmelstjerna Georg[2] and Feldmeier Hermann[3], [1]Coordinating Office for Control of Trypanosomiasis in Uganda Buganda Road Kampala, Uganda, [2]Institute for Parasitology and Tropical Veterinary Medicine, Freie Universität Berlin, Berlin, Germany, [3]Institute of Microbiology and Infection Immunology, Charité University Medicine, Berlin, Germany, [4]School of Veterinary Medicine and Animal Resources, College of Veterinary Medicine, Animal Resources and Biosecurity, Makerere University, Kampala, Uganda

Abstract: Tungiasis is a zoonotic ectoparasitic disease which is caused by T. penetrans in Africa. In addition to humans, T. penetrans affects a wide range of domestic and wild mammalian species including pigs, dogs, cats and rodents. Animal reservoirs have been described in South American transmission settings but little is known about the role of animals in the disease in Africa. A Cross sectional survey conducted among animal keeping households in 10 endemic villages in Uganda during a dry season revealed pigs, dogs, goats and cats as animal hosts of T. penetrans. Among villages, the prevalence of households with at least one case of animal tungiasis could be as high as 71% (median 22%). Pig infections were most common and were found in 9 out of 10 villages surveyed, with a household prevalence of up to 64% (median 16.2%). Dog tungiasis was detected in five of the 10 villages but at low median prevalence of 2%. Only two goat kids from two villages and a single cat were affected. There were strong correlations between animal and humans tungiasis at village ($rho=0.89$, $p<0.001$) and household ($rho=0.4$, $p<0.001$) level. Pigs presented with the highest intensity of infections and thus severe morbidity. These findings call for regular ectoparasite control among animals targeting T. penetrans as part of an integrated One Health control strategy.

Thrips vision: a morphological, functional and ecological view

Authors: Krueger Stephanie[1] and Moritz Gerald[1], [1]Martin-Luther-University Halle-Wittenberg

Abstract: How a thrips can see the world depends on the functional morphology of their eyes and behavioural ecology. A focus on pest thrips may illuminate the behavioural and pest potential of a few species, but it leaves out the ecological and evolutionary framework. Thousands of species of Thysanoptera show different abilities in the use of the optical sensory organs. Some are plant sap suckers (flower, leaf, pollen), others feed on fungi (hyphae, spores), and still others are predators. Visual system requirements differ between species. Finding of host plants or food, dispersal behaviour, spatial orientation or partner findings are crucial and specific for every species.

This becomes already evident by the different eye characteristics. Whereas some apterous species possess only up to 10 Ommatidia, others have over 100. Especially the Phlaeothripidae with the eucon dioptric apparatus seem to have a far more efficient visual system. Also, the species-specific manner of pigmented ommatidia is much more expressed in this family by forming stripe patterns of pigmented ommatidia, compared to 2 to 7 individual darkened ones in Thripidae.

All of them need special solutions for efficient analysis of their environment, which will be presented in the lecture.

Piecing the puzzle of the sex determination and dosage compensation pathways in Anopheles

Authors: Krzywinski Jaroslaw[3], Chen Chun-Hong[1] and Krzywinska Elzbieta[2], [3]The Pirbright Institute, United Kingdom, [1]National Health Research Institutes, Taiwan, [2]The Pirbright Institute, United Kingdom

Abstract: In the African malaria mosquito, Anopheles gambiae, two sex determination genes have been described: the male-determining gene Yob and the dsx. It is unclear how the instruction from Yob is mediated to dsx. Here we show that Drosophila tra2 ortholog is an element of the sex determination pathway necessary for splicing of dsx into the female form in A. gambiae. Mild stable knockdown of tra2 in transgenic mosquitoes leads to partial masculinization of females, whereas stronger knockdown leads to female lethality. Moreover, knockdown of tra2 through ectopic delivery of double-stranded RNA in embryos kills the females prior to hatching. These results indicate that, in addition to having a role in sex determination, tra2 is involved in regulating dosage compensation in A. gambiae.

A phylogenomic analysis of the hyper-diverse avian louse family Heptapsogasteridae (Phthiraptera, Ischnocera): a test of historical taxonomic hypotheses

Authors: Kuabara Kamila, Drexel University, United States

Abstract: The tinamous (Aves: Tinamiformes: Tinamidae) are Paleognathus birds endemic to the Neotropics, and one of the oldest extant avian lineages with fossils dating to the Miocene. Most bird species harbor two or three species of lice, but the tinamous possess the most diverse community of louse genera and species known, and typically have high-intensity infections of parasitic lice as well. This highly replicated parasite diversity on only one host lineage may be a product of tinamous' ancient evolutionary history, providing extensive time for parasite speciation, colonization, and back colonization, as well the high diversity of feather types. Tinamous are parasitized by the families Menoponidae (suborder Amblycera), Philopteridae, and Heptapsogasteridae (suborder Ischnocera), and the latter includes the bulk of the louse fauna found on tinamous. Over the years (1936-2022), the validity of the family Heptapsogasteridae was the focus of many studies, and nowadays it is not formerly recognized. Here I provide the first species-level molecular phylogenetic tree for the family Heptapsogasteridae, testing the monophyly of the genera and subfamilies using genomic data, as well analyzing some morphological characters (such as the shape of the head, thoracic features, chaetotaxy, and genital armature).

Could household use of mosquito coil be responsible for selecting F1534C insecticide resistance mutation in Aedes aegypti?

Authors: Kudom Andreas[1], Mensah Ben[1], Ayettey Joana[1] and Cofie Sarah[1], [1]University of Cape Coast, Ghana

Abstract: Mosquito coil is one of the heavily used domestic insecticides in many African countries. Aedes aegypti, the vector for yellow fever, dengue fever and other arboviral infections, breeds, rest and seek hosts in houses where mosquito coils could be in use. Thus, immediately from emergence through to oviposition, adult Ae. aegypti could be exposed to either sub-lethal or lethal doses of mosquito coil. The question is, could such an exposure select for resistance in Ae. aegypti population? This laboratory investigation was conducted to assess the impact of sub-lethal dose of mosquito coil on the selection of F1534C insecticide resistance mutation in Ae. Aegypti. Larvae collected from the Central Region of Ghana were reared to adult and exposed to sub-lethal or full doses of mosquito coil in a Peet-Grady chamber. Susceptibility to Deltamethrin (0.05%, 0.25%), and Permethrin (0.75%, 3.75%) was also determined using WHO test kits. The dead and alive mosquitoes from the two bioassays were screened for F1534C mutation using AS-PCR technique. The mosquito was resistant to permethrin 0.75% (71.7 ± 16.3) and deltamethrin 0.05% (75 ± 19.5) but susceptible to the coil (99.3 ± 1.2). A total of 250 mosquitoes were genotyped for the F1534C mutation with the overall resistant allele frequency of 80.4%. None of the wildtypes survived the sub-lethal dose of the coil. Mosquitoes with susceptible alleles had about a 5% chance of surviving the exposure compared to mosquitoes with resistant alleles (OR=0.0519, 95%CI=0.01-0.2, p=.0001). The result may suggest that in houses, Ae. aegypti with susceptible allele may likely die leaving behind those with resistant allele when exposed to sub-lethal doses of mosquito coil. Thus, mosquito coils could contribute to the selection of F1543C resistant population.

Novel delivery method of dsRNA to Japanese beetles assisted by peptide nano-capsules

Authors: Kunte Nitish[1], Carroll Elijah[1], McGraw Erin[1], Held David[1] and Avila-Flores Adriana[1], [1]Auburn University, Alabama, United States

Abstract: Gene silencing by introducing doubled-stranded RNA (dsRNA) through feeding can provide target specific control of pests like Japanese beetles. The use of dsRNA to trigger RNAi effects by downregulating essential gene functions in insect herbivores has been recognized for many insect species, but the stability of dsRNA during or after oral delivery remains a problem for this approach. Peptide nano-capsules are being evaluated to increase the stability of dsRNA and enhance cellular uptake by gut cells. To understand how transcytosis in midguts of larval and adult stages may influence the translocation of the dsRNA–nanoparticle complexes, we used isolated midgut tissues mounted into an Ussing chamber. Also, candidate sequences were identified from existing transcriptome data for Japanese beetles, and dsRNA produced. In lab experiments, delivery of those dsRNA to third instar larvae via injection and ingestion were evaluated. Similarly, dsRNA were delivered to adults in laboratory feeding assays. The results of these experiments will be presented. The application of nanotechnology has utility to produce sprayable forms of dsRNA for target specific control of Japanese beetles. This proof of concept work can support the biosecurity concerns with the ongoing range expansion of P. japonica. The identification of dsRNA and evaluation of novel delivery via nano-capsules can reduce reliance on insecticides for eradication efforts.

Comparative analysis of insect developmental responses to temperature

Authors: Kutcherov Dmitry, Saint Petersburg State University, Russia

Abstract: Temperature is an omnipresent ecological factor that exerts profound and diverse effects on insects. Low and high temperature extremes are among the key determinants of species distribution, and so there has been considerable effort in measuring insect performance under stressful conditions to identify the corresponding lower and upper limits and thresholds. Although immature development time and final body size are also among the most frequently measured temperature-dependent insect traits, surprisingly little is known about the patterns of their interspecific variation. The first attempts to discern evolutionary patterns in the thermal requirements for development in insects were undertaken almost 30 years ago. Since then, ecophysiologists have shifted from viewing the thermal phenotype as a set of species-specific parameters towards viewing it as a plastic continuum of thermal reaction norms. Further, it is now widely understood that multispecies datasets carry a genealogical structure that has to be accounted for in comparative analyses. Thus, the time is ripe to revisit the question of the evolution of insect developmental responses to temperature with the use of modern concepts and tools. During my talk, I will briefly show how phylogenetically informed comparative methods can be used for testing various hypotheses regarding the variation and evolution of development time in insects: Does phylogenetic inertia constrain the evolution of insect thermal phenotypes? Is developmental rate least variable at the temperatures which are most commonly experienced in nature? Is it true that adaptation to low temperatures encumbers the ability to develop quickly? Are the temperature optima for insect development, survival, and body size tightly linked or decoupled? All these questions are important both for our understanding of the evolution of insect life-histories in the past and for predicting insect responses to the consequences of human activity in the future. The study was supported by the Russian Foundation for Basic Research (grant no. 20-04-00185).

Drosophila melanogaster female pheromone induces oviposition aversion in D. suzukii

Authors: Kwadha Charles[1], Rehermann Guillermo[1], Bengtsson Marie[1], Witzgall Peter[1] and Becher Paul[1], [1]Swedish University of Agricultural Sciences, Sweden

Abstract: The spotted wing drosophila, Drosophila suzukii, infests ripening soft-skinned fruits causing economic damage. Recently, studies revealed that exposure of oviposition substrates to D. melanogaster, induces egg-laying aversion in D. suzukii. We hypothesized that pheromones of D. melanogaster could partly account for the aversion observed in D. suzukii. In dual-choice oviposition assays, we tested this hypothesis by firstly, exposing blueberries to D. melanogaster and secondly treating blueberries with D. melanogaster pheromones. We report that exposing blueberries to D. melanogaster, invoked consistent avoidance of egg-laying in D. suzukii, and that when berries were treated with female pheromone, it induced egg-laying aversion in D. suzukii. Additionally, using a flight assay, we show that the pheromone antagonizes attraction of D. suzukii to the yeast Hanseniaspora uvarum. Our findings are relevant in the context of finding sustainable ways of managing the invasive pest, particularly by manipulating D. suzukii behavior.

Control of the vector insect of Pinewood Nematode by Neonicotinoid insecticide trunk injections

Authors: Kwon Gunhyung[2], Lee Jinheung[2], Souvic Sarker[1] and Kwon Youngdae[2], [1]Department of plant medicals Andong National University, South Korea, [2]Gyeonggi-do Forestry Enviroment Research Center, South Korea

Abstract: Trunk injections to prevent pine wilt disease was made in a preventive way by using nematocide. This study was conducted to prevent insecticides by injecting trunk into pine trees and then feeding on new shoots containing drugs during the process of the fable insectivore's dessert. This method of insecticide tree injection minimizes the environmental impact compared to conventional aviation controls by only polluting sky bullion, which eats fresh herbs. In order to select the most suitable drug for insecticide tree injection, seven types of neonicotinoid insecticide were diluted indoors by 2,000 dilution each, and then 2µl was injected into the solider sky, and Clotianidin SL and Thiamethoxam DC had the best pesticide effect from digestive poisoning. They were installed in pine trees, and then they were installed in the mash pocket. In addition, the Japanese pine sawyer were installed in pine trees for site application and compared to the untreated tools, and the possibility of applying them to the site prevention system was found because there was no scattering in the scattered trees of the pesticide tree injection test sites.

Molecular and behavioral analysis of gustatory receptor neurons in Drosophila larvae

Authors: Kwon Jae Young[1], Choi Jaekyun[1], Sung Choi Min[1] and Yu Seungyun[1], [1]Sungkyunkwan University, South Korea

Abstract: Finding and feeding on food sources is necessary for the survival of all animals. This behavior is mainly influenced by the taste and nutrition of a food source, as well as the nutritional status of an individual organism. Sweet substances generally cause attractive behavior, and bitter substances generally cause aversive behavior. Feeding behavior can be defined as the entire process that encompasses searching for food to digestion and nutrient absorption. We use Drosophila larvae as a model system to study the process of choice, in which the quality of food is judged, and the process of ingestion, in which the selected food is ingested into the digestive tract. We examined larval behavioral responses to 23 bitter compounds, testing for choice and ingestion as separate processes. Several compounds caused differential responses for choice and ingestion behavior. For example, denatonium causes an aversive response in a choice assay, but has a neutral effect on ingestion behavior. We found that pharyngeal gustatory receptor neurons (GRNs) have a major role in regulating ingestion, and we constructed a Gr-GRN map of the pharyngeal sense organs.

Interspecific hierarchies from aggressiveness and body size among the invasive alien hornet, Vespa velutina nigrithorax, and five native hornets in South Korea

Authors: Kwon Ohseok[1], Choi Moonbo[1], [1]Kyungpook National University, South Korea

Abstract: The range of the invasive alien hornet, Vespa velutina nigrithorax, has been continuously expanding since its invasion of Korea in 2003. Here, we compared the aggressive behaviors and body size of V. velutina nigrithorax with five native hornet species to identify the interspecific hierarchies that contributes to the spread of this species. Aggressive behaviors were classified into 11 categories and each interaction was scored as a win, loss, or tie. As a result, V. velutina was superior to V. simillima in 153 fights where V. velutina won 71% and showed a high incidence of threatening behavior. V. mandarinia outperformed V. velutina in 104 fights where V. mandarinia won 91% and grappling behavior was common. V. analis was superior to V. velutina in 67 fights where V. analis won 76% and showed a high amount of threatening behavior. V. crabro was superior to V. velutina in 93 fights where V. crabro won 73% and showed a high rate of threatening behavior. V. dybowskii was superior to V. velutina in 132 fights where V. dybowskii won 91% and showed a high rate of threatening and grappling behaviors. The body size of V. velutina was larger than V. simillima (although not statistically significant) and smaller than all other Vespa species. Therefore, according to the results of this study, the low interspecific hierarchies of V. velutina seems to be a major cause of slower spreading rates than it has shown in Europe. However, over time, its density has gradually increased within the forest, in which it seems to be overcoming its disadvantages and expanding its range, possibly as large colonies and good flying abilities make it easier to secure food.

War in the darkness: the use of volatile organic compounds as biological alternatives to control wireworms

Authors: La Forgia Diana[2] and Verheggen François[1], [1]Chemical and Behavioural Ecology, Gembloux-Agro-Bio-Tech, TERRA, University of Liege, [2]Agroscope, Switzerland

Abstract: Wireworms (Coleoptera: Elateridae) are polyphagous soil-dwelling pest that feed on roots and tubers of crops of high economical value. This work was focused on the VOCs quantification from the roots of two maize varieties having experienced contrasted levels of wireworm infestation in the field. We showed that the least susceptible variety released a more diverse blend of VOCs. We also investigated whether wireworms are attracted by conspecifics. The compound 2-Pentylfuran was present in high quantity, particularly in treatments where larvae were present. Behavioral assays in dual-choice olfactometer showed a significant attraction to 2- Pentylfuran. The larvae aggregation with conspecifics on plant roots was highlighted for the first time, opening an important research path. Finally, we developed an attract-and-kill system proposing alginate beads filled with EPNs and spiked with potato extract to larvae. We found that the ingestion of these beads led to higher mortality rates. This method demonstrated some signs of reduction of the wireworms metabolism. Finally, the development of the attract-and-kill system combining VOCs with EPNs showed a long-term reduction of wireworms activity that needs to be tested in the field. The results obtained may open new paths in the study of the aggregation, the host selection and preference.

The Transition from a Gymnosperm to an Angiosperm Dominated Flora: What Happened to Herbivorous and Pollinating Insects at the Aptian-Albian Gap?

Authors: Labandeira Conrad, National Museum of Natural History; University of Maryland, United States

Abstract: Around the 1990s three studies determined that total insect diversity at the family level did not increase during the early ascendancy of angiosperms. These studies were controversial because they contravened the canonical expectation that the evolutionary and ecological expansion of early angiosperm lineages would have favored a similar expansion of their associated, trophically dependent, insect lineages. However, these studies were followed by additional examinations of data that also arrived at the same conclusion: at the family level, there was no increase in insect diversity that was synchronous with angiosperm expansion. What was the reason for this? A recent, separate analysis of 280 insect families that were associated with ferns, gymnosperms and angiosperms during most of the Mesozoic and Cenozoic, including the formative time interval in the Early Cretaceous from 120 to 100 million years ago, provides some clues. First, insect families dominated by fern host associations that made the switch to angiosperms were few and contributed little to a diversity increase through this time interval. Second, insect lineages with dominant gymnosperm hosts reached a level of 95 families in the 35 million years preceding the angiosperm radiation. Third, insect lineages dominated by gymnosperm-to-angiosperm host shifts and insect lineages newly originating with early angiosperms reached a level of 110 families after the early phase of the angiosperm radiation. Fourth, these two insect diversity maxima are separated by an approximately 20 million-year-long interval of the Early Cretaceous known as the Aptian–Albian Gap. The Aptian–Albian Gap indicates a major lull that is characterized by extinction of insect lineages with obligate gymnosperm associations that overlapped with the origination of new lineages having obligate angiosperm associations. This time interval indicates a period of heightened taxic turnover. Last, these taxic data are best demonstrated both for herbivores and pollinators. However, during the past decade, numerous studies of insect pollinators associated with instances of abundant gymnosperm and rare angiosperm pollen document the prolonged delay in this transition across the Aptian–Albian Gap. A preliminary and ongoing study is using a different approach by characterizing the pattern of herbivory, using damage types (DTs), on the latest, well-preserved, gymnosperm-dominated flora and the earliest, well-preserved, angiosperm-dominated flora. This study of involving DTs of insect herbivores immediately before and after the Aptian–Albian Gap suggests a similar pattern. These three approaches of examining plant-associated insect taxa immediately before, during and after the Aptian–Albian Gap-the (i) family-level taxic diversity of plant-associated insect families, (ii) the various insect pollinator studies, and (iii) examination of insect herbivory on diverse floras-collectively provide a compelling ecological explanation for the fla

BeeScanning

Authors: Lagerman Björn, BeeScanning Global AB https://beescanning.com, Sweden

Abstract: BeeScanning - monitors bees health

BeeScanning is an app that analyses images, taken with the smartphones camera. Knowledge when needed to discover parasite varroa, dwv, queen and colony strength.

With a smartphone using the camera and the BeeScanning app, beekeepers can instantly diagnose the parasite mite varroa destructor as well as other features in the hive. Images are taken on living bees on the comb. The tool will also form basis for selection in breeding programmes as well as the basis for population modelling research in the colony. New features are added including brood diseases and bee behaviours, evolving technology using video and sound. Enabling a tool for enhanced knowledge.

BeeScanning is funded by the European Innovation Program, the Swedish Board of Agriculture, The Swedish Agency of Innovations, via Kickstarter and 10 national and international awards.

The app is free to download and free to use for finding varroa. There are 6 000 users, 35 000 images and more than 15 000 manually annotated regions in 15 classes. View http://tagger.beescanning.com Analysed images are stored and used for furhter training the AI. Images are instantly analysed in the following classes :

Bees with varroa
Queen
Deformed wings
Number of bees
Mean average precision: 83% Recall 67%

Results are presented to the user in absolute figures and as mean varroa infestation level %.?Found objects are labeled and displayed to the user for review. Histograms indicates trends of the colony performance as a tool for decisions on treatment and/or breeding purposes.

The Beescanning technology is based on proprietary convolutional neural network, NN, and deep learning. Not by classification or algoritmic image analysing. This means results will continue to improve as the artificial intelligence learns from the ever increasing data its fed by the users.

Metadata as time, geopostion, breed is collected from growing the worlds largest database of images of bees on combs. We aim for a tool that can monitor events, nutritional status, health and make prognoses.

BeeScanning is based on our findings that there is a correlation between the actual varroa infestation level, as measured by alcohol washing or Apistan, and varroa that is optically detectable. https://beescanning.com

Arthropod pest management for winter strawberry production in USA

Authors: Lahiri Sriyanka[1], Yambisa Armand[2], Panthi Babu[3], Kaur Gagandeep[3] and Montemayor Joseph[3], [1]Gulf Coast Research and Education Center, Department of Entomology and Nematology, University of Florida, Wimauma, FL, United States, [2]Gulf Coast Research and Education Center, Department of Entomology and Nematology, University of Florida, Wimauma, FL Earth University, Costa Rica, United Stat, [3]Gulf Coast Research and Education Center, Department of Entomology and Nematology, University of Florida, Wimauma, FL, United States

Abstract: Winter strawberry production in Florida is a unique system, owing to the small window of economic opportunity, extent of global market demand, and the pest management challenges faced by the open-field production conditions. While, the Florida strawberry industry is working hard to adapt to the pest management and economic constraints, organic strawberry production is on the rise, due to public demand. Key pests including the invasive Scirtothrips dorsalis Hood, Frankliniella occidentalis (Pergande), and F. schultzei Trybom (Thysanoptera: Thripidae), and twospotted spider mite, Tetranychus urticae Koch (Arachnida: Acari: Tetranychidae) are managed using conventional pesticides, while 88% of Florida strawberry growers have integrated augmentative biocontrol tactics for management of T. urticae. Techniques such as the application of ultra-violet C (UV-C) spectrum are also being examined to facilitate pest management in strawberries. A greenhouse study was conducted to examine the efficacy of a capsicum oleoresin extract based biopesticide, a predatory mite, Amblyseius swirskii Athias-Henriot (Arachnida: Mesostigmata: Phytoseiidae), and a conventional insecticide spinetoram, to control S. dorsalis. Additionally, strawberry field studies were conducted to assess the spatial and temporal distribution of S. dorsalis and F. occidentalis and the efficacy of UV-C application to suppress key pests. Results showed that the biopesticide was as effective as spinetoram to suppress adult S. dorsalis populations in the greenhouse. The predator, A. swirskii, on the other hand was as effective as spinetoram to suppress plant damage and S. dorsalis larval populations. Further results and implication for future research will be discussed.

Regional population dynamics of northern geometrids: A Fennoscandian collaboration

Authors: Laksforsmo Vindstad Ole Petter[1], Bylund Helena[3], Uhd Jepsen Jane[2], Ruohomäki Kai[7], Gilles Yoccoz Nigel[4], Tenow Olle[3], Anker Ims Rolf[1] and Klemola Tero[7], [1]Department of Arctic and Marine Biology University of Tromsø (UiT) Tromsø, Norway, [2]Norwegian Institute for Nature Research, Norway, [3]Swedish University of Agricultural Sciences, Sweden, [4]University of Tromsø - The Arctic University of Norway, Norway, [5]University of Turku, Finland

Abstract: Population cycles of geometrid moths (Operophtera brumata and Epirrita autumnata) in northern Fennoscandia have received substantial attention in the ecological literature. This reflects a long-standing Fennoscandian tradition for research on the causes and consequences of moth population cycles. However, most of this research has been conducted with relatively minor cooperation between research groups in Finland, Norway and Sweden. Here, for the first time, we draw together moth population time series from all three Fennoscandian groups. This enables us to elucidate macro-scale regional patterns in key descriptors of cycle dynamics, including periodicity, amplitude, density-dependence and spatial synchrony.

Effects of Hosts on the Phenacoccus Solenopsis Tinsley

Authors: Lang Yang[1], Hong-song Chen[1], Li-fei Huang[1], Jian-jun Jiang[1], wei-lan Wang[1], [1]Plant Protection Research Institution, Guangxi Academy of Agricultural Sciences/ Guangxi Key Laboratory of Biology for Crop Diseases and Insect Pests, China

Abstract: Phenacoccus solenopsis Tinsley, a worldwide distributive malignant invasive pest. For its wide host range and strong adaptability, P. solenopsis has caused devastating effects to farm crops, cash crops and horticultural plants. In China, the pest has spread to 15 provinces and districts, which brings about enormous realistic harm and potential threat to agricultural production. There were obvious differences and preference for each instar in choosing seven different hosts. To further understand the population dynamics and adaptive capacity to different hosts, the work systematically studied the influences of hosts on the growth, survival, fecundity and longevity of P. solenopsis. The results showed the order of feeding preference of each instar was as follows. 1st instar: Bidens pilosa = Gossypium spp. >Solanum tuberosum > Malvaviscus arboreus > Ipomoea batatas > Hibiscus rosa-sinensis > Lycopersicon esculentum. 2nd instar: Gossypium spp. > M. arboreus = B. pilosa > L. esculentum > S. tuberosum = H. rosa-sinensis > I. batatas. 3rd instar: Gossypium spp. = M. arboreus > H. rosa-sinensis =B. pilosa > S. tuberosum = I. batatas > L. esculentum. Adult female: Gossypium spp. = H. rosa-sinensis = M. arboreus > B. pilosa > S. tuberosum > I. batatas = L. esculentum. The survival rate, developmental duration, female ratio, longevity and fecundity of females were different on different hosts. Nymphs survival rates were higher on M. arboreus, I. batatas and B. pilosa, the lowest was on L. esculentum. The longest nymphal developmental period was on B. pilosa (16.5 d), the shortest was on M. arboreus (11. 7 d). The entire lifespan of female on B. pilosa was the longest (62.1 d), the shortest were on I. batatas and L. esculentum (40.9 d and 41.0 d, separately). Female rations were the highest on L. esculentum and S. tuberosum (69.08% and 69.00%, respectively), on M. arboreus was the lowest (53.55%). The fecundity was the highest on M. arboreus, up to 647.92 nymphs per female, followed by S. tuberosum (503.33 nymphs per female), the lowest was on I. batatas, only 171.09 nymphs per female, followed by B. pilosa (195.33 nymphs per female). Experimental population life table parameters indicated that, M. arboreus was the most suitable host for P. solenopsis, S. tuberosum was the second, followed by Gossypium spp. However, B. pilosa, mealybug favorite host was not suitable for its growth and development. This study indicated P. solenopsis potential threat to different hosts.

Hormonal and neural control of egg production in the historically important model insect, Rhodnius Prolixus

Authors: Lange Angela[2], Leyria Jimena[2], Orchard Ian[1], [1]Department of Biology, University of Toronto Mississauga, Ontario, Canada, [2]University of Toronto Mississauga, Canada

Abstract: Rhodnius prolixus, the blood gorging kissing bug, is the model insect used by Sir Vincent Wigglesworth and others, upon which the foundations of insect physiology, endocrinology, and development have been built. R. prolixus is also medically important, being a principal vector of Trypanosoma cruzi, the causative agent of Chagas disease in humans. The blood meal stimulates and enables egg production, and since an adult mated female can take several blood meals in her lifetime, each female can produce hundreds of offspring. Understanding the reproductive biology of R. prolixus is therefore of some critical importance for controlling the transmission of Chagas disease. The R. prolixus genome is available and so the post-genomic era has arrived for this historic model insect. This talk focuses on the female reproductive system and coordination over the production of eggs, emphasizing the classical (neuro) endocrinological studies that led to a model describing inputs from feeding and mating, and including the neural control of egg-laying. Recent insights brought about by molecular analyses, including transcriptomics, confirm, support, and considerably extends this model.

Tracking thrips

Authors: Lankheet Martin[3], Lopez Reyes Karla[2] and van Tol Rob[1], [1]Biointeractions and Plant Health, Wageningen Plant Research, [2]Bio-Protection Research Centre, Lincoln University, New Zealand, [3]Wageningen University, Netherlands

Abstract: Developing effective traps for insect control requires knowledge on attraction and repulsion of different kinds of stimuli, in combination with their effects on flight behaviour. For thrips this is especially challenging, due to their small size and irregular flight behaviour. Discrimination experiments, therefore, mostly use sticky plates for registering landing sites disregarding many possible differences in behaviour dynamics. Measuring the dynamics of behaviour typically requires high-speed and high-resolution videos leading to extremely large data sets, which makes the whole procedure cumbersome and unattractive.

Here we describe a tracking system detects multiple thrips in video footage on the fly in high-speed video footage from two cameras in a three-dimensional configuration. Rather than raw images we save the locations of all visible thrips, from which the 3D paths of individual thrips are reconstructed off-line. We show several, dedicated steps to boost sensitivity for detecting thrips that are barely visible by the human eye. The methods will be illustrated with results from colour preference experiments where attractiveness is measured for single colour patches and for patches with different colour contrasts. The system allows for high-throughput measurements, providing dynamics of behaviour that would get lost when just counting the number of landings.

Where the wild rose galls grow: the phylogenomics and biogeographic history of Diplolepis (Hymenoptera: Cynipidae)

Authors: László Zoltán[1], Buffington Matthew[4], Looney Chris[6], Zhang Miles[5], Shorthouse Joe[2], Ide Tatsuya[3], Lucky Andrea[5], [1]Hungarian Department of Biology and Ecology, Faculty of Biology and Geology, UBB Cluj-Napoca, Romania, [2]Laurentian university, Canada, [3]NMNS, Tokyo, Japan, [4]Systematic Entomology Laboratory USDA-ARS, United States, [5]University of Florida, United States, [6]Washington State Department of Agriculture, United States

Abstract: Gall wasps of the genus Diplolepis induce structurally distinct galls on wild roses, which provide gallers with food and shelter. Currently many Diplolepis species are distinguished by their galls in addition to adult morphology. Previous work using mitochondrial gene COI has revealed discordance between gall morphology and DNA barcodes. To address these problems, we generated the first genus-wide genomic dataset of Diplolepis using ultraconserved elements (UCEs) to resolve phylogeny among hypothesized lineages, determine the age and biogeographic origin of the genus, and describe global biogeographic patterns.

Diplolepis species (Cynipidae) found in Siberia, Kazakhstan and the Caucasus region

Authors: László Zoltán[2], Lehel Dénes Avar[1] and Szabó Emerencia[2], [1]Babeș–Bolyai University, Cluj-Napoca, Romania, [2]Hungarian Department of Biology and Ecology, Babeş-Bolyai University, Romania

Abstract: The tribe Diplolepidini Latreille, 1802 is the only group from Cynipidae family (Hymenoptera) which causes galls on wild roses (Rosa sp.). It comprises two genera: Diplolepis Geoffroy, 1762 and Liebelia Kieffer, 1903. The Holarctic genus Diplolepis is more speciose in the Nearctic, while Liebelia is restricted to the Palearctic. Diplolepis is represented by cca. 12 species in Asia, while around 30 species are described from the Nearctic. However, many more wild rose species are known from Asia than from the Nearctic, and there is a probability that many Asian rose gall inducers have been overlooked until now. From the Siberian region data regarding Diplolepis species are especially scarce, and no species have been previously recorded in Georgia. In 2018, as part of the RO-CRES expedition (CNFIS-FDI-2018-0104), we collected samples of rose galls along a wide geographical range from Eastern Europe to Primorsky Krai, including Kazakhstan, North-Ossetia, and Georgia. Several samples were taken from Siberia. The species usually appeared on Rosa majalis and R. acicularis, but in Kazakhstan and Georgia also on R. rapini and R. oxyodon. In Siberia the most abundant and common Diplolepis species was D. spinosissimae. Based on mtCOI barcode sequences we identified two undescribed species, one from Novosibirsk Oblast and one from the eastern part of Kazakhstan, near Pavlodar. Furthermore, reared specimens of D. mayri and D. fructuum collected in North-Ossetia and Georgia differed from western European specimens based on mtCOI barcodes and morphometry. This information supports the assertion that Diplolepis diversity in the eastern Palearctic is poorly known and that more new species are likely to be discovered.

The parasitoid community of Diplolepis abei Pujade-Villar & Wang, 2020

Authors: László Zoltán[4], Zhu Qifan[2], Lehel Dénes Avar[1], Szabó Emerencia[3] and Wang Yiping[2], [1]Babeș–Bolyai University, Cluj-Napoca, Romania, [2]College of Forest and Biotechnology, Zhejiang Agricultural and Forestry University, China, [3]Hungarian Department of Biology and Ecology, Babeş-Bolyai University, Romania, [4]Hungarian Department of Biology and Ecology, Faculty of Biology and Geology, UBB Cluj-Napoca, Romania

Abstract: The genus Diplolepis Geoffroy, 1762, has a Holarctic distribution and causes galls on wild roses (Rosa sp.). Diplolepis is more speciose in the Nearctic than in the Palearctic, being represented by cca. 12 species in Asia, and cca. 30 species in the Nearctic. Diplolepis abei Pujade-Villar and Wang, 2020, is the first known rose gall-inducer of economic importance. It causes galls on the Chinese Kushui rose, a hybrid of Rosa sertata Rolfe × R. rugosa Thunb. which is cultivated mainly in Gansu Province (China) for its oil. Where the R. sertata × R. rugosa hybrid is commonly planted, gall-infected shrubs may suffer up to 70% yield loss according to rose oil farmers. Because in infected plantations D. abei is considered a significant pest, its parasitoid community is of great importance. Torymus bedeguaris is the only previously recorded parasitoid of D. abei. Here we report other parasitoid species belonging to the genera Pteromalus, Eupelmus, Eurytoma, and Orthopelma. Only half of the collected galls yielded gall inducers and parasitoids. In the galls with emerged inhabitants the parasitism ratios reached above 85%. This parasitism ratio is not significantly different from those found in the case of European uni- and multilocular species, which suggests that the parasitoid community and the gall inducer are not adventive, as was hypothesized by regional farmers.

Stink Bugs: Biorrational Control Based on Semiochemicals and Vibrational Communication

Authors: Laumann Raúl[3], Blassioli Moraes Maria Carolina[4], Borges Miguel[2], Cokl Andrej[1], [3]Laboratory of Semiochemicals Embrapa Genetic Resources and Biotechnlogy, Brazil, [4]Semiochemicals Laboratory, Embrapa Genetic Resources and Biotechnology, Brazil, [2]Laboratório de Semioquímicos, Embrapa Recursos Genéticos e Biotecnologia, Brasilia, Brazil, [1]Department of Organisms and Ecosystems Research National Institut of Biology, Slovenia

Abstract: Olfaction is the main channel used by several organisms to transmit and receive information. Stink bugs use semiochemicals to communicate inter- and interspecifically for different purposes, for example to aggregate, to locate a mate, food, plant hosts, or to identify danger, such as the presence of predators and parasitoids. The chemical signals are essential for their reproductive success. In most organisms, communication does not occur using only one channel, but in general, more than one channel is used simultaneously or successively to transmit information to another organism. The pivotal study with Nezara viridula (L.) indicated that stink bugs use vibrational and chemical signals during their reproductive behaviour. Laboratory studies showed that vibrational signals can be used to attract different conspecifics for mating purpose and, that heterospecific vibrational signals can disturb the reproductive behaviour of conspecifics. Recently, field experiments, conducted in Brazil, combining pheromone traps with vibrational signals enhanced the attraction of Euschistus heros (F.) females compared to traps baited only with the sex pheromone. In this presentation, we will summarize the main advances on pheromone studies on Neotropical stink bugs, and also the new tools that are been aggregated to pheromone traps, like vibrational signals and electronic sensors, to monitor stink bugs in arable crops.

The effect of intercroping on the assemblage of primary and secondary parasitoids of aphids of plum orchards

Authors: Lavandero Blas[1], Lavandero Blas[3], Zepeda-Paulo Francisca[2], alvarez jeniffer[2] and montealegre xiomara[2], [1]Instituto de Ciencias Biológicas, Universidad de Talca, Talca, Chile, [3]Laboratorio de Control Biológico, Instituto de Ciencias Biológicas, Universidad de Talca, Chile, Chile, [2]Laboratorio de Control Biológico, Instituto de Ciencias Biológicas, Universidad de Talca, Chile

Abstract: The use of intercropping to decrease herbivorous populations, through the increase and consequent effect on natural enemies' populations, can be considered as a remedy for agricultural intensification. Non-crop or alternative-crop resources could affect natural enemy diversity and activity by providing refuge, in which they may seek shelter from deleterious environmental factors, different food resources and habitat for alternative prey or hosts. Parasitoids are frequently used in biological control given that they are considered as specialist and efficient agents of control. The presence of alternative hosts in habitats adjacent to crops may provide a source of parasitoids at the beginning of the growing season, thereby maximizing biological control. The aphid species Brachycaudus helichrysi, Aphis spiraecola and Myzus persicae on plum orchards and Rhopalosiphum padi in cereals share parasitoid species. During the winter months in Chile, R. padi is parasitized by the same species during the first stages of winter cereals, that also attack plum aphids. We studied the effect of alternative hosts surrounding plum orchards on the control of plum aphids by parasitoids. We hypothesized that alternative hosts on an intercrop of oats represent a source and refuge for natural enemy populations to ensure the early arrival of parasitoids to plum orchards for the control of aphids in spring. To test this hypothesis, we compared the composition and abundance of parasitoids and aphids between plum orchards with an interow of Avena sativa and a control without the interow crop. The most abundant aphid species during the winter on the cover crops was R. padi and the parasitoid A. platensis, the most abundant parasitoid. On the other hand, during spring, the abundance of aphids on plums was higher on the controls compared to treatments. We examine the parasitism rates of all species, the species composition of primary and secondary parasitoids and the links between these and three most abundant aphid species of plum. The use of an oat interow although increased parasitoid abundance, reduced the overall diversity when compared to the parasitoids present on weeds in the control plots. The secondary parasitism events and unemerged mummies was greater than expected, the effects of these on the overall parasitism rates are discussed as well as the alternative hypotheses to explain aphid decline in treatment plots.

Host quality induces phenotypic plasticity in a wing polyphenic insect

Authors: Lavine Laura[3], Jiang Jianru[1], Lavine Mark[2], Lin Xinda[1] and Xu Yili[1], [1]College of Life Sciences China Jiliang University, Hangzhou, China, [2]Department of Entomology Washington State University, United States, [3]Department of Entomology Washington State University, United States

Abstract: The availability of food is a critical environmental condition that impacts an animal's growth and development. Many insects facing this challenge have evolved a phenotypically plastic, adaptive response that allows them to develop into adults that will face the appropriate environmental condition. For example, many species of insect exhibit facultative wing growth, which reflects a physiological and evolutionary trade-off between dispersal and reproduction, triggered by environmental conditions. What the environmental cues are and how they are transduced to produce these alternative forms, and their associated ecological shift from dispersal to reproduction, remains an important unsolved problem in evolutionary ecology. In our work, we investigate the role that host quality has on the induction of wing development in wing polyphenic insects exhibiting strong tradeoffs in investment between dispersal and reproduction, the brown planthopper, a serious pest of rice in Asia. As rice plants grow, the short-winged brown planthopper dominates the population, but a shift occurs as the plants mature and senesce in the field such that long-winged brown planthoppers emerge and migrate. It remains unknown how changes in the rice plant induce development of the long-winged morph, despite recent discoveries on the role of the insulin and JNK signaling pathways in wing development. We found that by mimicking the glucose concentration of senescing rice plants, we significantly increased the proportion of long-winged female planthoppers. The effects of glucose on wing morph are additive with previously described effects of density. Our results show that host quality both directly regulates phenotypic plasticity and interacts with other factors such as density to produce the appropriate phenotype for specific environmental conditions.

Global change and locust swarms: a synthesis of climate change and land degradation effects on insect populations booms

Authors: Lawton Douglas[6], Adams Abigail[6], Spessa Allan[1], Cease Arianne[4], Manneh Balanding[3], Wang Bin[9], Waters Cathy[2], Issac Crystal[6], Li Liu De[10], Brosemann Jonah[10], Le Gall Marion[5], Moroneso Matt[6], Seelig Matt[6], Sikes Melissa[7], Feng Puyu[8] and Deveson Ted[1], [1]Australian Plague Locust Commission, Department of Agriculture, Australia, [2]Dubbo District Office, New South Wales Department of Primary Industries; School of Sustainability, Arizona State University, Australia, [3]Faculty of Medicine, University of British Columbia, Canada, [4]Global Institute of Sustainability, Arizona State University, United States, [5]Julie Ann Wrigley Global Institute of Sustainability, United States, [6]School of Life Science, Arizona State University, United States, [7]School of Life Sciences, Arizona State University, Australia, [8]Wagga Wagga Agricultural Institute, New South Wales Department of Primary Industries; School of Life Sciences, University of Technology Sydney, Australia, [9]Wagga Wagga Agricultural Institute, NSW Department of Primary Industries, Australia, [10]Wagga Wagga Agricultural Institute, NSW Department of Primary Industries; Climate Change Research Centre and ARC Centre of Excellence for Climate Extremes

Abstract: Locust (Orthoptera: Acrididae) swarms have plagued human history by posing significant threats to global food security. For example, the Australian Bureau of Agricultural and Resource Economics estimated that there would have been USD $963 million in damage during the 2010-2011 Australian plague locust (Chortoicetes terminifera) plague without control. Therefore, understanding how global change may influence the probability of locust outbreaks is important for economies and food security. However, the effect of multiple aspects of global change on insect population booms remain difficult to predict. In this talk, I will synthesize our current research on the ecological underpinnings of Australian plague locust outbreaks with regards to global change.

To gain insight on possible factors that induce outbreaks, we constructed hierarchical additive models using a 30-year data set of Australian plague locust outbreaks. We found that outbreaks were overwhelmingly dictated by the lag effects of rainfall and temperature and were negatively correlated with soil nitrogen. Land degradation through overgrazing can lead to nutritionally optimal grasses for locusts and increase population sizes. Indeed, this has been shown in three other locust species and is anecdotally reported with the Australian plague locust. I will share data testing how land degradation can affect locust outbreaks through altering both the spatial distribution of the nutritional environment and the distribution of woody vegetation. To understand how climate change will impact locusts, we constructed random forest models using the same data set and predicted the effects of climate change under Representative Concentration Pathway 8.5 using BIOCLIM variables. We predicted that locust outbreak probability will decrease as much as 90% by 2071-2090 and become more localized in Southern Australia.

Climate change will influence how land is used around the world by allowing agriculture in new areas (e.g. northern latitudes) while preventing it in other areas (e.g. drylands). Therefore, climate change will have both direct and indirect impacts on insect population dynamics. Understanding these effects are important in making predictions on where and when the Australian plague locust and other insects will go through population booms.

Mosquitoes anticipate feeding by modulating their thermal tolerance

Authors: Lazzari Claudio[1], Moura Alexandre[2], Lahondère Chloé[3], Vinauger Clement[3], Loshouarn Henri[2], Giraud Silvère[2] and Boualem Yasmina[2], [1]University of Tours Insect Biology Research Institute, United States, France, [2]University of Tours, France, [3]Virginia Polytechnic Institute and State University, United States

Abstract: Each time they feed on a warm-blooded vertebrate host, blood-sucking arthropods undergo thermal stress, due to the rapid entry of a relatively large amount of a hot fluid into their body. To cope with this stress, two mechanisms have been uncovered in recent years: physiological thermoregulation and thermotolerance based on molecular protective measures. Until now, both strategies have been documented as triggered by the ingestion of warm blood. Yet, physiological thermotolerance can be anticipatory and endogenously controlled. Desert ants, for instance, synthesise heat-shock proteins not only as a response to heat but also at low temperature, anticipating midday excursion. We investigated whether or not Aedes aegypti mosquitoes, who do not thermoregulate, modulate their thermal tolerance along the day. We analysed the daily modulation of spontaneous activity, aggressiveness, maximal critical temperature, lethal time at critical temperature and HSP expression. Our results indicate that mosquitoes anticipate probable feeding opportunities by heightening their thermal tolerance.

Daily and circadian rhythms in disease vector mosquitoes

Authors: Lazzari Claudio[2], Eilerts Diane[4], Vinauger Clément[3], Pickerel Gretchen[3], Chandrasegaran Karthikeyan[3], Leis Mendias Miguel[1], VanderGiessen Morgen[3] and Evans Olivia[3], [1]University of Tours Insect Biology Research Institute, France, [2]University of Tours Insect Biology Research Institute, United States, France, [3]Virginia Tech, United States, [4]Virginia Tech, United States

Abstract: Aedes aegypti mosquitoes are the primary vector of Zika, dengue, and yellow fever viruses, for which treatment options are limited and infection can be deadly. In light of rising insecticide resistance among mosquito populations, novel approaches based on an improved understanding of mosquito biology are needed to reduce disease transmission. Mosquito host-seeking behavior largely depends on olfactory host detection, identification, and localization. Similar to other biological and physiological processes such as mosquito locomotor activity and gene expression, host-seeking and blood-feeding behaviors are modulated by biological clocks. However, there remains little known regarding the rhythmic modulation of fine-scale molecular olfactory processes. Here, we combined behavioral assays with biochemical and molecular approaches to address this knowledge gap. Electrophysiological and behavioral responses to host and plant odors were assessed throughout the day in Ae. aegypti females, revealing odorant specific patterns in sensitivity and responses. Because mosquito-host interactions are not limited to host-seeking, we next analyzed the interaction between time-of-day and blood-feeding. At this stage, female mosquitoes must cope with multiple stressors in order to obtain nutrients necessary for reproduction. They are subjected to extreme thermal stress and, upon digestion of the blood, they must cope with high levels of oxidative stress. We analyzed daily variations in the transcriptome of female Ae. aegypti heads and investigated rhythms in the metabolism of blood digestion using state-of-the-art respirometry methods. These are the first measurements reported on carbon dioxide release from individual Ae. aegypti female mosquitoes and provide new insights regarding mosquito respiratory and metabolic physiology. This work identifies mechanisms that represent novel potential targets for mosquito control.

Host-Pathogen Interplay Determines the Outcome of Bacterial Infection in Drosophila

Authors: Lazzaro Brian, Cornell University, United States

Abstract: Bacterial infection in Drosophila can result in two dramatically different outcomes, even for genetically identical, co-housed fruit flies given experimentally identical infections. Some individual flies die with high bacterial burden while others control the pathogen into a fairly asymptomatic chronic infection. The probability of death from infection can then be considered as the probability of entering into either the lethal state or the chronic state. We have identified multiple, diverse bacteria that are capable of establishing both classes of infection, and have demonstrated that the probability of entry into the lethal versus the chronic state is a combined function of bacterial and host physiology. While classical virulence and immunity are crucial determinants of infection outcome, the probability of state entry is also influenced by physiological factors that are outside these stereotypical determinants. Our findings suggest a mechanistic basis for individual variation in susceptibility to infection and for environmental effects on resistance.

The CYP9A cluster in Spodoptera frugiperda, implications in adaptation and resistance

Authors: Le Goff Gaelle[2], Fricaux Thierry[1] and Saladini di Rovetino Marlen[3], [1]INRAE, [2]INRAE, France, [3]UCA

Abstract: Spodoptera frugiperda is a polyphagous lepidopteran, a major crop pest. Although it originates from the American continent, in recent years it has gradually invaded the world. Moreover, it is ranked in the top 15 of the most resistant arthropods. It has therefore developed an efficient detoxification system to eliminate xenobiotics (plant secondary metabolites and insecticides) that it encounters in its environment. Cytochromes P450 (CYP) play a major role in these detoxification mechanisms. The S. frugiperda genome encodes 14 genes of the CYP9A family, twelve of which are organised in a cluster and have evolved rapidly in lepidopterans. These genes are inducible when the insect is exposed to xenobiotics and are found over-expressed in resistant populations. We set out to use the Sf9 cell model to investigate the role of these genes in adaptation and resistance using the CRISPR/Cas9 technique.

Characterization of the tick Ixodes ricinus nicotinic acetylcholine receptors expressed in the synganglion using membranes microtransplantation

Authors: LE MAUFF Anaïs[4], THANY Steeve[5], Cartereau Alison[1], Neveu Cédric[2], Charvet Claude[2], Rispe Claude[3], TAILLEBOIS Emiliane[4], Chouikh Hamza[4] and Plantard Olivier[3], [1]LBLGC, university d'Orléans (France), France, [2]UMR Infectiologie et Santé Publique, Centre de recherche Val de Loire, France, [3]Unité BioEpAR INRA ONIRIS 1300, Oniris, France, [4]Université d'Orléans, Laboratoire LBLGC USC INRA 1328, Orléans, France, [5]University of Orleans, France

Abstract: Ticks are known as harmful parasites and vectors of many pathogenic viruses, bacteria, and protozoa of medical and veterinary importance. Studies demonstrated that Ixodes ricinus nicotinic acetylcholine receptors (nAChRs) are particularly expressed in the central nervous system which is a condensed mass of fused nerve fibers known as the synganglion. But, studies are difficult to perform in I. ricinus nAChR subtypes because genes coding for nAChR subunits are not characterized. In the present study, we use the microtransplantation of purified membranes from neuronal tissues in Xenopus oocyte. Acetylcholine and nicotine-evoked currents were characterized in oocytes. We found that acetylcholine and nicotine currents are inhibited by alpha-bungarotoxin and sensitive to the neonicotinoid insecticides clothianidin, imidacloprid, acetamiprid and thiamethoxam. We also tested the effects of the nicotinic acetylcholine positive allosteric modulator, PNU-120596. The results obtained indicate that PNU-120596 strongly increase acetylcholine and nicotine-evoked currents. We conclude that microtransplantation of purified membrane from the tick synganglion could be a valuable tool for the development and screening of new acaricides targeting the tick I. ricinus nicotinic acetylcholine receptors.

Insecticide treated cattle as a One Health approach to tackling trypanosomiasis in Tanzania

Authors: Lea Rachel[2], Allan Fiona[3], Mramba Furaha[4], Mbata Geofrey[4], Auty Harriet[1], Lord Jennifer[2], Morrison Liam[3], Stanton Michelle[2], Manangwa Oliva[4], Buyugu Paul[4], Richards Shauna[1] and Torr Steve[2], [1]Epidemiology Research Unit, SRUC, United Kingdom, [2]Liverpool School of Tropical Medicine, United Kingdom, [3]Roslin Institute, University of Edinburgh, United Kingdom, [4]Vector and Vector-Borne Diseases Research Institute, Tanzania

Abstract: Tsetse transmit trypanosomes which cause human and animal African trypanosomiasis. The WHO aims to eliminate sleeping sickness as a public health problem by 2020, however the existence of Rhodesian HAT foci in conservation areas of east and southern Africa threaten this aim. In three wildlife-livestock interface areas of northern Tanzania, we are quantifying the (i) distribution and abundance of tsetse; (ii) proportion of tsetse and cattle testing PCR-positive for trypanosome DNA; and (iii) tsetse and trypanosomiasis control measures implemented by livestock farmers. The study areas in Mara, Simanjiro and Tanga regions provide a contrast in livestock production systems with mixed crop-livestock farming, traditional pastoralism and zero-grazing herds predominating respectively.

We have found that the abundance of tsetse declines by >99% from inside conservation areas to >6km into farming areas. The decline was correlated, in part, with farming-related degradation of natural habitat but also likely due to the presence of insecticide treated cattle. Questionnaire surveys of Serengeti livestock farmers suggested that 68% of herds were treated regularly with pyrethroids, and chemical analysis of cattle hair showed that ~27% of herds had detectable levels of pyrethroids. Surveys of cattle showed that Trypanosoma brucei rhodesiense was present in wild tsetse (0.03% (CI 0.004 – 0.12%)) caught inside the conservation area but not in cattle. Trypanosoma congolense was present in 5.3% (CI 4.8 – 5.9%) of tsetse and 16.7% (CI 14.1 – 19.5%) of cattle in the Serengeti study area. Data from around the Tarangire National Park is currently being analysed with preliminary data indicating livestock keepers are also using insecticides regularly.

Our results suggest that farmer-led interventions could reduce the risk of T. b. rhodesiense amplification in cattle at the wildlife-livestock interface, but that AAT will persist even in the presence of low numbers of tsetse. Our work also confirms that the difficulty of reducing AAT is related to teneral tsetse being more susceptible to T. congolense and T. vivax than T. brucei. Widespread treatment of cattle with pyrethroids is being promoted through government subsidy for pyrethroids and a national programme to rehabilitate dip tanks. Further improvements to control tsetse and AAT might be achieved through better provision of information to livestock keepers to improve their use of pyrethroids in combination with trypanocides. Our findings in Tanzania could provide a model for other countries aiming to promote One Health solutions to African trypanosomiases.

Outreach and education in the response to spotted lanternfly outbreaks in the United States

Authors: Leach Heather, Department of Entomology, Penn State University, United States

Abstract: Since it's detection in the U.S. in 2014, the invasive pest spotted lanternfly (SLF) has raised alarm among agricultural commodities, transport businesses, and homeowners alike. In part, this can be attributed to the large host range of SLF, feeding on over 70 different plant species, causing it to become a landscape-level pest. SLF is also a state-regulated pest under quarantine in several states within the Northeastern U.S. High populations of SLF combined with their high mobility and broad host range cause concern among business owners, nurseries, and fruit growers trying to remain SLF-free. High levels of feeding by SLF in both backyards and vineyards cause the build-up of honeydew and subsequent sooty mold, accumulating on patio furniture, cars, backyard plants, vines, and the fruit itself. In vineyards, SLF damage has led to yield losses and vine death, and growers struggle to maintain control with frequent reinvasion from the surrounding landscape. While research on SLF to better understand its biology and behavior is ongoing, public and industry outcry and demand for management strategies is increasing. The invasion response and extension efforts, SLF reported damage on key agronomic industries, and current strategies for addressing the needs of affected stakeholders will be highlighted.

Intrareceptor and intraneuronal inhibition in mosquito olfaction

Authors: Leal Walter, Department of Molecular and Cellular Biology, University of California-Davis, United States

Abstract: The integration of chemical signals at the peripheral sensory system (antennae, maxillary palps, and proboscis) is one of the least understood mechanisms of insect olfaction. We found odorants receptors in the southern house mosquito Culex quinquefasciatus and the yellow fever mosquito Aedes aeygpti that, when expressed in Xenopus oocytes, responded to some compounds with regular inward currents, whereas other compounds (inhibitors) elicited outward currents. Additional support for these regular and reverse currents was obtained with electroantennogram (EAG) and single sensillum recording (SSR) from mosquitoes as well as from transgenic vinegar fly, Drosophila melanogaster, carrying an "inhibitory receptor" whose expression was driven by DmelOrco promoter. Both in the Xenopus oocyte recording system and in vivo, inhibitory compounds attenuated responses elicited by excitatory compounds (odorants) in a dose-dependent manner. These intrareceptor interactions were also manifested in mosquito behavior as the response to a repellent odorant was attenuated by an inhibitory compound that acts on the same receptor as the repellent. SSR from OrcoGAL4/UAS-CquiOR32 flies provided evidence for possible intraneuronal lateral interactions. Hyperpolarization caused by interactions of inhibitory compounds with CquiOR32 attenuated responses of colocalized native receptors from the vinegar fly to their cognate ligands. In this presentation, we will address the following questions (Leal, in press): Do inhibitors bind to orthosteric or allosteric binding sites? Do they shift the equilibrium between the active and inactive states of a receptor thus reducing the probability of firing? Or do they form a different channel (e.g., Cl- channel) than the cation channels opened by agonists thus causing hyperpolarization?

Research data included in this presentation were supported by the National Institute of Allergy and Infectious Disease of the National Institutes of Health under award number R01AI095514.

Investigating the role of wheat variety on host plant selection and fitness of aphid BYDV vectors to improve the integrated pest management in cereal crops

Authors: Leandro Maria Elisa[1], Roberts Joe[1], Pope Tom[1] and Dickin Ed[1], [1]Harper Adams University, United Kingdom

Abstract: Transmission of barley yellow dwarf virus (BYDV) is economically the most damaging outcome from aphid infestations in autumn sown cereal crops (Walls et al., 2019). The most important vectors of BYDV in the UK are the bird cherry-oat aphid Rhopalosiphum padi (Linnaeus) and the grain aphid Sitobion avenae (Fabricius) (Hemiptera: Aphididae) (Dewar and Foster, 2017). Among cultural management approaches, trap crops are considered a useful strategy for insect pest control. Trap crops are plants that are grown alongside the main crop to attract insects or other pests that would otherwise cause economically important crop damage (Hokkanen, 1991). Furthermore, by providing a habitat for natural enemies and helping to conserve the soil, these crops can support the broader ecosystem (Cavanagh et al., 2009; Holden et al., 2012). This project tests whether the use of wheat varieties grown around the perimeter of the field that are more attractive to aphid BYDV vectors are effective as trap crops in reducing the numbers of aphids entering the main crop. In order to select suitable trap crops, we must understand host selection behaviour and fitness of aphid vectors. We are currently investigating the landing behaviour and fitness (development and fecundity) of BYDV vectors on different winter wheat varieties, including old genotypes associated with aphid outbreaks in the past, such as Maris Huntsman. With these results, we aim to identify varieties which are more attractive to aphids with the potential to be used as trap crops and investigate the olfactory basis for host selection in order to develop a better monitoring tool for BYDV vectors.

Why I Joined the Twitteratii – Tweeting and blogging for entomology

Authors: Leather Simon, Harper Adams University, United Kingdom

Abstract: Come and listen to me describe my journey from social media sceptic to evangelist Tweeter. I was always interested in science communication but realised that the 'traditional' ways of reaching the public and other scientists was, although comfortable, not very efficient. Being on Twitter and starting a Blog, has not only expanded my reach far beyond the scientific community, but has at the same time increased my scientific collaborations and taken my research into new and exciting directions. Come and be converted to the wonderful world of EntoTwitter????

Biological Crop Protection: A New ‘Slow Down-Speed Up’ Strategy for Aphid Management

Authors: Leather Simon[1], Pope Tom[1], Roberts Joe[1], Bruce Toby[2], Ali Jamin[2], Chandler Dave[3], Prince Gill[3], Teakle Graham[3] and D. J. Kirk William[2], [1]Harper Adams University, United Kingdom, [2]Keele University, United Kingdom, [3]University of Warwick, United Kingdom

Abstract: Aphids are important insect pests of a wide range of crop plants, causing over $1billion of crop losses annually. For field crops, the ‘standard’ method of managing aphids has been to apply synthetic insecticides. While this approach has been an effective control method for many years, overreliance on insecticides has led to the evolution of insecticide resistance in several key aphid pests. Compounding resistance issues are environmental concerns regarding insecticide use, leading to legislation changes and many products being withdrawn from sale. This has left farmers with few effective options for controlling the aphid pests that have now become a major threat to global crop production. A sustainable aphid management strategy that can help to protect harvests from pests is urgently needed to address this threat.

The project aims to develop the tools and knowledge needed for an effective IPM system to manage aphid pests of field crops using a model system comprising of Brassica spp. plants, the peach potato aphid (Myzus persicae) and parasitoid wasps such as Diaeretiella rapae. This model system will be used to test the hypothesis that plants with partial resistance ‘slow down’ aphid development and increase their susceptibility to biological control agents, while pest control can be ‘sped up’ using cis-jasmone to induce plant defence priming to attract and retain parasitoid wasps within a Brassica crop. Results so far indicate that several Brassica spp. genotypes from the Vegetable Genetic Improvement Network (VeGIN) exhibit partial aphid resistance, characterised by reduced intrinsic rate of increase (rm), fecundity, and mean relative growth rate (MRGR). Experiments will now focus on enhancing biocontrol and integrating it with this partial resistance to increase efficacy of pest management.

To achieve more sustainable crop protection methods that are less prone to resistance, farmers should not over-rely on any one intervention. Diversification of crop protection can be achieved through integrated pest management (IPM), which promotes the use of an appropriate combination of environmentally sustainable methods of pest control. Unfortunately, as farmers have been so reliant on synthetic insecticides as their principal form of pest control, there is currently no effective IPM system in place for most aphid pests in field crops but our ongoing research aims to develop an IPM system.

Integrating GWAS and transcriptomics to identify the molecular underpinnings of thermal stress responses in Drosophila melanogaster

Authors: Lecheta Melise[3], Powers Beck[5], Lockwood Brent[4], Awde David[3], Axen Heather[2], Waters James[1], Bora Katie[5], Unfried Laura[3], Whitlock Miles[3], Jacobs Nicholas[3], Teets Nicholas[3], Cahan Sara[4] and Frietze Seth[4], [1]Providence College, United States, [2]Salve Regina College, United States, [3]University of Kentucky, United States, [4]University of Vermont, United States

Abstract: Temperature is one of the primary abiotic factors affecting performance, survival, fitness, and consequently the geographic distribution of species. Knowledge of the critical thermal limits of an organism provides important insights about local adaptation and is essential for predicting changes in geographic distribution in response to climate change. Response to thermal stress involves dynamic shifts in gene expression, but previous work has not characterized the extent to which genetic variation in whole-organism thermal tolerance is associated with the transcriptomic response to temperature stress. Here, we use a combination of Genome Wide Association mapping (GWAS) and transcriptomic profiling to investigate whether molecular physiological phenomena, such as gene expression, underlie the mechanisms by which genetic variation causes variable responses to temperature. We measured the critical thermal maximum (CTmax) and critical thermal minimum (CTmin) of 100 lines of the Drosophila Genetic Reference Panel (DGRP) to estimate the thermal breadth of each line. Phenotypically, we observed greater variation in the lower thermal limit, with CTmin ranging from 1.8 to 8.5 °C, while CTmax ranged from 38.75 to 40.65 °C. GWAS identified candidate thermal limit loci in over 300 and 55 genes that were significantly associated with upper and lower thermal limits, respectively. RNA-seq analyses of transcriptional responses to acute heat or cold shock revealed that many of these candidate thermal limit genes exhibit dynamic changes in expression in response to acute thermal stress. Notably, these genes belong to developmental, metabolic, and neuronal pathways. Overall, our results suggest that transcriptional responses to acute thermal stress are a key aspect of the physiological basis for genetic variation in thermal tolerance in Drosophila.

Modulation of defense response in rice by the bacterial microbiota of the Spodoptera frugiperda oral secretions

Authors: Leclerc Laëtitia[1], Gaudriault Sophie[2], Negre Nicolas[2], Champion Antony[3], Duval Pénélope[2], Blanchot Amélie[2], Nguyen Trang Hieu[3], Petitot Anne-Sophie[3], Orjuela Julie[3] and Ogier Jean-Claude[2], [1]DGIMI INRAE - DIADE IRD - Univ Montpellier, France, [2]DGIMI, Univ Montpellier, INRAE, Montpellier, France, [3]DIADE, Univ Montpellier, IRD, Montpellier, France

Abstract: Spodoptera frugiperda is an insect pest native to America, which has recently spread throughout the world. Its polyphagous caterpillar attacks a wide variety of host plants, including some of great economic interest such as corn (Zea mays) and rice (Oryza sativa). These plants recognize herbivorous insects thanks to Herbivore Associated Molecular Patterns, present in the insect oral secretions (OS). Our objective is to study the activation of the rice defense response following herbivory and evaluate the role of the insect bacterial microbiota in this process. To this end, we used Spodoptera frugiperda larvae fed with antibiotic-treated artificial diet and showed that the treated OS (OS-) is cleared of cultivable microbiota compared to not treated larvae (OS+). We then mimicked a caterpillar attack on rice leaves using a mechanical wounding followed by deposition of OS+ or OS- and analyzed the modulation of rice defense responses by global transcriptomic analysis. We identified a set of genes involved in defense responses whose expression is specifically induced by the OS+ in comparison with the OS- treatment. These rice genes are interesting candidates for further analysis of the dialog between the OS microbiota and the plant.

Regulating mechanisms underlying sex-dimorphic circadian expression of mate-finding locomotion of the German cockroach

Authors: Lee How-Jing, Department of Entomology, National Taiwan University, Taiwan

Abstract: The German cockroach is a nocturnal species that displays active locomotion at night. The male adults show circadian rhythm in mate-finding locomotion, but the females do not express the matching circadian rhythm. Since the females possess cyclic reproduction, the mating window is limited within 3-4 days per reproductive cycle. The cost of unsuccessful mating is so high that forces the sexual mature female to actively search for mate regardless day or night during mating window. This sexual dimorphic phenomenon is regulated by a masking factor on the female reproduction. The endogenous circadian clock is running in female adults even though its expressing rhythm is masked by the developing ovaries. The developing ovaries can exert its masking effect through hormonal pathway. The hormone(s) involved in this regulation is not yet demonstrated. But, dopamine has been proved to be the neurotransmitter in the regulation of locomotion and reproduction. In the synthesized cascade of dopamine, tyrosine hydroxylase and dopa decarboxylase are the essential enzymes, and circadian rhythmicity of their mRNA expression levels are consistent with locomotor activity patterns of male and female adults. The mRNA expression level of tyrosine hydroxylase and dopa decarboxylase in male adults displayed circadian rhythm, but none of them displayed circadian rhythm in virgin female adults. Although the effect of extra dopamine and antagonist (cis(Z)-flupenthixol) on locomotor activities of male and female adults only last for one day, the injection does not alter the expression of circadian rhythm in both male and female adults regardless the changes in total amount of locomotion. These results suggest that dopamine does participate in downstream regulation of locomotion without affecting the circadian clock. The dopamine does not serve as a masking factor on the locomotor circadian rhythm.

Diversity pattern of moths in agricultural ecosystem with the effect of landscape composition and configuration

Authors: Lee Jae-Young[1] and Choi Sei-Woong[1], [1]Mokpo National University, South Korea

Abstract: This study is to investigate the response of the moth community according to the composition and configuration of the agricultural landscape in the southwestern part of Korea. We predicted that the diversity would increase as the landscape composition and configuration were more complicated.We also predicted that the composition of moth community based on moth's size would differ depending on the habitat type since species with high mobility respond better to environmental changes, whereas species with low mobility may or may not respond slowly. We found that the habitat type with more complex in composition and configuration possess the higher species richness and abundance. We found that there was a difference between moth groups and forest type: middle and large species than small species were more common in the complex landscape. Habitat size and number of patches have been shown to affect moth abundance, which is interpreted as one of major factors for maintaining species abundance. In addition, when considering mobility, small species group in less-complex landscape was predicted to be more vulnerable to population change and extinction risk because the small moths are slower to respond to environmental changes than relatively larger species.

Characterization of entomopathogenic fungal metabolites with high insecticidal activity against the green peach aphid, Myzus persicae

Authors: Lee Jin Yong[1], Woo Rami[1], Kim Hyunsoo[1] and Woo SooDong[1], [1]Chungbuk National University, Republic of Korea, South Korea

Abstract: It is known that entomopathogenic fungi not only infect and directly kill insects, but also inhibit the physiological function of insects through various secondary metabolites during the proliferation process. In this study, the insecticidal metabolites were investigated from the culture medium of Metarhizium anisopliae 15R strain, which has high insecticidal activity against the green peach aphid, Myzus persicae. The virulence of the culture medium produced in various culture media was compared, and insecticidal substances were elucidated by analyzing the properties and evaluating the stability of the produced insecticidal metabolites. As a result, specific substances showing high virulence were identified from the culture medium, and these results are expected to provide basic data to understand the insecticidal mechanism by metabolites, as well as help in the development of biochemical insecticides using metabolites.

Evaluation of the stability of recombinant baculovirus according to the transposition location of the target gene in the viral genome

Authors: Lee Jong Ho[1], Kim Hyun Soo[1], Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: The baculovirus expression system (BES) is widely used for the production of useful proteins through the generation of recombinant viruses. Recombinant viruses are generated using a method of homologous recombination or transposition between a target gene and viral DNA. In particular, a bacmid is conveniently used in BES because it can easily produce a recombinant virus by transposition of a target gene in Escherichia coli, but the low stability of the recombinant virus by this method is pointed out as a problem. In this study, the stability of the recombinant virus according to various transposition locations of the target gene in bacmid was evaluated, and the transposition site of the target gene was determined to produce a recombinant virus with increased stability.

Evaluation of insecticidal and antimicrobial activity of entomopathogenic fungal metabolites against the green peach aphid, Myzus persicae

Authors: Lee Jong Ho[1], Woo Ra Mi[1], Kim Hyun Soo[1] and Woo Soo Dong[1], [1]Chungbuk National University, Republic of Korea

Abstract: Entomopathogenic fungi are widely used for controlling various pests as representative biological control agents, and their metabolites have also reported various biological activities such as plant growth promotion, antioxidant activity and antibacterial activity. This study was conducted to

evaluate the possibility of simultaneous control of pests and plant diseases using fungal metabolites. The insecticidal activity and antimicrobial activity against plant pathogens were evaluated for metabolites of entomopathogenic fungi with high insecticidal activity against the green peach aphid, Myzus persicae. As a result, the metabolites of these fungal isolates showed antibacterial and antifungal activity against various plant pathogens such as Botrytis cinerea and Colletotrichum acutatum as well as insecticidal activity against the green peach aphid. The possibility of simultaneous control of pests and plant diseases using fungal metabolites was confirmed.

Effect of 385 nm wavelength LED light on Nesidiocoris tenuis (Reuter) (Hemiptera: Miridae) and Bemisia tabaci (Gennadius) (Hemiptera: Aleyrodidae)

Authors: Lee Joon Ho[2], Park Young-gyun[1], [2]Seoul National University, South Korea, [1]Entomology program, Department of Agricultural Biotechnology, Seoul National University, 1, Gwanakro, Gwanakgu, Seoul 08826, Republic of Korea, South Korea

Abstract: Nesidiocoris tenuis is a competent biological control agent for controlling Bemisia tabaci, which is a major pest of greenhouse crops. Successful establishment of predators in the target area in greenhouses is essential for effective biological control. In this study LED light was tested for enhancing the establishment rate of N. tenuis and successful control of B. tabaci in the greenhouse. The 385 nm wavelength, that showed high attractiveness to N. tenuis in the Y-tube test, was applied. The 385 nm wavelength LED light positively affected populations of N. tenuis and B. tabaci, and combination of N. tenuis and 385 nm wavelength LED light was successful for suppressing the B. tabaci population. Life history characteristics of N. tenuis and B. tabaci under the 385 nm wavelength LED light are currently being investigated and will be presented.

Models for predicting immigration and emigration of Metcalfa pruinosa (Hemiptera: Flatidae) in crop fields

Authors: Lee Joon Ho[1], Kim Min-Jung[1], [1]Seoul National University, South Korea

Abstract: Since the polyphagous hemipteran insect, Metcalfa pruinosa (Say), was introduced in Korea in 2009, it has caused serious damage to various herbaceous corps and fruit trees. M. pruinosa hibernates under barks of trees as eggs, and hatched nymphs persistently dispersed to surrounding vegetation from their overwintering habitats. In this study, dispersal of hatched nymphs of M. pruinosa from trees and their immigration into crop fields were monitored for two years. Hatching and dispersal models of first instar nymphs were developed and validated, and their immigration pattern was also modeled. The infestation risk of M. purinosa nymphs in herbaceous crops fields was gradually decreased as time goes by. The optimal management time in orchards was estimated as 423 DD to 474 DD (base temperature, 10.1 ?C) through simulation of population size on trees, with egg hatching model and dispersal model of first instar nymphs. The management time of M. pruinosa in herbaceous crop fields were also suggested according to different growing seasons of crop plants. In addition, models of adult occurrence and emigration were developed.

Relationship of population genetic structure of Bemisia tabaci MED (Hemiptera: Aleyrodidae) with its fitness and insecticide resistance in Korea

Authors: Lee Joon Ho[1], Park Yujeong[1], [1]Seoul National University, South Korea

Abstract: The sweet potato whitefly, Bemisia tabaci (Gennadius) (Hemiptera: Aleyrodidae) is a major pest that causes serious economic damage worldwide. In Korea, B. tabaci MED (Mediterranean) was first detected in 2004. Our previous study showed that most of B. tabaci MED populations converged into one genetic cluster during one year even in the same tomato greenhouses. To explore the factors responsible for this phenomenon, study was conducted to compared the fitness of the two different genetic cluster of B. tabci MED, and to reveal the three type of major insecticide resistance (organophosphates, pyrethroid, and neonicotinodids) among B. tabci MED populations. Our result indicated that the rapidly converged phenomenon of genetic cluster in B. tabaci MED populations appeared to be related with their fitness parameters and insecticide resistance revel.

Kind of Blue: the gene makes lepidopteran larval integuments blue

Authors: Lee Jung[1] and Shimada Toru[1], [1]Gakuhusin University, Japan

Abstract: The larvae of lepidopteran insects show bluish-green body colours in many species, as indicated by their Japanese description as ‘Aomushi,’ which literally means blue caterpillar. A mixture of yellow pigment carotenoids and blue pigment bilins in varying proportions forms the green colours of Aomushi.

The eri silkmoth (Samia ricini) have strains with the different body colour: blue and white strains. We determined the whole genome sequences of the white strain to locate the responsible gene for the difference in larval body colour (Lee et al., 2021). We found that a point mutation in a gene located on chromosome 8 causes the loss-of-function of the protein, resulting in the absence of Biliverdin IXγ, a member of the bilins, in epidermal cells of white strain. Therefore, we designated this gene as BVT, Biliverdin transporter. Interestingly, functional analysis of BVT orthologues in Chinese oak moth (Antheraea pernyi) and Asian swallowtail butterfly (Papilio xuthus) revealed that BVT is responsible for the transport of bilins to the epidermal cells in both A. pernyi and P. xuthus. Currently, we quantitatively assess the ability of BVT using Xenopus laevis oocytes.

Divergence history and high-altitude adaptations of Alpine geometrid moths (Lepidoptera)

Authors: Lee Kyung Min[3], Murillo-Ramos Leidys[3], Huemer Peter[6], Hausmann Axel[5], Staude Hermann S.[1], Mayr Toni[2] and Sihvonen Pasi[4], [1]Caterpillar Rearing Group, LepSoc Africa, South Africa, [2]Egelseestraße, Feldkirch, Austria, [3]Finnish Museum of Natural History, University of Helsinki, Finland, [4]Finnish Museum of Natural History, Finland, [5]SNSB, Bavarian State Collection of Zoology, Munich, Germany, [6]Tiroler Landesmuseen Betriebsgesellschaft m.b.H., Tirol, Austria

Abstract: Many unique high-altitude mountain habitats have been declining due to climate change, threatening their flora and fauna, which have adapted well to these ecosystems. We study how high-altitude adaptations such as wing length reduction and daily activity have evolved in the European Alps using geometrid moths in the tribe Gnophini as the study group. These moths are an excellent insect group for studying such questions because of well-researched life histories and taxonomy, many with narrow ecological niches including restricted altitudinal ranges, and short life cycles. Using molecular data, we built a phylogenetic hypothesis for Gnophini moths to understand whether the various high-altitude habitats have been colonised by a single moth lineage and they share a common ancestor through adaptations, or whether there have been several colonisations by non-related lineages and the adaptations are a result of convergent evolution. Our results also provide a robust basis for classification of these moths and we demonstrate how phylogenies can be used to make more informed conservation prioritisation decisions.

Population Genetic Structure of Anoplophora glabripennis in South Korea: Invasive Populations in the Native Range?

Authors: Lee Seunghyun[2], Lee Seunghwan[2] and Lee Yerim[1], [1]none, South Korea, [2]Seoul National University, South Korea

Abstract: Native to China and the Korean Peninsula, the Asian longhorned beetle (ALB), Anoplophora glabripennis, has spread to North America and Europe. In both its native range and the territory it has invaded, ALB is responsible for the death or removal of millions of urban, roadside, and forest trees. Here, we present the population genetics of ALB in South Korea, using 801 bp of mitochondrial DNA and the most comprehensive sampling to date. ALB populations in South Korea are divided into three distinct geographical subgroups: the northeastern natural forest and the western and southern urban areas. Historical records suggest that the forest-dwelling subgroup is native, as does the moderate genetic diversity of this population. Meanwhile, the fact that ALB was first observed in the western and southern areas only recently, the extreme genetic bottleneck status of these populations, their distribution in large port cities and adjacent areas, and the difference in observed host plants used by the forest subgroup and the urban subgroups suggest that the urban populations are non-native recent invaders. Approximate Bayesian computation suggested that the western and southern subgroups most likely originated from northeastern and northwestern China, respectively. Therefore, our study demonstrates that ALB invasion has occurred even within the species' native territory. This finding alters our perception of biological invasion by providing a unique example of a species that has invaded its own native range.

Identification of a sex pheromone of Anomis privata (Lepidoptera: Noctuidae)

Authors: Lee Sujin[1] and Kim Junheon[1], [1]National Institute of Forest Science

Abstract: Anomis privata (Lepidoptera: Noctuidae), is one of the primary defoliator insects on Hibiscus spp. in Korea. The moths of this family are difficult to detect without pheromone traps due to being active at night. To develop a suitable tool for monitoring this pest in Hibiscus syriacus, we investigated the attractiveness of sex pheromone to A. privata adults. We performed gas chromatography-mass spectrometry (GC-MS) analysis of female abdominal tip extracts and identified 7-methylheptadecane (7-MeC17) as a major component of sex pheromone candidate. 7-MeC17 was chemically synthesized and were tested for field attractancy. Male A. privata were captured in 7-MeC17 baited traps from April to August in Seoul and Suwon, Korea in 2021. In field tests, traps baited with 7-MeC17 attracted significantly more males than those with hexane as control. Based on these results, it was revealed that 7-MeC17 is one of pheromone components of A. privata. And it suggests that 7-MeC17 could be useful in a monitoring strategy, which can determine an accurate assessment of the threshold for insecticide applications of target insects.

Volatile disease markers derived from American foulbrood as putative hygienic cues in Apis mellfiera

Authors: Lee Sujin[1], Han Giyoun[1], Noh Gwangrae[1], Wook Kwon Hyung[1], Lee Myeong-Lyeol[1], Lim Sooho[1], [1]Department of Life Sciences & Convergence Research Center for Insect Vectors, Incheon National University, Republic of Korea

Abstract: The honey bee, which lives in a crowded environment of a social hive, is vulnerable to disease infection and spread. Hygienic behavioral responses are especially important for honey bee resistance to American foulbrood (AFB), a fatal bacterial disease of honey bee brood among honey bees worldwide. Successful resistance relies on early detection and removal of infected larvae before they serve as a source for disease propagation within the colony. Here we investigated the volatile disease markers (VDMs) of AFB as well as differences in olfactory responses in hygienic-aged bees and foragers. Upon the inoculation of AFB pathogen to honey bee larvae in lab condition, we identified propionic acid, valeric acid, and 2-nonanone as VDMs of AFB infection using GC/MS. Electrophysiological recordings demonstrated that middle-aged bees, the hygienic-aged bees, are more sensitive to these VDMs than foragers, indicating that these VDMs are efficient and significant for detecting sick honey bee larvae in bee hives. Our finding shows that these VDMs might be exploited by adult workers seeking to removed diseased larvae as putative hygienic cues. This study is considerable value both in understanding VDMs associated with honey bee to study the molecular and neural correlates of given hygienic behaviour detecting these volatile chemicals by honey bees.

Transcriptome studies of the floodwater mosquito, Aedes vexans (Diptera: Culicidae) with potential as secondary vectors using Illumina HiSeq 4,000 sequencing

Authors: Lee Yong Seok, Soonchunhyang University, South Korea

Abstract: Aedes vexans is the inland floodwater mosquito widely distributed in every continent excepting Antarctica and South America. They are opportunistic feeders preferring blood meal of larger animals including cattle, horses, deer, and humans. Further, the mosquito species is a compatible vector of several diseases, including West Nile virus and dog heartworm. In this study, we performed transcriptome characterization of Ae. vexans using Illumina HiSeq 4,000 sequencing and assembly of sequenced reads using Trinity. A total of 55,813,852 raw read and 54,630,771 clean reads (97.88% of raw reads) were obtained after Illumina paired-end sequencing and pre-processing steps. After Trinity de novo assembly, TransDecoder and TGICL clustering, a total of 37,111 unigenes were obtained. Out of the total unigenes count, 28,733, 17,893, 14,626, and 17,055 showed homologous matches against the PANM, UniGene, SwissProt, and KOG databases. A total of 9,483 unigenes were assigned to Gene Ontology (GO) terms, and 3,741 unigenes were mapped to 483 KEGG pathways. The zinc finger (C2H2-type), reverse transcriptase, integrase (catalytic core), protein kinase, and RNA recognition motif domain among others showed as the top InterProScan domains. The obtained datasets serves as a basis for future studies towards understanding ecology, metabolism, and parasitism potential of Ae. vexans.

Characterization of Haemaphysalis longicornis microbiome collected from different regions of Korean Peninsula

Authors: Lee Yong Seok[9], Sang Min Kyu[8], Park Jie eun[8], Lee Hee Il[4], Song Dae Kwon[8], Hwang Hee Ju[5], Kim Hyun woo[4], Kim Tae Yun[4], Park So Young[7], Kang Se Won[6], Bharat Bhusan Patnaik[2], Cha Sung-Jae[3] and Han Yeon Soo[1], [1]Chonnam National University, [2]Fakir Mohan University, [3]Johns Hopkins Bloomberg School of Public Health, [4]Korea Disease Control and Prevention Agency, [5]Korea Native Animal Resources Utilization Convergence Research Institute , [6]Korea Research Institute of Bioscience and Biotechnology, [7]Nakdonggang National Institute of Biological Resources, [8]Soonchunhyang university, [9]Soonchunhyang University, South Korea

Abstract: Ticks are vectors that cause disease by transmiting bacteria, viruses, and protozoa to humans or animals. The Asian longhorned tick Haemaphysalis longicornis, a vector of medical and veterinary importance is widely distributed in Korean peninsula and can transmit various pathogens including Rickettsia spp., Borrelia spp., and severe fever with thrombocytopenia syndrome virus (SFTS virus). Despite the abundance and importance, studies on the microbiome of H. longicornis in Korea are limiting. Here we first report the microbiome diversity of H. longicornis in terms of region, stage and sex. H. longicornis used in this study were collected from 16 different regions of the Korea Centers for Disease Control and Prevention's Climate Change Media Monitoring Center from June to July 2019. The V3-V4 region of the 16S rRNA gene was amplified by PCR, and sequenced using the Illumina MiSeq platform. The microbial diversity analysis was performed using Qiime2. A total of 1,754,418 non-chimeric reads were obtained from a total of 46 samples, and an average of 126 operational taxonomic units (OTUs) and a total of 1,398 OTUs were identified. Our results were used for H. longicornis microbial community database construction for each region that enables to identify singularities in each region.

Leveraging genomics for integrated mosquito control in the Dutch Caribbean

Authors: Lee Yoosook[5], Weakley Allison[5], Cornel Anthony[5], Blosser Erik[5], Davelaar Gerald[4], Lanzaro Gregory[5], Bargielowski Irka[5], Hulshof Koen[2], Braks Marieta[1], Leslie Teresa[3] and Collier Travis[5], [1]Centre for Zoonoses and Environmental Microbiology, National Institute for Public Health and the Environment (RIVM), Netherlands, [2]Public Entity Saba. Public Health Department, Saba, Netherlands, [3]The Caribbean Public Health Agency, Sint Eustatius, Netherlands, [4]the Sint Maarten Ministry of Public Health, Netherlands, [5]University of California - Davis, United States

Abstract: The Aedes aegypti mosquito is a vector of several arthropod-borne viruses (arboviruses), such as dengue, Zika, yellow fever, and chikungunya. Dengue alone causes 96 million clinical cases annually and 50% of world population lives under the risk of contracting dengue viruses, including Saba Island residents (Bhatt et al., 2013). In order to reduce this arboviral disease transmission risk as much as possible, the Public Health Department of Saba started conducting genetic studies on Saba and surrounding Dutch Caribbean islands to collect data that could be used in application for both novel and conventional vector control strategies. The ultimate goal is to develop an effective control strategy to reduce and possibly eliminate Ae. aegypti populations from Saba island. To accomplish this long term goal, we first investigated on the population structure of Ae. aegypti within Saba and between Saba and its neighboring two islands. Recent advances in genetic and genomic tools in Ae. aegypti (Lee et al., 2019) allow estimating dispersal from genomic data, which will inform the design and use of genetic and other control systems. Genetic information from this study provides knowledge on several issues critical to the design of novel elimination strategies. For example the data inform: a) the overall population structure and whether population bottlenecks occur; b) trapping network requirements for population assessment and surveillance when the control or elimination intervention is being applied; and c) the extent of migration between locations within Saba and between Saba and the neighboring islands.

Survival Rate Variation According to Winter Temperature of Lantern Fly, Lycorma delicatula (Hemiptera: Fulgoridae) and Selection of Organic Farming Materials in South Korea

Authors: Lee Young Su[2], Ju Lee Hyun[1], Yoon Choi Jong[1], Lee Sang-Woo[1] and Soon Lee Young[2], [1]Environmental Agricultural Research Division, Gyeonggi Agricultural Research and Extension Services, South Korea, [2]Gyeonggi-do Agricultural Research and Extension Services, South Korea

Abstract: Lantern fly, Lycorma delicatula is the invasion insect pests introduced to South Korea in 2006. There are 41 species of insects known as host plants, and nymphs and adult suck the plant and emit nectar in the process, causing damage to grapes, a major fruit tree in Korea. In terms of predicting the occurrence of outdoor wintering populations, it is necessary to investigate the survival rate of populations exposed to low temperatures during wintering conditions under outdoor conditions. We have analyzed the survival rate and weather data of this wintering pest and share the findings from 2011 to 2019. This pest responds sensitively to Korean weather conditions, especially winter temperatures. In addition, as eco-friendly cultivation of crops is expanding, we will introduce organic farming materials that can effectively control this pest.

Plant breeding strategies to improve integrated pest management of the tomato russet mite

Authors: Legarrea Saioa[4], Dong Lin[3], Glas Joris[2] and van Houten Yvonne[1], [1]Koppert Biological Systems, [2]Rijk Zwaan Breeding B.V., [3]University of Amsterdam, [4]University of La Rioja, Spain

Abstract: Biological control of the tomato russet mite is still difficult on tomato. Two main factors play a significant role: 1) the small size of the mite allows it to seek refuge in between plant trichomes; and 2) the tomato leaf hairs make it a hostile environment for many natural predators, such as phytoseiid mites. As a strategy to improve the control of the tomato russet mite using predatory mites, we assessed biological control on a tomato mutant (hairless: LA3556) that shows a distorted trichome phenotype.

We first described the interaction between the herbivore and the hairless tomato accession. To our surprise, we found that a genotype with distorted constitutive defences (i.e. trichomes) deployed an increased resistance against the tomato russet mite. Secondly, we observed that the fecundity of predatory mites was higher on hairless (with a surplus of russet mite prey) than on the normal accession. Finally, population dynamics experiments showed that biological control of the russet mite was most effective on the hairless tomato genotype. Overall, we show that removing a resistance plant trait can promote biological control agents, and consequently achieve a better control of a challenging pest, such as the tomato russet mite.

Whole genome sequencing reveals conserved and specific features of endogenous polydnaviruses in ichneumonid wasps

Authors: Legeai Fabrice[2], Robin Stéphanie[1], Santos Bernardo[6], Volkoff Anne-Nathalie[5], Bretaudeau Anthony[4], Tagu Denis[3], Dikow Rebecca[8] and Brady Sean[7], [1]BIPAA Platform, INRAE, IGEPP, Le Rheu GenOuest Platform, INRIA/IRISA, Rennes, France, [2]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, 35653 Le Rheu, France INRIA, IRISA, Genscale, Campus Beaulieu, Rennes, France, [3]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, 35653 Le Rheu, France, [4]Institut National de la Recherche Agronomique, France, [5]Institut National de la Recherche Agronomique, France, [6]Muséum National d'Histoire Naturelle, United States, [7]National Museum of Natural History, United States, [8]Office of the Chief Information Officer, Smithsonian Institution, United States

Abstract: Polydnaviruses (PDVs) are mutualistic endogenous viruses associated with some lineages of parasitoid wasps that allow successful development of the wasps within their hosts. Bracoviruses are PDVs associated with braconid wasps whereas ichnoviruses are associated with ichneumonids. These viruses result from separate events of integration of an ancestral viruses into the wasp genome, but share some common features. Polydnaviruses are unusual viruses in that their relatively large genomes are divided into separate, circular DNA molecules (hence the name "poly-dna virus"). Furthermore, their genomes are fully incorporated into the wasp genomes and comprise two major elements: (1) virulence genes located on proviral segments that are packaged into the viral particle, and (2) genes involved in the production of the viral particles, which are found in the wasp genome but not encapsidated. Whereas the genomic organization of bracoviruses within the wasp genome is relatively well known, the architecture of endogenous ichnoviruses remained poorly understood. We sequenced the genome of multiple ichnovirus-carrying ichneumonid wasps. Assemblies with long scaffold size allowed mapping of the integrated ichnovirus sequences against the wasp genome. We found that proviral segments are widely dispersed across the wasp genome, with their position widely variable between the two wasp species. Conversely, the replication genes in both species were grouped in clusters harboring a conserved organization in terms of gene content and gene order. This distinction is consistent with the biological properties of these two viral elements: proviral segments need to be fine-tuned to the host physiology, while viral architecture genes should have largely conserved biological function. This genomic architecture, however, is entirely diverse from that found in bracoviruses, highlighting different evolutionary pathways for the domestication of mutualistic viruses in the two lineages.

Deciphering the genetic programs defining the sexual and parthenogenetic reproductive modes of the pea aphid

Authors: Legeai Fabrice[5], Le Trionnaire Gaël[9], Robin Stéphanie[1], TAGU Denis[7], Richard Gautier[6], Nicolas Jacques[4], Bourneuf Lucas[3], Hudaverdian Sylvie[9], Tanguy Sylvie[8] and Wucher Valentin[2], [1]BIPAA Platform, INRAE, IGEPP, Le Rheu GenOuest Platform, INRIA/IRISA, Rennes, France, [2]CRG, Barcelona, Spain, [3]Dyliss, INRIA/IRISA, Rennes, France, [4]Genscale, INRIA/IRISA, Rennes, France, [5]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, France; INRIA, IRISA, Genscale, Campus Beaulieu, Rennes, France, [6]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, France; Max Planck Institute of Immunobiology and Epigenetics, Freiburg, [7]IGEPP, INRAE, Le Rheu, France, [8]IGEPP, INRAE, Rennes, France, [9]INRAE, Agrocampus Ouest, University of Rennes, IGEPP, France

Abstract: In aphids (Hemiptera), there are several morphs of females, mainly sexual oviparous females and parthenogenetic viviparous females. Those morphs alternate in a season-dependent manner by phenotypic plasticity. This involves the capacity of embryos to sense external local environmental cues during their development with alternative routes providing a final phenotype adapted to those new cues. In our lab, we currently describe and analyse the gene expression regulation patterns during the establishment of the phenotypic plasticity of the reproductive mode in aphids due to the shortening of the photoperiod at autumn arrival. The development of sexual and asexual embryos that differ mainly by their production of haploid meiotic gametes or diploid non-recombinant gametes is thus compared. We developed an integrative genomics approach that aims at defining most of the functional DNA elements associated with the formation of alternative morphs. For this, we sequenced the long (containing mRNAs and lncRNAs) and small RNAs (focusing on miRNAs) of embryos at different stages of development from the pea aphid A. pisum individuals in the course of selecting the sexual or parthenogenetic reproductive mode. We described a new repertoire of 19387 mRNAs, 2720 lncRNAs and 276 miRNAs (with 786 new mRNAs, 1124 new lncRNA and 173 new miRNAs identified from this study). Then we analysed the differential expression of these different RNA types during the development of sexual or asexual embryos, as well as during key decision points for the entry in the sexual or parthenogenetic development of the embryos. We combined genomics, bioinformatics and mathematic modelling to construct gene networks describing and modelling the molecular processes associated with the phenotypic plasticity of the reproductive mode. We predicted their putative interactions and modelled their network functioning. We analysed more deeply some of the candidates to fill the gap between prediction, hypotheses and biological observations.

3-D wing structure determines aerodynamic efficiency in flapping fly wings

Authors: Lehmann Fritz[1], Wehmann Henja-Niniane[1] and Engels Thomas[2], [1]Department of Animal Physiology, University of Rostock, Germany, [2]LMD-CNRS, École Normale Supérieure and PSL, Paris, France

Abstract: The aerial performance of flying insects largely depends on how flapping wings interact with the surrounding air. It has been suggested that the wing's mechanical properties governed by three-dimensional camber and corrugation stiffen the wing against aerodynamic and inertial loading during flapping motion. However. there is an ongoing controversy on the benefit of wing corrugation and camber for vertical, weight-supporting force production. Some authors reported an improvement in performance owing to corrugation, while others argue that corrugation attenuates performance. To solve these opposing findings, we investigated the potential benefit of 3-D wing shape in three different-sized species of flies using models of microCT-scanned natural wings and wings, in which we numerically removed either camber, corrugation, or both properties. Aerodynamic forces and power requirements during flapping were derived from computational fluid dynamic modeling. Our data show that 3-D camber has no benefit for lift production and attenuates Rankine-Froude flight efficiency compared to a flat wing. There is no evidence for lift-enhancing trapped vortices in corrugation valleys of fly wings. As the size of flow structures depends on Reynolds number, we suggest that corrugation structures should be more coarse in small insects than in larger animals for pronounced wing-vortex interaction. Altogether, our research strongly supports the assumption that the wing's three-dimensional structure provides mechanical support against external forces rather than improving lift or saving energetic costs associated to active wing flapping.

The effects of microclimate variability on overwintering dynamics in the butterfly Pieris napi

Authors: Lehmann Philipp[2], Gotthard Karl[1], Süess Philip[3], Greiser Caroline[2] and von Schmalensee Loke[2], [1]Dept. of Zoology and Bolin Centre for Climate Research, Stockholm University, Sweden, [2]Stockholm University, Sweden, [3]Sweden

Abstract: Studies on overwintering dynamics generally use climate chambers and low temperatures to simulate winter conditions. However, diapause in the field occurs in varying microclimates, and fitness of overwintering insects is dependent on both conditions before winter, during winter and after winter.
We have delineated an area of around 1.5 km2 in a fenced field site characterized by a variation of open field, wetlands and open forests in southern Sweden, where we have established a dense network of 120+ near-ground climate loggers. In this area, we are now performing a range of experiments where we test effects of microclimate variability on overwintering dynamics in a butterfly with facultative pupal diapause, Pieris napi.

Many studies on thermal performance biology focus on single life-stages, often the one with the longest duration. Since life-stages can differ dramatically in thermal sensitivity, and coincide with seasonal variability in temperature, we tested thermal performance in both single life-stages as well as across the whole ontogeny. To our surprise, we found that thermal dependence was mostly additive and that conclusions drawn from experiments with single life-stages are surprisingly similar to those where the whole life-cycle is exposed.

There is a general appreciation of relatively warm temperatures being optimal for ontogenetic development in insects. At the same time, there is a general appreciation of relatively cold temperatures being optimal for diapause, for both for energetic and timing reasons. How, then, do these integrate into overall fitness for an individual insect that experiences both summer and winter thermal variability? Our data suggests large idiosyncratic effects of temperature on fitness that varies in a life-stage dependent manner. Sites that are optimal during summer are not likely to be optimal during winter.

Finally, while larvae can to some extent choose microhabitat and manipulate their thermal range, adult females have a much larger potential to control the microhabitat available for their offspring. Females flying early in the season lay eggs that will develop without diapause, while females flying late in the season lay eggs that will undergo diapause. Since we know that thermal optima differ for these two groups of offspring, for a large part of their life span, we ask if females optimize fitness by selecting different oviposition microhabitats during different parts of the season. Our preliminary data suggest that this is not the case, females choose warm sites regardless of time of year, and are more likely to make choices based on host plant quality than microhabitat quality.

Together the studies suggest that winter and summer fitness optima are poorly correlated, and that females show little appreciation for winter dynamics when making choices for their offspring.

Diapause in the pine processionary moth (Thaumetopoea pityocampa): ecological and applied significance

Authors: Lehmann Philipp[4], Battisti Andrea[1], Laparie Mathieu[3] and Rahman Salman Habibur[2], [1]DAFNAE, University of Padua, Italy, [2]Disaster Management Watch (DM WATCH), Bangladesh, [3]INRAE, URZF, Orléans, France, [4]Stockholm University, Sweden

Abstract: Several studies reporting incidence of pupal prolonged diapause across the species range were reviewed, indicating a U-shaped relationship between incidence of prolonged diapause and winter temperature, and a negative correlation between overall pupal survival and the proportion of diapausing individuals. There is evidence of at least 7-year long prolonged diapause in one alpine population, with important consequences on population dynamics and pest management.

Diapause termination mechanism in both univoltine (emerging in the same year) and prolonged diapausing (returning to diapause) individuals has been previously hypothesized based on the occurrence of a key period during the pupal stage. By using two measures of metabolic activity, such as body temperature and O2 consumption, the existence of a transient restoration of activity (termination) has been confirmed in both univoltine and prolonged diapausing pupae. The two methods clearly detected simultaneous diapause termination through increased metabolic rate in both types of pupae before any morphological or behavioural changes could be observed, but univoltine individuals were characterized by a continuous increase until emergence while prolonged diapause individuals later returned to previous activity levels. This finding is a starting point for the study of diapause development in PPM from an ecological point of view.

In addition to pupal diapause, there is evidence of a prepupal dormant stage implicated in synchronizing of emergences. Through a weekly sampling spanning a two-month procession period, prepupae were found to differentially regulate their development time in such a way that adult emergences were concentrated and synchronized in less than one month. Early-descending larvae don't pupate immediately whereas late-descending prepupae develop into pupae much faster. The finding of prepupal diapause and its significance in synchronization of emergence may improve phenological models and provide managers with a new tool to handle this pest.

Wireworm control with Metarhizium- what factors influence the success?

Authors: Lehmhus Joern[2] and Paluch Maximilian[1], [2]Julius-Kühn-Institute, Germany, [1]Julius-Kühn-Institute, Germany

Abstract: Among the main subterranean pests of potatos in Europe are the wireworms. With more than 15 different species often occurring in mixed populations in single fields, they pose a difficult problem for the grower. As in potato no chemical alternatives are abvailable in in many European countries, the interest is turning to entomopathogenic fungi. Metarhizium spp. strains can exhibit good efficacy in the lab, but the efficacy of Metarhizium formulations in the field is often not sufficient so far.
In the project „AgriMet“ new Metarhizium formulations, based on coated autoclaved millet grains and on a wettable powder, were developed for use in potato and subsequently tested with different wireworm species and under different environmental conditions in field and lab. Also the distribution of wireworms in-field and wireworm behaviour of different species is assessed. Results show that the use of entomopathogenic fungi and also of entomopathogenic nematodes is on the one hand very dependent on environmental conditions, but additionally also very much species dependent. This challenges the idea that a single antagonist may always be enough to control wireworms.

Sublethal Effects of Entomopathogenic Fungi, Beauveria bassiana, on Group-Reared Life Table of Delia antiqua

Authors: Lei Zhongren, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: We assessed effects of parental exposure to Beauveria bassiana on life history traits of subsequent generations of Delia antiqua (Meigen) on Group-Reared Life Table with a sublethal concentration (LC10) of B. bassiana (isolate XJWLMQ-32). The developmental time of progeny larvae and male longevity were shorter at fungal-treated group than at control group values. The male to female ratio and fecundity were reduced in fungal-treated group offspring flies. We calculated life table parameters for the progeny and found the intrinsic rate of increase (r), the finite rate of increase (?) and the net reproduction rate (R0) of fungal-treated group were significantly less than the progeny of untreated parents. These results demonstrate that B. bassiana has sublethal effects that reduce the reproductive success of onion maggot and these effects should be taken into account when evaluating its use in management programs for onion maggot.

Utilization of trap nest in the breeding environment of hole-nesting aculeates (Hymenoptera, Aculeata) in Finland

Authors: Leinonen Reima, Kainuu ELY-Centre, Finland

Abstract: The populations of hole-nesting stinging wasps and bees have been decreasing during the last years and many species have become very endangered. The main reason has been the drastic change in agricultural surroundings. The amount of suitable nesting holes has decreased strongly due to the fact that wooden building materials have been changed to stone or metal. At the same time various meadow and dry meadow vegetation types have been modified into monotonic hayfields. Consequently, the so called edge areas have also decreased dramatically. During the years 2001-2019 I studied the suitability of various materials as artificial nests for aculeate wasps and bees. I tested the suitability of different sized plastic straws, reed, cow parsley, pieces of logs and laths, with drilled holes of differing diameter. Based on these results I tested an artificial combination nest with natural straws and a wooden cubic with drilled holes of differing sizes. In total, 92 test objects and 362 artificial nests resulted 7516 individuals representing 121 aculeate species.
Based on the present study, the use of artificial nests is most succesful in natural surroundings. Natural materials (reed, cow parsley, wood with holes) are better building materials of artificial nests in comparison to plastic straws. Humidity concentrating into the walls of plastic straws makes the walls between cells of nests to collapse. The smallest plastic straws seem to be too small, because no nesting was observed in them. A clear difference was observed between reed and cow parsley in favor for reed what comes to the number of species nesting in them. In birch blocks there were significantly more nests in holes of six mm in diameter as compared to smaller ones (diameter 4 mm).
Most species nested in birch block in alder forest. These habitats are diverse rural landscapes dating back to swidden culture and pastures. I did not observe any significant differences in species compositions between birch, aspen and alder habitats. In addition, I did not find any significant difference between birch blocks in cultural surroundings differing from each other in land use (fallow, pasture area and cereal field).
Based on the present study, artificial nests made of natural materials (straws, blocks, combination nests and laths) may be used as nesting sites for all hole nesting wasps and bees in Finland. The placing of nests is crucial for the success of nesting. The artificial nests must be placed in warm places. In addition, the nesting holes must be drilled horizontally and directed to morning sun.

Distributional changes in Finnish moth fauna during 1993-2012

Authors: Leinonen Reima[2] and Pöyry Juha[1], [1]Finnish Environment Institute, Finland, [2]Kainuu ELY-Centre, Finland

Abstract: The Finnish moth monitoring scheme (Nocturna) was launched in 1993 as a long-term monitoring project of biodiversity covering a species-rich taxon, nocturnal moths, with ca. 900 species observed in the country. Since the late 1990s the monitoring has mainly focused on forested environments. The monitoring network included at highest 152 light traps in 1996, but later the number of trap sites decreased so that in 2010s the trap number has varied between 40 and 45. Previously, the regional environmental authorities were responsible for maintaining the traps, but this changed after 2015 and now traps are increasingly maintained by voluntary lepidopterists. In 2017, the trap network consisted of 60 sites. Voluntary lepidopterists have also identified the moth samples and saved the observations into a database. The monitoring scheme is currently coordinated the Finnish Environment Institute (SYKE).

Several significant large-scale changes have been observed in the Finnish moth communities during the period 1993-2012. The annually observed species richness and community evenness, as described by Fisher's alpha index, have increased. These increases are most pronounced in Southwestern Finland. Incidence of multivoltinism, i.e. production of more than one generation during the season, has also increased with the strongest change again in the SW parts of the country. Several moth species of southern origin have strongly increased in abundance, whereas a lower number of northern species, typical of the boreal climate, have declined. Following changes in the abundance of individual species, community composition has shifted towards predominance of southwestern faunal elements. Total abundance of all moth species has varied periodically so that abundance peaks have occurred during 1995-96 and 2005-06, i.e. with intervals of ten years.

The most likely explanation for most of the observed changes in the Finnish moth communities is the climate warming that has occurred across Northern Europe during the monitoring period. Moths feeding on nitrophilous plant species, i.e. plants benefiting from high soil nitrogen contents, have also become more abundant due to nitrogen deposition. In addition, Decrease in the acid rain has probably affected positively populations of moth species feeding on lichens in the larval stage.

Layers of immunity: Deconstructing the Drosophila effector response

Authors: Lemaitre Bruno, EPFL, Lausanne, Switzerland

Abstract: We are currently dissecting the Drosophila innate immune response with a focus on effectors. Since immune effectors are members of multigene families, their function cannot be adequately addressed by the single mutant approach that still prevails today. Thus, we are generating flies carrying single and multiple mutations of immune effectors in a defined genetic background, which will allow comparative analysis of gene function either individually or collectively at the level of gene families. Our study will be done both at the level of individual effectors and immune modules. Recently, we have characterized how antimicrobial peptides individually or collectively contribute to host defense. Our studies reveal an unexpected level of specificality at the effector level as a single antimicrobial peptide can determine survival or death to a defined pathogen. We also address the role of immune effectors beyond immunity in contexts that have been implied but not well demonstrated, notably in the control of the gut microbiota and the elimination of tumor cells, neurodegeneration, and aging. By deciphering how immune effectors combat infectious microbes and impact non-immune processes, our work will illuminate critical aspects of Drosophila host defense, and will be instrumental in comprehension of innate immunity in general.

The Drosophila antimicrobial response: deconstructing the immune effector program using CRISPR/Cas9 technology

Authors: Lemaitre Bruno, EPFL, Lausanne, Switzerland

Abstract: While neglected during the decades where adaptive immunity captured most of the attention, innate immune mechanisms have become central to our understanding of immunology. The recent emphasis on innate immunity has, however, mostly focused on the first two phases of the immune response: recognition and signaling. In contrast, how innate immune effectors individually or collectively contribute to host resistance has not yet been investigated to the same extent. The existence of multiple effectors that redundantly contribute to host resistance has hampered their functional characterization by genetic approaches. As a consequence, the logic underlying the role of effectors is only poorly defined, and exactly how immune parameters contribute to survival is not well characterized. To fill this gap, ware currently studying the deployment of the immune response with a focus on immune effectors taking advantage of the CRISPR/Cas9 editing approach. To carry out this ambitious program, we systematically inactivate putative immune effector genes and generate compound mutants with mutations in various effector genes. This approach allows us to overcome functional redundancy, and to disentangle the respective contribution of each effector to host resistance. We are currently characterizing the role of antimicrobial peptides in immunity and beyond infection, notably aging. We are also studying the metabolic and physiological landscape required to mount an effective immune response while preserving vital host functions. Collectively, our study aims at providing a high-resolution map of the Drosophila immune response by deciphering the relative contribution of each immune effector to combat infectious microbes. Taking into consideration the key role that the immune system plays in many processes including microbiota control, neurodegeneration, and aging, our study is likely to have a global impact.

Effects of trans-generational immune priming on honeybee colonies

Authors: Leponiemi Matti[1], Moreno-Torres Miguel[1], Wirta Helena[2] and Freitak Dalial[1], [1]University of Graz, Austria, [2]University of Helsinki, Finland

Abstract: The health of managed honeybee (Apis mellifera) colonies has decreased, along with decreasing numbers of many pollinators. Pathogens are one of the many reasons for the decline, so studying the responses of honeybees against pathogens could provide ways to help these important pollinators. Immune priming is a function of the invertebrate immune system that can improve resistance against a previously encountered pathogen, and the priming effect can even extend to the next generation. While trans-generational immune priming (TGIP) has been shown to increase the pathogen resistance of the honeybee larvae in the lab, potential tradeoffs or behavioral changes related to TGIP have not been studied in honeybees. Working with Finnish beekeepers, we plan to set up experimental beehives with immune-primed and control queens. The foraging preferences, foraging efficiency and general performance of these colonies is then compared by specifying the sources of collected nectar and pollen, measuring colony growth and the quantity of produced honey, and further by contrasting the forage to the available floral resources in the surrounding landscape. Benefits of TGIP will be assessed by following colony survival and pathogens in the hives. The findings will shed light on potential behavioral changes and tradeoffs related to TGIP on the level of the honeybee colony.

Insect Rearing Science and Education Development and Applications

Authors: Leppla Norman, University of Florida Institute of Food and Agricultural Sciences Entomology and Nematology Department, United States

Abstract: Insect rearing has advanced from using relatively crude small-scale methods and natural diets prior to the 1960s to an industrial scale that includes specialized facility design and management, complex production systems that incorporate artificial diets and automated equipment, effective microbial management, and sophisticated production, process and product quality control. These advancements depended on the development of supporting insect rearing science and technology, along with unique education and training. The symposium on “Principles and procedures for rearing beneficial and other economically important arthropods” will address the following: Nutrition and diets, microbial management, quality control, population genetics, environmental biology, and facility design. These topics will be presented by the instructors for them at the International Insect Rearing Workshop conducted annually at Mississippi State University. Thus, the field of insect rearing and its associated profession have been created and advanced. This, in turn, has made possible a wide range of applications that require a dependable supply of high-quality insects. Included are the sterile insect technique, biological control, insecticide development, pheromone identification and synthesis, educational displays, conservation, human food and animal feed, and many other important purposes for colonized insects. Recently, an unprecedented increase in the magnitude of insect mass rearing for animal feed and human food has resulted in the maximum output of a facility extending from billions to tons per week. Due to this scale of insect mass rearing, renewable sources of feed are available for farm-raised fish and other farm animals. Regardless of the purpose and magnitude of insect rearing, the capability now exists to provide a reliable supply of high quality and affordable insects.

Hoverflies as ecosystem service providers in an urbanizing world

Authors: Lequerica Manuel[1], Threlfall Caragh[1], Hochuli Dieter[1] and Latty Tanya[1], [1]The University of Sydney, Australia

Abstract: Australian hoverflies (approximately 180 species) provide important ecosystem services such as pollination and control of phytophagous pests. The role of hoverfly larvae as predators of aphids has the potential to reduce pesticide use while the role of adults as pollinators can benefit the conservation of native vegetation. Although 86% of Australia’s population is urban, little is known about the impact of urbanization on hoverfly diversity and distribution. We surveyed hoverflies from 30 urban sites in four consecutive seasons during one year. We used a multi-scale approach to quantify habitat attributes and compared hoverfly richness and diversity to the measured environmental variables. Multiple regression analyses revealed that hoverfly diversity was higher on less frequently mowed sites and in sites with higher abundance of flowers, regardless of human population density. Hoverfly abundance was positively related to sunshine, but it was not related either to temperature or honey bee (Apis mellifera) abundance.

The ability of hoverflies to stay active during the coldest months, inhabit densely populated urban areas, and having a generalist flower diet are characteristics that make them suitable candidates for the provision of multiple ecosystem services in cities. Cities can be transformed into reservoirs of hoverfly diversity with simple interventions such as assuring a constant flower supply throughout the year or decreasing the frequency in which ground cover is mowed. We suggest a series of environmental practices that can increase the diversity and abundance of native hoverfly species in urban areas, thus enhancing the provision of important ecosystem services such as pollination and control of hemipteran pests.

Responses of hover fly diversity and abundance to local and landscape attributes of urban greenspaces in Sydney, Australia

Authors: Lequerica Tamara Manuel[1], Latty Tanya[1], Threlfall Caragh[1], Young Andrew[2] and Hochuli Dieter[1], [1]The University of Sydney, Australia, [2]University of Guelph

Abstract: Urban greenspaces are vital refugia for insect biodiversity, but seasonal responses of insect taxa to landscape and local attributes of urban greenspaces are not well known. Regions with mild temperate climates and winter-flowering plants have active winter pollinators that are often neglected. A thorough knowledge of the seasonally fluctuating ecological needs of insects is essential for insect-friendly greenspace management. Hoverflies are cosmopolitan inhabitants of urban greenspaces where they provide multiple ecosystem services. We used a multi-scale approach to determine the seasonal effects of urbanisation on hover fly populations. We selected 30 sites along an urbanisation gradient in Sydney, Australia and sampled each site over a year across seasons. We found that hover fly species richness was higher in winter and spring than in summer, while abundance was highest in winter and lowest in summer. Our results also show that a combination of local and landscape attributes of urban greenspaces affect hover fly species richness and abundance in seasonally dependant ways. Hover flies are especially abundant and diverse during winter- a time of the year when other native floral visitors are less active. Thus, hover flies may be important pollinators of the large community of winter-flowering plants in Australia.

Feeding patterns of an aphid parasitoid: influence of host presence and of the distance between host and extrafloral nectar

Authors: Lérault Louise[1], Weishaar Marine[1], Branger Johanna[1], Viel Pierre-Antoine[1], Lavandero Blas[2], Plantegenest Manuel[3] and Jaloux Bruno[1], [1]IGEPP, INRAE, l'Institut Agro, Université de Rennes 1, France, [2]Instituto de Ciencias Biológicas, Universidad de Talca, Talca, Chile, [3]L'Institut Agro, UMR IGEPP

Abstract: Extrafloral nectar (EFN) is one of the principal carbohydrates resources used by many parasitoid species, including Aphidius ervi Haliday [Hymenoptera: Braconidae], in order to extend its lifespan and, for a female, to increase its egg load. Providing parasitoids with EFN sources can improve their efficiency as biological control agents against aphid pests. The frequency at which parasitoids such as A. ervi females need to feed in order to optimize their time between ovipositing or re-strengthening through nectar uptake is unknown: no study using video recording to observe the feeding patterns of parasitoids has been found so far. In this study, we used a movement detection software in order to estimate EFN uptakes and the duration of every uptake by A. ervi females, either in the absence of its host or in its presence, successively at two distances from the EFN providing plant, under controlled conditions. A segmentation/clustering method identified a tendency of feeding twice a day for females in the absence of its hosts. Interestingly, they tended to feed only once a day in the presence of aphids (next to the providing plant or 80cm away). Our results give valuable information on the effect of hosts on parasitoids feeding behaviour

Access and benefit-sharing for genetic resources for food and agriculture

Authors: Leskien Dan, Commission on Genetic Resources for Food and Agriculture Food and Agriculture Organization of the United Nations, Italy

Abstract: It is widely acknowledged that genetic resources for food and agriculture (GRFA) are in many respects different from 'wild' biodiversity. In fact, the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity (Protocol) recognizes "the special nature of agricultural biodiversity, its distinctive features and problems needing distinctive solutions." The Protocol also requires its Parties to consider "in the development and implementation of its access and benefit-sharing legislation or regulatory requirements […] the importance of genetic resources for food and agriculture and their special role for food security" – a complex challenge for governments and administrators alike.

The Commission on Genetic Resources for Food and Agriculture that once negotiated the International Treaty on Plant Genetic Resources for Food and Agriculture, a special agreement that provides a tailor-made multilateral ABS system for a particular subsector of GRFA, prepared "ABS Elements"(*). The ABS Elements aim to assist governments considering developing, adapting or implementing access and benefit-sharing measures to take into account the importance of GRFA, their special role for food security and the distinctive features of the different subsectors of GRFA, including micro-organism and invertebrate genetic resources (MIGR).

The ABS Elements stress the importance of assessing the use and exchange mechanisms of concerned subsectors of GRFA and of consulting relevant governmental and non-governmental entities holding, providing or using specific genetic resources. Many agricultural stakeholder have not paid much attention to the development of the Protocol. It is therefore important to inform them, seek their views and involve them in the decision-making process prior to the adoption of national ABS measures that may have significant impact on the different subsectors and how they may utilize and exchange genetic resources for research and development.

The ABS Elements indicate a significant amount of flexibility Governments have in the design of ABS policies. A whole range of options is available to adequately reflect the distinctive features of specific subsectors of GRFA in ABS regimes. None of the international instruments require to restrict access to micro-organism and invertebrate genetic resources. Governments may also opt for specific provisions addressing research and development of genetic resources for the purpose of developing biological control agents. The presentation will provide an overview of options and elements, governments and stakeholders may take into account when considering policy, administrative or legislative measures on ABS.

Silencing immunity to determine how pathogens influence invasion success

Authors: Lester Phil[1], Felden Antoine[1], [1]Victoria University of Wellington, New Zealand

Abstract: Pathogens have been proposed as a cause of boom-and-bust dynamics in invasive species. The globally invasive Argentine ant (<i>Linepithema humile</i>) forms large “supercolonies” within which pathogens have the potential to quickly spread. Here, we used a RNAi approach to target core components of the ants’ immune system in order to manipulate their immunity. We effectively disrupted expression of genes across multiple immune signalling pathways, and present data on phenotypic changes associated with dsRNA treatment. Through a range of behavioural and molecular assays, we investigate how pathogens might influence invasion success, and explore the possibility of using RNAi targeted at the immune system as a pest control strategy.

Transcriptomic signatures associated with social behaviour in the Argentine ant reveal variation in genes associated with biogenic amines, hormones and chemoreception

Authors: Lester Phil[1], Felden Antoine[1] and A. M. Gruber Monica[1], [1]Victoria University of Wellington, New Zealand

Abstract: Social behaviour is considered as a key factor in the success of social insects, including invasive ants that often have substantial disruptive effects on ecosystems. Beyond the reproductive division of labour between workers and queens, social insect worker castes are also often characterised by behavioural variation, with different individual workers engaging in different tasks. Here, we used high-throughput RNA-Sequencing to investigate transcriptome-wide variations associated with morphological castes (i.e. queens versus workers), as well as worker age and worker foraging propensity in the globally invasive Argentine ant (<i>Linepithema humile</i>). We found that morphological castes, worker age and foraging propensity were associated with distinct transcriptomic signatures, including variation in genes associated with biogenic amines, hormonal control and chemoreception. JH-related genes (e.g. gonadotropin-releasing hormone, farnesol-dehydrogenase, hexamerin, ecdysteroid-regulated protein) were differentially regulated in queens versus workers, but also associated with worker foraging propensity. Gene co-expression network analysis (WGCNA) also indicated significant enrichment of hormone-signalling pathways in gene modules associated with worker age and foraging propensity. Overall, our results indicate that variation in social behaviour has a molecular basis in Argentine ants, and provide directions to further investigate the complexity of their social organisation.

Do invasive Argentine ants affect viral infection dynamics in honey bee colonies?

Authors: Lester Phil[2], Felden Antoine[2], Dobelmann Jana[1], [1]Institute of Evolutionary Ecology and Conservation Genomics, University of Ulm, Germany, [2]Victoria University of Wellington, New Zealand,

Abstract: Determining what effect invasive species have on local disease dynamics is critical to understand disease emergence. Honey bee-associated viruses, which are linked to colony collapses are found in many arthropod species, including invasive ants. The invasive Argentine ant, which reaches high densities and infests beehives possibly exposes bees to viral pathogens. We monitored viral and non-viral infections in honey bees in the presence and absence of Argentine ants over seven months. Black queen cell virus and deformed wing virus (DWV) levels, but not prevalence, in bees significantly increased with ant presence. Kashmir bee virus infected only a few colonies from ant-infested sites. All three viruses were found in ants throughout the experiment. Microsporidian and trypanosomatid infections, which are more bee-specific, were not affected. An analysis of the bee virome in autumn found that DWV had the highest infection levels and that no ant-associated viruses were infecting bees. Virus spillback from ants could increase infections in bees and indicates that ants vector bee pathogens. In addition, stress from ant attacks may affect viral susceptibility. Our study contributes to unravel how a globally invasive species is associated with disease emergence in an economically important pollinator.

CRISPR gene drives to eradicate or suppress globally invasive social wasps?

Authors: Lester Phil[4], Dearden Peter[2], Baty James[4], Kean John[1], Guhlin Joseph[3] and Bulgarella Mariana[4], [1]AgResearch, Hamilton, New Zealand, [2]The Laboratory for Evolution and Development Department of Biochemistry University of Otago, New Zealand, [3]University of Otago, New Zealand, [4]Victoria University of Wellington, New Zealand,

Abstract: CRISPR gene drives are a novel technology with the potential for widespread and cost-efficient pest control, but are also highly controversial. We examined a potential gene drive targeting spermatogenesis to control the invasive common wasp (Vespula vulgaris). Vespula wasps and many other globally invasive pests are haplodiploid and widespread in native ecosystems. Their life cycle makes gene drive production challenging. We show that different spermatogenesis genes have different levels of variation between introduced and native ranges, enabling a potential ‘precision drive’ that could target the reduced genetic diversity and genotypes within the invaded range. In vitro testing showed guide-RNA target specificity and efficacy that was dependent on the gene target within Vespula, but no cross-reactivity in other Hymenoptera. Mathematical modelling incorporating the genetic and life history traits of Vespula wasps identified the necessary characteristics for a male sterility drive to achieve population suppression or eradication. There was a trade-off between drive infiltration and impact: a drive causing complete male sterility would not spread. Partial sterility could be effective in limiting or suppressing population size if the homing rate is sufficiently high. Our results indicate that gene drives may offer viable suppression for wasps and other haplodiploid pests, when homing rates are sufficiently high, but pest eradication is likely to be challenging.

New findings on biology and ecology of entomopathogenic nematodes inform the development of new formulation and application methods

Authors: Lewis Ed[1], Shaprio-Ilan David[3] and Kaplan Fatma[2], [1]1Department of Entomology, Plant Pathology and Nematology, University of Idaho, Moscow, ID 83844 USA, United States, [3]USDA-ARS, Southeastern Fruit and Tree Nut Research Lab, Byron, GA 31008 USA, United States, [2]Pheronym, Inc, Davis, CA, United States

Abstract: Entomopathogenic nematodes are applied to numerous crops to control insect pests. Two claimed advantages of using entomopathogenic nematodes have been that they are formulated in ways that resemble other insecticidal products, and they can be applied using equipment that most growers currently use with only minor modifications. But these aspects of using entomopathogenic nematode-based products often fail to exploit new findings of nematode biology and ecology, nor do they encourage customizing formulations and application methods to specific characteristics of cropping systems. Our efforts to incorporate new biological findings into formulation and application methods, especially in terms of behavioral modification, can lead to increased efficacy of entomopathogenic nematodes.

JHSB3 signaling and egg production in the classical insect model, Rhodnius Prolixus

Authors: Leyria Jimena[1], Orchard Ian[1], Lange Angela[1], [1]Department of Biology, University of Toronto Mississauga, Ontario, Canada

Abstract: Juvenile hormones (JH) are sesquiterpenoids secreted from the corpus allatum. In female adults of several insect species, JH acts as a gonadotrophic hormone, regulating vitellogenesis and oogenesis. JH binds to its nuclear receptor, the bHLH-PAS protein Methoprene tolerant (Met), triggering its dimerization with the protein Taiman (Tai). The resulting active complex induces transcription of JH response genes, such as the transcription factor Krüppel homolog 1 (Kr-h1). Although the kissing bug, Rhodnius prolixus, has been widely used as a model to study endocrine signaling in insects, the mechanisms and target genes underlying JH action are not fully understood. In this study, we report for the first time the participation of JH III skipped bisepoxide (JHSB3) signaling (the JH isoform shown by Noriega and colleagues to be present in the hemolymph of R. prolixus) on the synthesis of yolk protein precursors (YPPs) by the fat body and the ovaries, and impact on reproductive fitness. By RT-qPCR we find that RhoprMet and RhoprTai transcripts are not regulated nutritionally by blood feeding, as the YPPs are. We also show that topical application of synthetic JHSB3 on insect females increases transcript and protein expression of YPPs, mainly by the fat body but also by the ovaries, a second YPPs source. These results are confirmed by ex vivo assays and by downregulating RhoprMet and RhoprTai transcripts using RNA interference (RNAi). When the JHBS3 signaling cascade is impaired by RNAi, the synthesis of YPPs decreases and ovarian follicles do not take up nutrients, thereby inhibiting egg production. Interestingly, we also observe that expression of RhoprKr-h1 transcript is highly dependent on JHSB3 signaling, which opens doors to study the role of this transcription factor in R. prolixus reproduction. Overall, the results suggest that follicular synthesis of YPPs is dependent on JHSB3 signaling, and indicate a major participation of not only RhoprMet but also RhoprTai in successful reproduction. This research contributes some missing pieces in JH action in the insect model in which a JH was first reported almost 100 years ago.

Pathogen prevalence in the blacklegged tick Ixodes scapularis: does pathogen infection alter tick behaviors

Authors: Li Andrew[1] and Xu Guang[2], [1]Agricultural Research Station United States Department of Agriculture Beltsville, Maryland, United States, [2]University of Massachusetts Amherst, MA, United States

Abstract: The blacklegged tick Ixodes scapularis is the vector of various pathogens that cause serious human and animal diseases. Over 30,000 human cases of Lyme disease are reported to CDC annually and Borrelia burgdoferi is the causative disease agent that is transmitted to humans by the blacklegged ticks. It is known that pathogen infection can alter host-seeking behaviors in mosquitoes. The objective of this study is to determine pathogen prevalence in questing Ixodes scapularis ticks collected from parks and natural areas in Maryland and test if pathogen infection alters tick behaviors. Each tick was subjected to laboratory repellent tests involving a series of ascending DEET concentrations to determine the concentration of DEET that repels the tick. DNA extractions were obtained from individual ticks after behavioral assays. RT-PCR was used for detection of various tick-borne pathogens, including Borrelia burgdorferi (sl), Borrelia miyamotoi, Babesia microti, and Anaplasma phagocytophilum. Statistical analysis was performed to determine if there is a correlation between tick's response to DEET and the pathogen infection status of the tick. Preliminary analysis of data indicate pathogen-infected and non-infected adult ticks may be equally sensitive to DEET in laboratory bioassay. Research are currently being conducted to evaluate the responses in nymphs, and to study the potential impact of pathogen infection on tick's host-seeking behaviors.

Monitoring and control of Colorado potato beetle: from field to large–scale region

Authors: Li Chao[3], Liao Jianghua[3], Liu Juan[3], Fu Kaiyun[2], Guo Wenchao[1] and Ding Xinhua[2], [1]Institute of Microorganism Application in Xinjiang Academy of Agricultural Sciences, China, [2]Key Laboratory of Integrated Pest Management on Crop in Northwestern Oasis, Ministry Agriculture PRChina, Institute of Plant Protection, Xinjiang Academy of Agr, [3]Key Laboratory of the Pest Monitoring and Safety Control on Crop and Forest in Universities of Xinjiang Uyghur Autonomous Region, College of Agronomy, Xinjiang

Abstract: Colorado potato beetle (CPB) is internationally recognized as not only the devastating quarantine pests, but also the major foreign quarantine objects and invasive alien species. Natural migration is the major dispersal strategy of its spreading. It spread to Kazakhstan of Central Asia in 1980s where near from Xinjiang of China. And then CPB was found for the first time in 1993 in Xinjiang. Since then, it continued to spread from west to east. And the risk of its further spread eastward into Gansu, Inner Mongolia and other potato main producing areas of China is increasing. In the other side, in recent years, invasions of CPB from Russia to China have become a threat in northeastern China.

The spatial distribution pattern of CPB is affected by temperature, moisture, topography and human activities. The temperature factor is mainly the main temperature of the wettest quarter and the warmest quarter, due to the warmest quarter in Xinjiang, China. The wettest quarters are basically coincident, all in the summer of June-August, so we can think that the average temperature in summer is the most critical factor affecting the distribution of CPB. The main factor of the moisture factor is the lowest temperature in the coldest month and the average precipitation in the coldest month. The lowest temperature in the coldest month can be regarded as a part of the temperature factor, that is, the influence of low temperature. However, the temperature, especially the low temperature in winter, also plays a role in the use of water by insects. Among the topographic factors, the ratio of altitude, day and night temperature difference to annual temperature difference reflects the influence of terrain. In human activities, the distance from the settlement point is the main advantage. The four main factors have different effects on the spatial distribution pattern of CPB because of their different contribution rates. They are ranked according to the contribution rate: temperature factor>water factor>topographic factor>human activity factor.

To further clarify the role of airflow in the spread of CPB in Xinjiang, the direction and speed of airflow were analyzed in Northwestern China from June to September in 2007-2014 in 850 hPa with the method of atmospheric background field analysis by using GrADS software and NCEP and NCAR joint meteorological reanalysis data; In the colonized regions of CPB in Xinjiang, the direction of airflow was same as the CPB spread direction in the early years of its invasion in China. And the airflow played an important role in the invasion process from Kazakhstan. While in the current frontier regions, the airflow direction was not conducive to CPB dispersal from west to east, and the airflow intensity and duration were not enough to make CPB spread into Hexi Corridor of Gansu Province; The role of airflow carrying for CPB had a certain effect on it invaded China and dispersal in the early year of its invasion.

Survey of household termite species composition and dispersal flight season with synergy of citizen science project in Taiwan

Authors: Li Hou-Feng[1], Huang Shih-Ying[1], Li Wei-Jie[1] and Tsai Yi-Ying[1], [1]Department of Entomology, National Chung Hsing University, Taiwan

Abstract: The Formosan subterranean termite, Coptotermes formosanus Shiraki, and Asian subterranean termite, C. gestroi (Wasmann) are both destructive economic pests worldwide. Their alates have swarming behavior during late-spring to early-summer to establish new colonies and to extend their distribution. In 2008, a questionnaire survey to local pest control operators indicated that C. formosanus and C. gestroi were major household pests in Taiwan. However, quantitative infestation data was unavailable. Conducting termite infestation surveys is difficult because access to private constructions is limited. In addition to infestation surveys, estimation of the nationwide swarming season is also challenging, since termite swarming occurred unpredictably and usually lasted for less than an hour.

In this study, we launched a citizen science project to collect household termite samples by cooperating with homeowners and local pest control operators. A species identification service website, termite.nchu.edu.tw, was established for acquiring information, including collection date, address, and infested items. In addition, a Facebook group was used for advertisement and to recruit more people to collect and send termite samples to our laboratory. Species identification results were provided to collectors through e-mails, with all termite samples preserved in the NCHU Termite Collection for further biological studies.

In the past five years, 2015-2019, > 3,000 termite samples were sent to our laboratory. A total of 1,296 household termite samples showed C. formosanus and C. gestroi, were responsible for 95% of the termite infestations, but species compositions were significantly different in Northern and Southern Taiwan. C. formosanus and C. gestroi are dominant in Northern and Southern Taiwan, respectively, with >90% infestation rates in the respective areas. In Central Taiwan, infestation rates were similar. Three other minor household termites, Odontotermes formosanus (Shiraki), Reticulitermes flaviceps (Oshima) and Cryptotermes domesticus (Haviland), were together responsible for <~5% termite infestations in each county. A total of 363 termite alate collections showed C. formosanus’s and C. gestroi‘s swarming peaked in April and May, respectively. The sympatric distribution and overlapped swarming seasons of the two Coptotermes spp. were observed in Central Taiwan between late-April and mid-May.

This study showed that a citizen science project can help scientists access household pest samples, infestation status, and pest biological information with the help of homeowners and pest control operators. Citizen science projects also provide an extension platform for citizens, industry, and academia, which will further facilitate pest management in urban environments.

Multiple bacterial symbionts affect the metabolism of insecticides by brown planthopper (Nilaparvata lugens)

Authors: Li Jianhong[2], Wan Hu[1], Zhang yunhua[1], Tang Tao[1], [1]College of Plant Science and Technology, Huazhong Agricultural University, Wuhan, China, [2]Huazhong Agricutural University, China

Abstract: Symbionts participate in various physiological activities of their insect hosts, including detoxification metabolism. Emerging evidence indicates that the bacterial symbiont Arsenophonus is involved in insecticide detoxification metabolism in N. lugens, which harbors diverse symbionts. Whether other bacterial symbionts play a role in this process is still unknown. The present study showed that the toxicity of imidacloprid, chlorpyrifos and clothianidin to N. lugens was significantly increased in N. lugens pretreated with antibiotics, and the detoxifying enzyme activities of cytochrome P450 enzyme (P450) and glutathione S-transferase (GST) were significantly weakened. In addition, three GST (NlGSTd2, NlGSTe1, and NlGSTs1) and five P450 (NlCYP303A1, NlCYP306A2, NlCYP4DD1, NlCYP425A1, and NlCYP3115A1) genes were both significantly downregulated in N. lugens treated with antibiotics (tetracycline or ciprofloxacin). Furthermore, the expression levels of various detoxifying genes were significantly correlated with Wolbachia, Arsenophonus, Acinetobacter, and Staphylococcus. These results suggested that multiple bacterial symbionts affect the metabolism of insecticides by N. lugens by regulating the expression of the GST and P450 genes. The present study enriched the theory of insect toxicology, laying the foundation for further study on the mechanism of host detoxification metabolism mediated by symbionts in insect pests.

Transcriptional response of ATP-binding cassette (ABC) transporters to insecticide in the brown planthopper, Nilaparvata lugens (Stål)

Authors: Li Jianhong[3], Wan Hu[1], Li Zhao[1], [1]College of Plant Science and Technology, Huazhong Agricultural University, China [2]Huazhong Agricutural University, China

Abstract: ABC transporter superfamily is one of the largest group of proteins and play a non-negligible role in the phase ? of the detoxification process, which is an important mechanism for insects to defend against environmental stress (toxic secondary plant metabolites and insecticides). In the present study, we have identified 32 ABC transporters in the Nilaparvata lugens, which are grouped into eight subfamilies (ABCA-H) based on phylogenetic analysis. The temporal and spatial expression profiles suggested that the first-instar, second-instar, third-instar, fourth-instar, fifth-instar and male showed a certain similarity, which was different from egg and female. The spatial expression profiles showed that NlABCA1, NlABCA2, NlABCB6, NlABCD2, NlABCG4, NlABCG12, NlABCG15, NlABCH1 were highly expressed in the midgut and the Malpighian tube. In addition, ABCG12, which belongs to the ABC transporter G subfamily, was significantly up-regulated after exposure to sulfoxaflor, nitenpyram, clothianidin, etofenprox, chlorpyrifos and isoprocarb. Moreover, verapamil significantly increased the sensitivity of N. lugens to nitenpyram, clothianidin, etofenprox, chlorpyrifos and isoprocarb. This study was conducted to provide a basis for further studies on ABC transporter genes in N. lugens, and for more comprehensive understanding of the response of N. lugens under environmental stress such as insecticides.

Horizontal Transfer of a Retrotransposon from the Rice Planthopper to the Genome of an Insect DNA Virus

Authors: Li Junmin[3], Yan Fei[3], Kondo Hideki[2], Bagus Andika Ida[2], Chen Jianping[3], Li Linying[1], Yang Qiankun[5], Zhang Yan[3], Lu Yanhua[3], Cheng Ye[3], Wu Yuanhua[5], Qi Yuhua[3], He Yujuan[3], He Yuqing[4], Liao Zhenfeng[4] and Sun Zongtao[3], [1]College of Horticulture and Plant Protection, Yangzhou University, China, [2]Institute of Plant Science and Resources, Okayama University, Kurashiki, Japan, [3]Institute of Plant Virology, Ningbo University, China, [45]Key Laboratory of Biotechnology in Plant Protection of MOA of China and Zhejiang Province, Zhejiang Academy of Agricultural Sciences, Hangzhou, China, [5]Plant Protection College, Shenyang Agricultural University, Shenyang, China

Abstract: Horizontal transfer of genetic materials between virus and host has been frequently identified. Three rice planthoppers, Laodelphax striatellus, Nilaparvata lugens, and Sogatella furcifera, are agriculturally important insects because they are destructive rice pests and also the vector of a number of phytopathogenic viruses. In this study, we discovered that a small region (~300 nucleotides [nt]) of the genome of invertebrate iridescent virus 6 (IIV-6; genus Iridovirus, family Iridoviridae), a giant DNA virus that infects invertebrates but is not known to infect planthoppers, is highly homologous to the sequences present in high copy numbers in these three planthopper genomes. These sequences are related to the short interspersed nuclear elements (SINEs), a class of non-long terminal repeat (LTR) retrotransposons (retroposons), suggesting a horizontal transfer event of a transposable element from the rice planthopper genome to the IIV-6 genome. In addition, a number of planthopper transcripts mapped to these rice planthopper SINE-like sequences (RPSISs) were identi?ed and appear to be transcriptionally regulated along the different developmental stages of planthoppers. Small RNAs derived from these RPSISs are predominantly 26 to 28 nt long, which is a typical characteristic of PIWI-interacting RNAs. Phylogenetic analysis suggests that IIV-6 acquires a SINE-like retrotransposon from S. furcifera after the evolutionary divergence of the three rice planthoppers. This study provides further examples of the horizontal transfer of an insect transposon to virus and suggests the association of rice planthoppers with iridoviruses in the past or present.

Can we pyramid Bt toxins and plant allelochemicals to combat pests?

Authors: Li Leyao[2], Wang Shan[2], Huang Jinyong[2], Zhang Min[2], Li Xianchun[1] and Deng Zhongyuan[2], [1]University of Arizona, United States, [2]Zhengzhou University, China

Abstract: Genetically engineered crops that simultaneously produce Bacillus thuringiensis (Bt) toxin proteins and higher concentration of defensive allelochemicals may act synergistically to kill devastating insect pests and delay their resistance to either of the two types of toxins. To evaluate the possibility of pyramiding Bt toxins and plant allelochemicals to mange pests, we examined the toxicological interactions between Cry1Ac, a major Bt toxin protein expressed in the current Bt crops, and flavone, a representative of the ubiquitous flavonoid allelochemicals, in Helicoverpa armigera, a world-wide devastating pest targeted by Bt cotton and Bt corn. Two lethal (LC25 and LC50) and one sublethal (LC10) doses were selected from the dose-response lines of the two toxins to reveal the nature of their interactions. Simultaneous exposure of H. armigera neonates to Cry1Ac and flavone of the LC25 dose caused a mortality significantly higher than that of either toxin alone and their expected additive mortality. Preexposure for 24 h to the sublethal dose of Cry1Ac followed by 6-day simultaneous exposure to the LC50 dose (1.6 mg/g diets) of flavone plus the sublethal dose of Cry1Ac resulted in a mortality significantly higher than that of the LC50 dose of flavone alone and the expected additive mortality of the LC50 dose of flavone plus the sublethal dose of Cry1Ac. One-day preexposure to the sublethal dose of flavone followed by 6-day simultaneous exposure to the LC50 dose (6 ng/cm2) of Cry1Ac plus the sublethal dose of flavone, however, did not enhance the mortality of the LC50 dose of Cry1Ac. The results suggest that Cry1Ac and flavone synergistically enhance each other's toxicity when H. armigera larvae ingest lethal doses of both toxins from Bt crops. The results also show that when only one of the two toxins reaches its lethal doses in Bt crops, sublethal dose of Cry1Ac induces the toxicity of flavone, whereas sublethal dose of flavone has no impacts on the toxicity of Cry1Ac.

Comparative analysis and functional study of microRNA of the testis and ovary of the Helicoverpa armigera

Authors: Li Leyao[2], Huang Jinyong[2], Zhang Min[2], Wang Shan[2], Li Xianchun[1] and Deng Zhongyuan[2], [1]University of Arizona, United States, [2]Zhengzhou University, China

Abstract: MicroRNAs (miRNAs) are a class of short (18-24 nucleotides), small non-coding RNAs that bind to 3'UTR to regulate gene expression by post-transcriptional suppression of mRNA. Several studies have demonstrated that miRNAs are involved in the development of testis and ovary of Drosophila melanogaster and Bombyx mori but there are few studies of Helicoverpa armigera. In this study, two small RNAs libraries of H. armigera ovary and testis were constructed using deep sequencing technology. The results showed that the types of small RNA enriched in the testis and ovary were different. MiRNAs are mainly found in testis and piRNAs in ovary. Two miRNAs (miR-252a-5p and miR-263b-5p) were selected from the libraries and qRT-PCR showed that they had different expression profiles in other tissues (head, throax, abdomen, foot, wing and fay body) and different development stages. Target prediction showed that a total of 2,134 candidate genes of miR-252a-5p and 5,474 of miR-263b-5p were found respectively. Among them, we chose 3 of miR-252a-5p (DPP, OVOL and JHEH) and 4 of miR-263b-5p (FOXO, BTB, EGFR and JHEs) as target genes. Furthermore, injection of two miRNAs mimics/inhibitors lead to the opposite expression profile with their target genes. Using a dual luciferase reporter assay in S2 cells, we confirmed that miR-252a-5p and miR-263b-5p suppressed transcription of their target genes suggesting that these miRNAs as minor regulators play vital regulatory roles in H. armigera. Taken together, this study provides insights into reproductive development in miRNA expression of H. armigera.

Insect Identification Based on Spectral Fringes Produced by Clear Wings

Authors: Li Meng[5], Runemark Anna[4], Hernandez Julio[6], Guilcher Noelie[3], Rota Jadranka[1] and Brydegaard Mikkel[2], [1]Biological Museum, Department of Biology, Lund University, Sweden, [2]Dept. of Physics, Lund University, Lund, Skåne, Sweden , [3]Dept. of Biology, Polytech Clermont Ferrand, France , [4]Lund University, [5]Lund University, Sweden, [6]Norsk Elektro Optikk A/S, Norway

Abstract: Due to the growing awareness that insects' diversity and populations are in decline, there is an increased need for monitoring insects. Entomological lidars and photonic sensors can monitor and remotely identify flying insects based on their back-scattered signal in terms of modulation-, polarization, and spectral content. The back-scattered light from insects is predominantly oscillatory and derives from the wings. This part of the signal is also more coherent and co-polarized than the light reflected from the insect's abdomen. Clear membranes display soap-bubble colors due to thin-film interference, a feature that associated with the thickness of the wing. A hyperspectral camera can capture these wing interference patterns and accurately identify the wing thickness. Here we investigate whether the spectral fringes can provide complementary information to aid remote insect identification. We demonstrate that we can extract wing thickness and modulation depth information from spectral fringes of 87 species of common insect pollinators in Skåne, Sweden. The modulation depth of a fringe provides information related to insect wing thickness homogeneity, wrinkleness, or anti-reflectance features. Our results show that examined species display distinct modulation and wing thickness, and therefore such features can be used to improve the specificity of species identification of photonics sensors.

W chromosome and sex determining genes in Bombyx mori

Authors: Li Shenglong[3], Arunkumar Kallare[1], Li Wanshun[3], Ajimura Masahiro[3], Abe Hiroaki[4], Marec Frantisek[2] and Mita Kazuei[3], [1]Central Muga Eri Research and Training Institute, (CMER&TI), Central Silk Board Lahdoigarh, Jorhat, India State Key Laboratory of Silkworm Genome Biology, [2]Institute of Entomology, Biology Centre, The Czech Academy of Sciences, [3]State Key Laboratory of Silkworm Genome Biology, Southwest University, [4]Tokyo University of Agriculture and Technology

Abstract: Deciphering the regulatory factors involved in the sex determination Bombyx mori, has been a puzzle challenging researchers for nearly a century now. Femaleness in B. mori is determined by the presence of a single W chromosome, irrespective of the numbers of autosomes or Z chromosome. We still lack the complete sequence of a W chromosome in a system of female heterogamety and, obtaining this information will be central to the understanding of the evolution of non-recombining sex chromosomes. We sequenced W chromosome of B. mori using different molecular biological and computational tools. The combination of molecular biological tools like 3D BAC pools, Laser Microdissection of W bodies, NGS, HI-C, PacBio and nanopore ultra-long sequencing coupled with computational analysis of large sequence data, provided us with a good coverage of W chromosome sequence. We de novo assembled 9 W-derived genome contigs of 19.8 Mb which contains Fem-piRNA cluster gene and CCCH-type Zn-finger protein genes. W sequencing of sex-limited yellow cocoon W mutant and sex-limited Zebra W mutant was also performed confirming the presence of Fem-piRNA cluster gene and CCCH-type Zn-finger protein genes, Now we are studying the function of Zn-finger protein expressed on W on Fem-piRNA gene expression and sex-determination pathway.

Effects of warming on insect herbivory and herbivore-induced plant volatiles in the Arctic tundra

Authors: Li Tao[1], Michelsen Anders[1], Rieksta Jolanta[1] and Rinnan Riikka[1], [1]University of Copenhagen, Denmark

Abstract: Climate change is altering plant-herbivore interactions with ecosystem-level consequences. This is particularly the case in the Arctic, which is warming at twice the global average. In the boreal mountain birch forest, for example, distribution shifts towards higher elevations have been observed for notorious geometrid moths such as Epirrita autumnata and Operophtera brumata. One important mechanisms underlying insect range expansion involves climate-driven changes in host plant defensive chemistry, such as emissions of volatile organic compounds (VOCs). Plant VOCs are known to play multiple roles in plant-insect interactions, including attracting/deterring insect herbivore and attracting predators and parasitoids of the attacking herbivores. However, it remains largely unexplored how insect herbivory in the Arctic influences plant VOC emissions, particularly with ongoing climate warming. This presentation will attempt to address this issue. We employed short-term (one month), medium-term (9 years) and long-term (19 years) experimental warming in an arctic heath ecosystem (Abisko, Northern Sweden) to 1) investigate the impacts of in situ warming on insect herbivory and 2) assess the importance of herbivore-induced plant VOCs and interactions with warming in the Sub-Arctic tundra. We will present these data and discuss the ecological consequences.

Screening, evaluation and optimization of artificial diet for Neoseiulus barkeri

Authors: Li Yaying[1], Liu Huai[1], Wang Jinjun[1], [1]Key Laboratory of Entomology and Pest Control Engineering, College of Plant Protection, Southwest University, China

Abstract: Neosuiulus barkeri is an effective commercial biological control agent on the sustainable pest management on spider mites, whiteflies and thrips. Its mass rearing procedures based on alternative prey like storage mites involved space and labor to maintain large parallel cultures of the factitious prey. Further, storage mites may cause potential health problems for workers in production facilities or application fields caused by allergy or asthma associated with the storage mites. The availability of an effective artificial diet for predatory mites provides an opportunity to avoid such problems for the mass and standardized production. This study screened a better artificial diet formula by adding different animal source components to the basic artificial diet. The life table parameters, predation functions and cannibalism levels of N. barkeri population on artificial diets were evaluated. The nutrients information of the best artificial diet, target prey (Tetranychus urticae) and alternative prey (Aleuroglyphus ovatus) were measured and further the artificial diet was optimized. The age, stage, two-sex life table analysis was used to compare the development, survivals, and fecundities of N. barkeri fed on four artificial diets and two prey species (T. urticae and A. ovatus). When fed on four artificial diets, N. barkeri held a lower fecundity and intrinsic rate of increase than those fed on two prey species. Among the N. barkeri fed on artificial diets, fecundity was highest on AD3 (24.94 eggs) and lowest on AD2 (14.25 eggs). It indicated that AD3 had better potential for mass rearing of N. barkeri. Compared with rearing prey species, the predation ability of N. barkeri under artificial diet was decreased, and the cannibalism level in the population was higher after 24 h. The contents of main saccharides, amino acids and fatty acids in the T. urticae, A. ovatus, and artificial diet were determined. The total content of the three saccharides in the artificial diet (AD3) was 10.7 times and 20.8 times that of the T. urticae and A. ovatus, respectively. The total content of amino acids in T. urticae and A. ovatus were higher 9.1% and 19.3% than AD3, respectively. According to the measurement results, the AD3 was improved by separately supplement Corcyra cephalonica eggs (AD5) and amino acid mixture (AD6). After rearing AD5 and AD6, the developmental duration of nymph was longer. The oviposition duration, the intrinsic rate of increase and the net reproductive rate of N. barkeri reared on AD5 and AD6 were no significantly different with that on AD3. After supplement of the C. cephalonica eggs and amino acid mixture, the pre-ovipositional period of N. barkeri was shorter than that of AD3, and the fecundity increased after supplement of the C. cephalonica eggs. The results indicated the potential artificial diets for use in the mass rearing of N. barkeri.

Insect flight velocity sensing with a CW near-IR Scheimpflug lidar system

Authors: Li Yiyun[1], Wang Kai, Han Zehua, Quintero-Torres Rafael, Brick Robert, Sokolov Alexei and Scully Marlan, [1]IQSE, Texas A&M University, United States

Abstract: Flight velocity measurement plays an important role in insect research that can aid insect identification, facilitate studies and monitoring of insect movements, and enable the early alert on the invasion of agricultural pests and disease vectors. A NIR Scheimpflug lidar-based novel scheme for the 1-D flight velocity measurement of insects has been proposed. We implement this new technique and apply it to study insects at the Salter Research Farm, Robertson County, Texas. The resolution property in the direction perpendicular to the probing direction of the Scheimpflug lidar system is explored and reveals the capability of retrieving the velocity component normal to the probing direction of insects passing through the field of view of our system. During the field measurement, a shift in the wingbeat frequency distribution is observed, which indicates a change in the local species component on the farm. The velocity information further shows that this change could be attributed to a net directional movement of insects. With Hierarchical Clustering Algorithm, the net flux of insects with similar wingbeat power spectra can also be revealed.

From studies to applications: the development of invasion ecology and surveillance on economically important fruit flies in China

Authors: Li Zhihong, China Agricultural University, China

Abstract: Tephritids are regarded as economically important pests and spread widely in the world under the background of global change and international economic integration. According to current regulations, there are six genera and five species of Tephritidae listed as quarantine species in China, which gained more attentions on the studies and applications of prevention and control. This review focused on the development of studies and applications on invasion ecology and surveillance of economically important fruit flies in recent ten years in China. It reviewed the related studies of establishment probability, potential geographical distribution, potential economic loss, invasion tracing and temperature adaptation mechanism of Tephritids, such as Bactrocera dorsalis. Meanwhile, it analyzed the related applications of surveillance based on above studies in China, e.g., identification of areas, months, species and source of monitoring survey on economically important fruit flies. The perspectives and suggestions of further studies and applications of invasion ecology and phytosanitary measures on Tephritids were illustrated for reference.

A study of Halyomorpha halys populations in kiwi orchards using Remote Sensing and Geostatistics

Authors: Liakos Vasileios[6], Navrozidis Ioannis[5], Andreadis Stefanos[4], Ioannidis Phillipos[3], Faraslis Ioannis[1] and Chadoulis Rizos - Theodoros[2], [1]Department of Environmental Sciences, University of Thessaly, Greece, [2]Department of Informatics, Aristotle University of Thessaloniki, Greece, [3]Eurofarm SA, 3rdkm O.N.R. Alexandria –Veria, 59300 Alexandria, Greece, [4]Hellenic Agricultural Organization-DIMITRA, IPBGR, Greece, [5]Lab of Remote Sensing, Spectroscopy and GIS, School of Agriculture, AUTH, Greece, [6]Laboratory of Precision Agriculture, University of Thessaly, Greece

Abstract: Halyomorpha halys' invasion from Asia to the US and Europe caused serious damages to fruit and vegetables. In Greece, damages are mainly reported in kiwi orchards. The aim of this research is to study a) if the crops nearest to the kiwi orchards affect the H. halys population and b) if kiwi plant vigour has an impact on H. halys populations. Two kiwi orchards were selected and ten traps were installed from early June to late October in each orchard – two types of traps at every side and at the center. Afterwards, crops that were up to 500m far from the selected orchards were identified. Traps were examined weekly. Additionally, sentinel satellite images were analyzed using Geostatistics to calculate the vegetation index NDVI. Moreover, we recorded the terrain variability using RTK GNSS and the spatial variability of elevation presented in maps using Geostatistics. The results showed that the nearest crops to the kiwi orchards have an impact on the populations of H. halys. Furtehrmore, population of H. halys was higher at the areas with high NDVI values. Finally, H. halys showed a preference to develop in the highest altitudes within an orchard.

Molecular and epigenetic control of reproduction in response to social context in ants

Authors: Libbrecht Romain, Johannes Gutenberg University of Mainz, Germany

Abstract: Understanding the evolution of social life is one of the great challenges in evolutionary biology. Particular attention has been given to the extreme case of insect societies, and to the evolution of reproductive division of labor between fertile queens and sterile workers. The typical approach to investigate the mechanisms underlying the evolution of reproductive division of labor is to compare queens and workers in species with morphologically distinct castes, but the interpretation of such comparisons is limited by multiple confounding factors and the fact that castes are typically fixed and cannot be manipulated at the adult stage. In this talk, I will present two alternative study systems to investigate the evolution of reproductive division of labor in ants. These study systems are the phasic life cycle of the clonal raider ant Ooceraea biroi and the colony foundation process of the black garden ant Lasius niger. In both systems, reproductive physiology changes in response to the social environment, thus allowing for experimental manipulation of reproduction. I will elaborate on some of our recent and on-going work on how gene expression, epigenetic processes and hormones underlie variation in reproduction, and on their potential role in the evolution of reproductive division of labor in insect societies.

Cellular and molecular mechanisms of a unique parasitic behavioral manipulation

Authors: Libersat Frederic, Ben Gurion University of the negevity, Beer Sheva, Israel

Abstract: Neuro-parasitology is a field that explores how parasites control the nervous system of their host. The parasitoid jewel wasp Ampulex compressa stings cockroaches and injects venom directly into and around the central complex (CC), a central region in the insect brain. In order to provide a fresh food supply for its offspring, the wasp venom induces and long-lasting sedative condition in the cockroach, termed “hypokinesia”. Our aim is to investigate the cellular and molecular mechanisms underlying this unique behavioral manipulation.

In order to decipher the physiological mechanism of such manipulation, we have recorded spontaneous descending activity in stung and control cockroaches. The descending activity in stung animals was decreased compared to that of control. Using direct injections of procaine (a Na voltage dependent reversible blockers) or venom into the CC show similar results. In order to decipher the molecular mechanisms underlying the behavioral manipulation, we used affinity chromatography for identification of venom targets in the cockroach brain and Label Free Quantitative Mass Spectrometry (LFQMS) to identify changes in protein expression that occur in the stung cockroach brain. We found that the venom binds to synaptic proteins and numerous proteins are differentially expressed in the brain of stung cockroaches, many of which are involved in signal transduction pathways such as the Rho GTPase pathway implicated in synaptic plasticity.

Altogether, our data suggest that the jewel wasp exerts control over cockroach behavior through molecular cross-talk between venom components and molecular targets in the host brain, leading to broad-based alteration of synaptic efficacy in the CC. Such a decrease in synaptic drive to the CC results in a decrease in descending activity and a reduction in excitatory drive from the brain to the thoracic motor circuitries. This may account for the observed motor impairments induced by the venom to promote successful development of wasp progeny.

Parasitoid wasp venom manipulates host innate behavior via subtype-specific dopamine receptor activation

Authors: Libersat Frederic[2], Nordio Stefania[1] and Kaiser Maayan[1], [2]Ben Gurion University of the negevity, Beer Sheva, Israel, [1]Ben Gurion University

Abstract: The subjugation strategy employed by the Jewel wasp is unique in that it manipulates the behavior of its host, the American cockroach, rather than inducing outright paralysis. Upon envenomation directly into the central complex (CX), a sensory-motor center in the brain, the stung cockroach initially engages in intense grooming behavior, then falls into a lethargic “sleep-like” state referred to as “hypokinesia”. Behavioral changes evoked by the sting are due at least in part to presence of dopamine in the venom. The specific roles played by dopamine receptor subtypes in venom-induced behavioral manipulation by the jewel wasp remain largely unknown. In the present study, we used a pharmacological approach to investigate roles of D1-like and D2-like receptors in behaviors exhibited by stung cockroaches, focusing on grooming. Specifically, we assessed behavioral outcomes of focal CX injections of dopamine receptor agonists and antagonists. Both specific and non-specific compounds were used. Our results strongly implicate D1-like dopamine receptors in venom-induced grooming. Regarding induction of hypokinesia, our findings demonstrate that dopamine signaling is necessary for induction of long-lasting hypokinesia caused by brain envenomation.

Oxidative stress and ageing in feral honey bees

Authors: Li-Byarlay Hongmei[1], Ward Kilea and Cleare Xaryn, [1]Central State University

Abstract: Molecular damage caused by oxidative stress may lead to organismal aging and result in acute mortality to organisms. Thus, oxidative stress resistance and longevity are closely linked. Honey bees are the most important managed pollinator in agriculture, but the long-term survival of honey bees is seriously threatened. Feral honey bee colonies display persistence to Varroa mites. However, whether feral honey bees are stress-resistant or survive longer than managed bee populations is unknown. More work is needed to determine the impact of oxidative stress on honey bee health and survival. In this study, we used a paired colony design to determine the life span of worker bees from either a feral or a managed colony and their levels of oxidative stress. Each pair of colonies shared similar foraging resources. The results indicated that foragers in feral colonies had longer survival times and life spans than those in managed colonies.

In vivo antioxidant effect of reared edible cricket (Order: Orthoptera) peptides using a Caenorhabditis elegans model

Authors: Liceaga Andrea M.[1], Mudd Natalie[2], [1]Protein Chemistry & Bioactive Peptides Lab, Purdue Univ, United States, [2]Purdue University

Abstract: Entomophagy has become relevant as it could potentially help reduce food insecurity, due to the highly nutritious and sustainable characteristics of reared edible insects. In addition to their nutritional content, research on the potential bioactive components of insect extracts has also gained interest. In this study, the antioxidant activity effect of simulated gastrointestinal digested (SGD) cricket (Gryllodes sigillatus) peptides was evaluated. Antioxidant activity was determined by 2,2′-azino-bis (3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) radical scavenging activity, oxygen radical antioxidant capacity (ORAC), and using a caco-2 cellular antioxidant model. In vivo acute and chronic oxidative stress was determined using Caenorhabditis elegans as a model. Results showed that SGD peptides had greater ($p < 0.05$) antioxidant activity than the control. In the Caco-2 model, cells exposed to SGD peptides showed the same level of antioxidant activity as those exposed to ascorbic acid under oxidative stress ($p<0.05$). After exposure to cricket peptides (0.125 to 1.0 mg/mL), the lifespan of C. elegans was increased ($p<0.05$) under chronic and acute oxidative stress conditions. Under acute oxidative stress, mean survival time of control nematodes was 322 minutes, while the mean survival time in nematodes exposed to SGD-peptides was 537 minutes. Under chronic oxidative stress, the same trend was observed with mean survival time of nematodes exposed to SGD-peptides being significantly ($p<0.05$) longer than that of the control, 4.6 days and 3.5 days, respectively. RT-PCR studies revealed that the increased resistance to oxidative stress in C. elegans fed SGD-peptides could be due to the increased expression of the stress-related gene gst-4. These results indicate that C. elegans can effectively be used as an in vivo model to evaluate bioactive properties of cricket peptides, and edible cricket peptides have potential use as nutraceutical & pharmaceutical compounds to combat oxidative stress.

Human Impacts on the Polynesian Beetle Fauna: An Ongoing Apocalypse

Authors: Liebherr James[1] and Porch Nick[2], [1]Cornell University, United States, [2]Deakin University

Abstract: Polynesia is home to numerous diverse beetle lineages. We combine data from pre-colonization subfossil deposits with comprehensive field collecting of extant species to provide a deep temporal view of biodiversity loss in Polynesia. Man's earliest impacts on smaller islands resulted in mass extinctions. The Austral Islands, French Polynesia, hosted a diverse prehistoric radiation of 17 species of saproxylic Pycnomerus beetles (Zopheridae), though only four persist after human colonization. In Kauai, Hawaii, the predatory carabid beetle genus Blackburnia is represented by 34 species, 7 of which are known only from subfossils from lowland pre-Polynesian deposits. Today extant species are restricted to habitats above 800 m elevation. Finally, in Oahu, Hawaii, the Polynesian island with the longest and densest history of entomological exploration, 14 of 66 known native Carabidae have not been collected for over a Century. Loss of beetle diversity has been driven by habitat destruction associated first with agriculture, and now with urbanization, complemented by waves of invasive species. Thus forces reducing Polynesian beetle diversity are consistent with those hypothesized for other taxa across the World, though their effects are especially apparent in Polynesia due to the large numbers of endemic beetle species that have evolved on these small islands.

Comparing host associations of native and non-native Scolytines

Authors: Liebhold Andrew, USDA Forest Service Northern Research Station, Czech Republic

Abstract: The Scolytinae exhibit considerable variation in the specificity of host associations with some species associated with a single host tree species and others with hosts that span multiple plant families. Here we report on a comprehensive analysis of host associations, comparing native vs. non-native species, European vs. North American species and true bark beetles vs. ambrosia beetles. We fine that ambrosia beetles tend to be more polyphagous than bark beetles, non-native species tend to be ore polyphagous than native species and European and North American species are comparable in their host specificities. These results contribute to a more comprehensive understanding of non-native Scolytine species.

Taxonomic patterns of global insect invasions reflect historical pathways, socioeconomic drivers and insect invasiveness

Authors: Liebhold Andrew, USDA Forest Service Northern Research Station, Czech Republic

Abstract: Biological invasions are largely an unintended consequence of globalization. With increasing mobility, humans have accidentally transported organisms around the world, breaking the geographical boundaries that separated species ranges that persisted for millions of years of evolution. Among animals, insects are the most numerous group of species, with thousands of insect species having been established outside of their native ranges and many of these species causing immense impacts on agriculture, human health and conservation of native ecosystems. Here, we report on an analysis of historical insect invasions in 11 world regions. We use these data to compare frequencies of invasions among different insect orders and among different insect families. Certain groups, such as the Hemiptera, Formicidae and the Staphylinidae are generally over-represented in non-native insect assemblages, while other taxa are under-represented. These patterns generally reflect characteristics of these insects that cause them to enter important invasion pathways and biological characteristics that facilitate invasions. These results ultimately can be of use when conducting invasive pest risk analysis.

Research Actions for Conservation of an Endangered Species and a Korean Natural Monument, Callipogon relictus Semenov (Coleoptera: Cerambycidae: Prioninae) in South Korea

Authors: Lim Jongok[1], Lee Bong-Woo[1], Kim Cheol-Hak[2], Lee Seung-Gyu[1] and Oh Seunghwan[1], [1]Korea National Arboretum, Korea Forest Service, South Korea, [2]Osang K-insect Biological Resource Research Center, South Korea

Abstract: The relict longhorned beetle, Callipogon relictus Semenov (Coleoptera: Cerambycidae), is the unique species among the species of Callipogon which is distributed in the Palearctic region. The cerambycid species was designated as an endangered species and a Korean natural monument in South Korea and it has been protected by the Korean laws. The distribution records of Callipogon relictus in South Korea were from several northern regions of South Korea, however, the species has been just discovered from a Gwangneung forest where the Korea national arboretum located in. For conservation of C. relictus in S. Korea, we have studied the biological features and developed useful techniques for mass-rearing in short period with accumulation of survey data of inhabitation over last ten years in S. Korea. In this presentation, we introduce recent studies for conservation of C. relictus and the results in South Korea to discuss on further studies.

Negative effect of tau-fluvalinate on olfactory sensitivity in honey bees

Authors: Lim Sooho[1], Kim Dong-In[1], Wook Kwon Hyung[1], Ilyasov Rustem[1], Woo Sehoon[1] and Yunusbaev Ural[1], [1]Department of Life Sciences & Convergence Research Center for Insect Vectors, Incheon National University, South Korea

Abstract: tau–Fluvalinate (fluvalinate) is commonly used against Varroa mites, the major drivers of colony collapse disorder (CCD), in the apicultural industry. Although honey bees have tolerance and low toxicity to this miticide, little is known about the effects on sensory modulation in honey bees. Here, we demonstrated that abdominal contact of fluvalinate has adverse effects on mortality and olfactory sensitivity of Apis mellifera. First, we found that topical application of fluvalinate to honeybee abdomen elicited somewhat severe toxicity to honey bees. Then, electrophysiology showed that honey bees treated with sub-lethal doses of fluvalinate significantly decreased in olfactory responses. At the molecular level, there was no change in molecular expression patterns of cytochrome p450s monooxygenases (CYP9Q1-3), odorant receptor co-receptor (Orco) and tachykinin (TK) in antennae of treated bees. Rather, the expression level of short neuropeptide F (sNPF) which would be involved in olfactory sensitivity was increased after fluvalinate treatment. Insulin expression levels in the brain of honey bees suggested that it would be associated with the olfactory cascade pathways in antennae, indicating that olfactory deficits induced by abdominal contact of fluvalinate may stem from specific neuropeptide pathways rather than the direct effects of neurotoxins. The current study was the first attempt to demonstrate the effects of xenobiotic chemicals on olfactory modulation in honey bees.

Efficacy of Beauveria bassiana ARP14 against egg of Bemisia tabaci (Homoptera: Aleyrodidae)

Authors: Lim Un Taek[2], Eun Jang La[1] and Arefur Rahman Md.[1], [1]Andong National University, South Korea, [2]Andong National University, South Sudan, South Korea

Abstract: We compared efficacy of Beauveria bassiana strain (ARP14) with commercial one (GHA) against eggs of Bemisia tabaci (Gennadius), important pest of many crops worldwide. After dipping eggs of B. tabaci in a concentration of 1×108 conidia/mL of the entomopathogenic fungus, mycosis rate of the eggs were assessed and found low for both ARP14 (12.5%) and GHA (10.0%) without statistical significance. However, mortality of hatched 1st instar became higher for both ARP14 (65.6%) and B. bassiana GHA (80.0%) with statistical significance. The egg period was significantly shorter in ARP14 (7.1 d) than either GHA (7.4 d) or control (7.5 d) at 25°C with unknown reason. In conclusion, B. bassiana ARP14 can be developed as a new mycoinsecticide to control B. tabaci.

Enzymatic characterization and evolution of a unique lepidopteran GMC oxidoreductase that re-arranges the green leaf volatile profile of plants

Authors: Lin Yu-Hsien[3], Allmann Silke[2], Wu Chia-Hsiang[4], Heijblom Sophie[2], Tan Ching-Wen[1] and Silven Juliette[2], [1]Department of Entomology, Penn State University, United States, [2]Department of Plant Physiology, University of Amsterdam, [3]Department of Plant Physiology, University of Amsterdam, Netherlands, [4]Institute of Entomology, Biology Centre CAS

Abstract: Lepidopteran hexenal isomerases (Hi) which are part of the GMC oxidoreductase family were first identified in the oral secretions (OS) of the Manduca sexta. When caterpillar OS comes in contact with damaged leaf, Hi causes a re-arrangement of the plant-derived green leaf volatile Z-3-hexenal (Z3AL) to E-2-hexenal. This change in the volatile profile serves as host location cue for conspecific moths, as well as their natural enemies. Phylogenetic analysis of putative Hi homologs from 32 Lepidopteran species revealed the presence of several Hi candidates in the advanced Ditrysia clade. Putative Hi homologs were furthermore sporadically present in some superfamilies of Obtectomera but ubiquitously in superfamilies of Macroheterocera. This suggests that Hi arose from the mid-Cretaceous, and its occurrence might be associated with the expansion of angiosperms. We further synthesized recombinant protein of Hi from Chloridea virescens, Danaus plexippus and Bombyx mori, and confirmed Hi activity under both in vitro (with synthetic Z3AL) and in vivo (on host plants) conditions. Interestingly, these Hi homologs not only showed different tissue-specific expression profiles, but also distinct pH optima. In summary, our study demonstrates the divergent enzymatic properties between different lepidopteran Hi and gives first insides into the evolutionary history of Hi in Lepidoptera.

Chalcidoidea Phylogeny in the Era of Genomics (Hymenoptera)

Authors: Lindsey Amelia[2], Zhang Junxia[1] and S. Peters Ralph[3], [1]Hebei University, China, [2]Indiana University, United States, [3]Zoologisches Forschungsmuseum Alexander Koenig, Germany

Abstract: Chalcidoidea (Hymenoptera) are a megadiverse superfamily of wasps that rank numerically among the largest groups of insects with an estimated 500,000 species. They are by far the most important group of natural enemies of insects in terrestrial ecosystems, and the majority of successful biological control projects have utilized these minute wasps for partial or complete control of insect pests. Currently, the superfamily is classified into 23 families and about 90 subfamilies. A recent temporal divergence study of Chalcidoidea suggested these wasps likely originated in late Jurassic, followed with rapid diversification between late Cretaceous and early Paleogene (75-53 mya). The rapid early radiation of Chalcidoidea has made it difficult to resolve its early evolutionary history using morphological and Sanger-sequencing data. In this globally collaborative project, we explore the application of phylogenomic approaches to resolve the backbone phylogeny of this megaradiation of wasps, utilizing the taxon-poor but gene-rich transcriptome data and the taxon-rich but gene-poor anchored enrichment data. The results provide valuable insights into the phylogenetics and character evolution across the superfamily. However, some of the backbone relationships on the Chalcidoidea phylogeny are still poorly supported even with the great wealth of genomic data. At the deeper nodes, the results uncover a wide spectrum of gene discordance in the transcriptomic markers and identified a strong signal of functional bias in genes supporting alternative phylogenies which is likely a signature of incomplete lineage sorting.

Roles of acetylcholinesterase genes in organophosphate and carbamate resistance in Leptinotarsa decemlineata

Authors: Lindström Leena[2], Lehmann Philipp[1], Chen Yolanda[4], Margus Aigi[2], Grapputo Alessandro[3], Gilbert Leona[2] and Piiroinen Saija[2], [1]Stockholm University, Sweden, [2]University of Jyväskylä, Finland, [3]University of Padova, Italy, [4]University of Vermont, United States

Abstract: The evolution of insecticide resistance is a major challenge for pest control and can also have great impact on human health, the environment, and non-target species. Pests can become resistant to insecticides through both quantitative (e.g. altered gene expression) and qualitative (e.g. mutation in binding sites) mechanisms. Despite increasing knowledge on the biochemical basis of insecticide resistance, there is little knowledge as to whether geographic populations may differ in their response to insecticides. We tested whether two populations of the Colorado potato beetle, Leptinotarsa decemlineata (Vermont, USA and Belchow, Poland) differ qualitatively or quantitatively in the expression of acetylcholinesterase genes (AChE), Ldace1 and Ldace2, which is the major contributor of the AChE catalytic enzyme and are associated with resistance to two commonly used insecticides, organophosphates and carbamates. We found that native USA beetles were 107 and 20 fold more resistant to azinphos-methyl and carbaryl insecticides, respectively, than introduced Polish beetles. Although both populations possessed similar frequency in the resistance-associated mutation (i.e. S291G) in the Ldace2 gene, the Vermont population had two nonsynonymous mutations (G192S and F402Y) in the Ldace1 gene that were absent in the Belchow population. Moreover, the Vermont population showed higher expression for the Ldace1 gene, and the Vermont population was also less sensitive to AChE inhibition by azinphos methyl oxon than the Belchow population. These findings demonstrate that the insecticide resistance can involve many different mechanisms, as native population possesses both qualitative and quantitative changes in target site, which both confer resistance to two common insecticides when compared to the introduced population.

Glyphosate-based herbicide affects the oxidative status and microbial composition of the Colorado potato beetle indirectly via soil

Authors: Lindström Leena[5], Rainio Miia[6], Mounger Jeannie[1], Margus Aigi[5], Gómez Gallego Carlos[4], Carmen Collado Maria[3] and Salminen Seppo[2], [1]Biodiversity Unit University of Turku, Finland, [2]Functional Foods Forum, University of Turku, Finland, [3]Institute of Agrochemistry and Food Technology, National Research Council (IATA-CSIC), Valencia, Spain, [4]University of Eastern Finland, Finland, [5]University of Jyväskylä, Finland, [6]University of Turku, Finland

Abstract: We examined whether glyphosate, a commonly used herbicide, affects the survival, oxidative status and intestinal microbiota of herbivores feeding on non-target plants. For our experiment, the Colorado potato beetles (Leptinotarsa decemlineata) were reared on potato plants grown in pots containing soil treated with glyphosate-based herbicide (GBH) or untreated soil. Per the manufacturer's safety recommendations, the GBH soil treatments were done two weeks prior to the potato planting. Three weeks after potato planting, two-day-old larvae were introduced to the potato plants and then collected in two phases, as 4th instar larvae and as adults. We found that GBH treatment had no effects on survival of the larvae or the adults. The oxidative status was affected by the GBH treatment. In larvae, total glutathione (tGSH) concentration and the enzyme activities of catalase (CAT), superoxide dismutase (SOD) and glutathione-S-transferase (GST) were increased in GBH treated group, suggesting GBH-induced activation in antioxidant enzyme activities to defend the beetles against reactive oxygen species. In adults, GR and CAT activities and tGSH levels were affected by interactive effect of GBH treatment and body mass of the adult beetles. The adult beetles had a higher overall microbial diversity and richness compared to the larvae, but neither diversity nor richness were significantly affected by the GBH treatment. However, the microbial composition of the beetles was affected by the GBH treatment, and the difference was more pronounced in the adults than in the larvae. The GBH treatment increased the number of Agrobacterium in the larvae and the adults. This effect may be related to the tolerance of some Agrobacterium species to glyphosate or to glyphosate-mediated changes in potato plants. On the other hand, the reduction of Enterobacteriaceae, Rhodobacter, Rhizobium and Acidovorax in the adult beetles and Ochrobactrum in the larvae after GBH treatment suggests their sensitivity to glyphosate. These results demonstrate that glyphosate can affect the antioxidant defence and intestinal microbiota of herbivores feeding on non-target crop plants.

Commercialization of a Successful Monitoring System and Other Practical Applications of Attractants for Brown Marmorated Stink Bug (Halyomorpha halys) Management

Authors: Lingren Bill[1], Short Brent[1], Kirkpatrick Danielle[1] and Chebny Vincent[1], [1]Trece, Inc, United States

Abstract: Commercialization of the brown marmorated stink bug (BMSB) monitoring system involved USDA ARS, multiple universities and many elements of Trécé's chemistry laboratory, field research and development, engineering and manufacturing teams all working together towards a common goal. Legal agreements in some cases were used to provide flexibility to cooperate and communicate between government and industry entities. Video conference, email and other communication technology along with site visits were strategically used to speed the development process. Careful planning and execution by all cooperating entities resulted in a rapid pace of development, where some projects were repeated in the same season to expedite data collection. The BMSB monitoring system development was highly complex, but other commercial products were created or benefited from related developments in a relatively short period of time. The creation and development of a long-lasting, reliable monitoring system focused on multiple tiers of technology including the active ingredient chemistry, controlled-release formulations, adhesives suitable for adult and nymphal insect capture under all outdoor environmental extremes, trap design and limitation of capture of non-target insects.

The phenology of ambrosia beetles (Coleoptera: Scolytinae) and their clerid predators in a montane forest in Taiwan

Authors: Liu Lan-Yu, Department of Science Communication National Pingtung University Taiwan, Taiwan

Abstract: The author investigated the wood-boring beetle fauna in the Cilan montane cloud forest area in Northeast Taiwan from 1 Jan. to 31 Dec. 2019. The Cilan Mountain Cypress Forest is an area of steep peaks and deep valleys at an elevation of c. 1,200 m, and home to some of the rarest fauna and flora in Taiwan. An average rainfall of 5,000 mm per year has given rise to a year-round mist that shrouds the forest's peaks. In this study, 6 multiple funnel traps baited with ethanol or ethanol and pinene were installed from 1520m to 1780m above sea level. This is the first study on ambrosia beetles to be carried out in the Cilan montane forest in Taiwan.

The results of the whole year investigation show that ambrosia beetles, mainly belonging to the tribe Xyleborini (Anisandrus, Euwallacea, Xyleborinus, Xyleborus and Xylosandrus), and to the genus Scolytoplatypus dominated the scolytine fauna. The tribe Xyleborini emerged mainly in April, and genus Scolytoplatypus mainly between Jan. and April. Three clerid predators of ambrosia beetles were found in this study. Callimerus sp. mainly emerged from Feb. to Apr., Diplopherusa sp. mainly emerged from Apr. to May in large numbers, and Opilo sp. emerged mainly in May and in low numbers compared to the other two species.

The emergence of ambrosia beetles in Cilan forest is primarily related to temperature. Trap location affects the diversity of ambrosia beetles, but the addition of alpha- or beta-pinene to the ethyl alcohol bait had no distinct effect on the results.

Changing gut bacteria diversity using antibiotic suppressed the reproduction of Bactrocera dorsalis

Authors: Liu Lijun[2], Li Zhihong[1], Shi Ge[3], Zheng Linyu[4], Shibly Norman Md[5] and Bai Zhenzhen[3], [1]China Agricultural University, China, [2]Department of Entomology, College of Plant Protection, China Agricultral University, China, [3]Department of Entomology, College of Plant Protection, China Agricultrual University, China, [4]Department of Entomology, College of Plant Protection, China Agricultural University, China, [5]Department of Entomology,College of Plant Protection, China Agricultural University, China

Abstract: The oriental fruit fly Bactrocera dorsalis (Hendel) is a destructive insect pest of a wide range of fruit crops. Because of the important part of gut bacteria in the development, reproduction and fitness of their host fruit fly, uncovering their function has become a worldwide question. Using antibiotics to remove gut bacteria is a common method to investigate gut bacteria function. In our previous study, the combination of three types of antibiotics (tetracycline, ampicillin and streptomycin) can significantly change the gut bacteria diversity of laboratory-reared Bactrocera dorsalis. However, the function of special gut bacteria is still not clear. In this study, we detected the infection of gut bacteria on the reproduction of B. dorsalis through feeding back experiment. The result showed that gut bacteria diversity changes using antibiotic prolonged the preoviposition period, suppressed the development of ovary and reduced the egg production significantly. RT-qPCR showed that the changes also resulted in different expression of the key genes in Insulin pathway (Akt, InR, IRS, FoxO), JH pathway (JHAMT, JHEH, Kr-h1) and 20E pathway (EcR, USP, E75). Feedback of one strain of bacteria named Enterobacter cloacae, which was isolated from the gut of B. dorsalis can eliminate these effects. This study forms a basis for deciphering the molecular mechanisms underlying the gut bacteria regulate reproduction via three important pathway in the oriental fruit fly. It also provides valuable resources for future studies on the correlation between insect and their gut bacteria.

Key words: Bactrocera dorsalis, gut symbionts, reproduction, Enterobacter cloacae, different expressed genes.

Effects of Viruses on Phytohormone Pathways and Plant-Insect Interaction

Authors: Liu Shu-Sheng, Zhejiang University, China

Abstract: Co-infection of plants by both viruses and insects is common in nature. Yet the dynamics of the tripartite system, in particular the effects of viral infection on plant-insect interactions and the factors involved, remained little studied until very recently. In this article we review the progress in research on these aspects of the tripartite interactions, explore the questions associated with the investigation, and suggest direction for future research on this exiting and likely fruitful field. Virus-induced changes of the tripartite interaction are in many cases attributable to the modulation of phytohormone pathways by viruses. Infection of viruses can affect significantly the synthesis and function of the three well-known phytohormones, i.e., jasmonates, salicylic acid and ethylene as well as plant-insect interactions associated with these phytohormones. The virus-induced changes of the dynamics of these phytohormones and other aspects in the tripartite system are influenced by both intrinsic and external factors such as plant nutrition, secondary metabolites and natural enemies of the vector insects. The effects of viral infection on other phytohormones, such as auxin, gibberellins, cytokinins, brassinosteroids and abscisic acids are yet to be investigated.

Effects of temperature and host instar on competition of two whitefly parasitoids

Authors: Liu Shu-Sheng[1], Liu Yin-Quan[1], Shao Yue[1] and Zhong Yu-Wei[1], [1]Zhejiang University, China

Abstract: For augmentation biological control, the choice of biological control agent is critical for scientists and growers. Eretmocerus hayati and Encarsia formosa are two species of important parasitoids of the whitefly Bemisia tabaci. In order to evaluate the parasitoids for more effectively usage, interspecific competition between the two species and effects of temperature and host instar were conducted in laboratory and plastic houses. The results showed that Er. hayati dominated in interspecific competition and could affect the outcome of En. formosa at 20°C, 27°C and 32°C. Parasitism rate per female of En. formosa was significantly reduced due to interspecific competition, whereas Er. hayati was not affected significantly. Both species of parasitoids showed preference to host instar. More offspring of Er. hayati were obtained from young nymphs of whitefly whereas En. formosa prefered to old nymphs of whitefly. However, the parasitoid Er. hayati is in a dominant position in competition regardless the host instar. The ability to discriminate and avoid hosts parasitized is a possible behavioral mechanism underlying.

The Unique Function of Buckwheat on Wireworm Control

Authors: Liu Suqi[3], Noronha Christine[1] and Bahar MD[1], [1]Agriculture and Agri-Food Canada, Canada, [2]Department of Agriculture and Land, Prince Edward Island, Canada

Abstract: Agriotes sputator is the principal wireworm species confronted by the agricultural industries in Prince Edward Island, Canada. Due to the lack of effective control methods and mounting population pressure, this pest has become a major concern not only in potato, but also many other crops.

Buckwheat (Fagopyrum esculentum) is usually cultivated as a cover crop to suppress or reduce weeds and improve soil condition. In our previous study, buckwheat gave significant potato tuber protection from wireworm damage. To clarify the potential mechanism, A series of bioassays were designed. The food choice test of wireworms with three commonly used rotation crops revealed a higher wireworm number with buckwheat plants compared to barley and red clover under both greenhouse and field conditions. Paired food choice test between two cover crops, buckwheat and clover, demonstrated a significantly higher larval number in buckwheat under greenhouse condition ($P<0.05$).

When neonate wireworm larvae were reared with either barley or buckwheat plants for 120 days, the body weight and head capsule of larvae fed on buckwheat were 60% and 30% less than the ones fed on barley. Compared to 44% larval survival rate on barley, only 15% neonate wireworms survived in buckwheat plants.

Under the laboratory condition with fresh carrot as a food source, medium sized wireworms spent three to seven weeks to fully develop and reach the next growth stage with the maximum percentage of increased head capsule size at 16.9 % after once molting. However, wireworm larvae produced as high as 37.9 % increased head capsule size by feeding on buckwheat root for 13 days. Feeding on buckwheat over 60 days resulted in a slow increased body weight but significantly greater increased size of the head capsule of medium sized wireworms compared to those reared on potato. Therefore, buckwheat does not repel wireworms, and the secondary metabolites in buckwheat roots impact the normal growth rate of wireworm larvae and eventually kill wireworms.

Systematics and evolutionary history of pleasing lacewings (Neuroptera: Dilaridae)

Authors: Liu Xingyue, Department of Entomology, China Agricultural University, Beijing, China

Abstract: The family Dilaridae, commonly called pleasing lacewing, is a small group of Neuroptera, which contains approximately 100 species in four genera worldwide except Australian region. This family is group of distinctive lacewings, characterized by the sexually dimorphic antennae, the presence of three ocellus-like tubercles on the head, and the narrowly elongate female ovipositor. Recent phylogenomic studies recovered that Dilaridae is a transitional lineage between the lower neuropterans (Coniopterygidae + Osmyloidea) and the clade including all higher neuropteran superfamilies. The faunal diversity of Dilaridae, particularly from the Oriental region, has been considerably increased by recent extensive taxonomic revisions. Here we summarized the current knowledge and recent progress on phylogeny of Dilaridae. The global species diversity of extant Dilaridae is overviewed. The latest results from the phylogenetic analyses of Dilaridae at the genus as well as the species level based on morphological and molecular data are presented. With combination of recently found dilarid fossils and distribution information, the evolution of the antennal sexual dimorphism and the historical biogeography of Dilaridae are recovered under the present phylogenetic framework.

Identification and functional characterization of sex pheromone receptors in mirid bugs

Authors: Liu Yang[1], Li Bin[1], Wang Guirong[1], Zhang Sai[1], [1]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: The mechanism of olfactory recognition in insects is a hot issue in neurology and chemical ecology, and the functions of pheromone receptors attract more attentions because of their special importance. Mirid bugs are a group of the important pests and cause a great amount of production lost in the fields. Due to the wide application of sex pheromones in the control of insect pests, extensive studies were focus on the isolation and identification sex pheromones in mirid bugs and the component and biological activity of the sex pheromones has also been studied. However, few studies have been focused on the mechanisms of pheromone perceiving.

Apolygus lucorum, Adelphocoris lineolatus, and Adelphocoris suturalis are the three common and seriously harmful pests in China. All of these three miridae species used (E)-2-hexenyl butyrate (E2HB), hexyl butyrate (HB), and (E)-4-oxo-2-hexenal (4-OHE) as the main components of the sex pheromone, which makes them an ideal model for studying the sex pheromone recognition mechanism of the mirid bugs. In this study, we first identified the OR repertoires in three mirid bugs Apolygus lucorum, Adelphocoris lineolatus and Adelphocoris suturalis through antennal transcriptomic sequence and bioinformatics analysis. The expression of all the candidate AlucOR genes in male and female antennae were analyzed by semi-quantitative RT-PCR (RT-PCR). Four AlucORs, five AlinORs, and five AsutORs, which were clustered in two branches of the evolutionary tree, were predicted as candidate PRs by comparative analysis of expression patterns and sequence alignment. And full length ORF of the 14 PR genes were verified by rapid amplification of cDNA ends (RACE) and cloned. Finally, we functionally characterized the 14 PRs in vitro using the heterologous expressing in Xenopus oocytes with two-electrode voltage-clamp recordings, and found 13 PRs could be activated by E2HB or HB. This work could provide a basis on understanding the olfactory recognition molecular mechanism in mirid bugs and lay foundation for developing novel strategies for the pest control.

Population regulatory possibilities of Aedes egg hatch inhibition by larvae

Authors: Livdahl Todd[1], [1]Department of Biology Clark University Worcester, Massachusetts, United States

Abstract: The inhibition or Aedes eggs by larvae, presumably through grazing of stimulatory microbes from egg surfaces, merits further attention. Experimental evidence of this phenomenon at both the intra- and interspecific levels is reviewed here, along with simple models developed to explore the theoretical possibility of inhibition as a regulatory mechanism as well as a factor influencing species coexistence or extinction. Laboratory evidence for inhibition is shown for Ochlerotatus triseriatus, Aedes albopictus and Aedes aegypti. Field evidence has been shown for Ochlerotatus triseriatus. Preliminary results of population models indicate that this phenomenon can regulate populations even in the absence of food limitations or other density dependent factors, as long as some minimal egg mortality occurs between hatch stimuli.

Sensory adaptation and dynamic odor representation in the honey bee antennal lobes

Authors: Locatelli Fernando[1], Gascue Federico[2] and Pirez Nicolas[2], [1]School of Exact and Natural Sciences University of Buenos Aires, Argentina, [2]University of Buenos Aires, School of Exact and Natural Sciences, Argentina

Abstract: Animals process and perceive environmental information in a flexible way. Some changes in perception are sustained and involve learning and memory processes while others occur quickly and are only transient. In this framework, sensory adaptation is defined as the phenomenon by which the sensitivity to a stimulus decreases after a sustained exposure to it. This phenomenon is characterized by a rapid loss of sensitivity and full recovery within few seconds after the stimulus disappears. Curiously, this phenomenon has been mostly studied by focusing on what the animal fails to perceive, but not on the consequences that it has on the perception of the stimuli for which the animal has not experienced adaptation. In this project we study the enriching effect that sensory adaptation has on the ability of animals to detect stimuli to which it has not been adapted and that would remain overshadowed by dominant stimuli under normal conditions. We use honey bees Apis mellífera that have a high capacity to learn and recognize odors. We perform behavior experiments to show that sensory adaptation reduces appetitive learning of adapted stimuli while it favors learning of minor components that would normally stay occluded. We studied this phenomenon at the level of sensory and projection neurons of the olfactory system. We determine that antennal lobe activation patterns that encode mixtures in the antennal lobe are drastically altered after sensory adaptation, in a way that favors the representation of stimuli that are present at sub-threshold concentrations. The results obtained so far emphasize that sensory adaptation is a fundamental mechanism to increase the sensitivity of the animal and not to reduce it.

Evolution of the genetic load in invasive insects: first insights from a genomic cross-species study

Authors: Lombaert Eric[2], Deleury Emeline[1] and Guillemaud Thomas[1], [1]INRA, ISA (INRA/UNSA/CNRS), France, [2]National Institute for Agronomical Research (INRA), France

Abstract: Biological invasions are a major component of global change. Yet it is still not understood why some introduced populations are invasive and others are not. Among the most interesting hypotheses is the purging of deleterious mutations during the introduction process. Deleterious mutations constitute what is called the genetic load because they are responsible for a decrease in the fitness of individuals by accumulating in the genome over time. After the introduction of a small number of individuals into a new area, high levels of inbreeding and genetic drift can have two major consequences: either the fixation or the purging of deleterious mutations. The assumption we make is that the populations that successfully become invasive are those that have purged part of their deleterious alleles. We currently work on a project that aims at testing the purge hypothesis on a large taxonomic scale – at least 10 invasive insect species. Using a pool-seq transcriptome-based exon capture protocol developed in our laboratory and suited to non-model species, we are quantifying and comparing the genetic load of native versus invasive populations. In this presentation, we will present a first round of results on two emblematic insect invasive species, the Asian ladybird Harmonia axyridis and the western corn rootworm Diabrotica virgifera virgifera.

My wave is THAT pushed: quantitative characterization of expansion dynamics with genetic and demographic data

Authors: Lombaert Eric[3], Vercken Elodie[3], Mailleret Ludovic[2] and Dahirel Maxime[1], [1]INRA, UMR 1355 Institut Sophia Agrobiotech, Sophia Antipolis, France, [2]National Institute for Agronomical Research (INRA), France, [3]National Institute for Agronomical Research (INRA), France

Abstract: Spatial expansions, like those of insect pests or their biological control agents, are characterized by strong variations in population density and composition that interact with evolutionary processes. The distribution of demographic, phenotypic and genetic diversity across time and space is thus a critical determinant of how populations are expected to evolve, sometimes dramatically, during expansion.

Propagation waves have been described as “pulled”, when expansion is driven by the reproduction and dispersal of few individuals on the edge of the propagation front, or “pushed”, when individuals from the core of the population are involved in its expansion. While pulled and pushed waves are likely to display contrasted eco-evolutionary dynamics, the definition currently available of the nature of a wave is based on specific mathematical properties of certain types of reaction-diffusion models, which strongly limits their use in practice and pleads for the definition of other, more practical, indicators.

Earlier results using numerical simulations revealed (i) that pure pulled waves tend to become pushed under stochastic conditions, and (ii) that depending on the demographic mechanism implied, pushed expansion dynamics deviated more or less severely from pulled expectations. Therefore, it appears that the distinction between pushed and pulled waves in empirical datasets is more likely a continuum than deriving from discrete categories.

In this work, we propose to define a “pushness index” to help characterizing more accurately the diversity of expansion patterns in nature. Using individual-based simulations and empirical data from laboratory expansions of parasitoid wasps of the genus Trichogramma, we investigate how expansions characterized by different underlying demographic mechanisms associated with pulled or pushed waves can be discriminated using quantitative metrics related to population and genetic dynamics in time and space.

Ecology of the chestnut gall wasp (Dryocosmus kuriphilus) in the western edge of sweet chestnut tree distribution in Europe

Authors: Lombardero María J.[4], Alvarez-Alvarez Pedro[5], Ayres Matthew P.[1], Nieves-Aldrey Jose Luis[3] and Castedo-Dorado Fernando[2], [1]Department of Biological Sciences Dartmouth College Hanover, United States, [2]Department of Engineering and Agricultural Sciences. University of Leon, Spain, [3]Museo Nacional de Ciencias Naturales (CSIC), [4]Unit for Sustainable Forest and Environmental Management. University of Santiago de Compostela, Spain, [5]Universidad de Oviedo

Abstract: The Asian chestnut gall wasp, Dryocosmus kuriphilus Yasumatsu, 1951 (Hymenoptera: Cynipidae), is a parthenogenetic species original from China that rapidly invaded Europe since its detection in 2002. The wasps lay eggs in the buds of chestnut trees (Castanea spp.) inducing galls on leaves, stipule, flowers and shoots. The consequences are significant economic damage due to a reduction of nuts and wood production, as well as a progressive decrease in tree vigour, which can make the tree susceptible to other secondary pests. We report here the results of a 4-year study of this species conducted in Galicia (NW of Iberian Peninsula), one of the most important areas for chestnut production in southern Europe. The insect was detected in 2014 but was apparently present at least two years earlier. It has since spread rapidly throughout the territory. It mainly dispersed naturally, although some long-distance dispersal events influenced the rate of spread across the landscape. Population abundance varies throughout the territory, and we were able to establish hotspot and coldspot areas, mainly associated with maximum temperatures in the summer months. At a local scale, the trees attacked by D. kuriphilus and the number of galls on each tree were spatially clustered in the first years from the invasion. Tree height significantly predicted both variables, suggesting that gall wasps may use visual cues to locate suitable host trees, at least in the early stage of invasion. The species showed a rapid recruitment of native parasitoids: three years after detection we found 19 species of native parasitoids attacking D. kuriphilus in Galicia. Percent parasitism by native parasitoids decreased greatly with time since introduction. This was because galls became larger, more thickly walled, and with more individuals per gall as the abundance of D. kuriphilus increased. Per capita growth rate of D. kuriphilus was linearly density dependent with an apparent equilibrium of ≈ 5.2 galls/shoot. D. kuriphilus in plots with low abundance had higher population growth rates. At high abundance, the number of suitable buds for oviposition decreased because the crowns had thinned, and only current year buds were available. Population abundance was higher in low quality sites. Our studies revealed seven hybrid clones resistant to the pest as well as high variability in the susceptibility of another 24 hybrid chestnut clones. Susceptibility did not depend on insect selection since there was no differences in number of eggs per bud among resistant or susceptible genotypes, and neither on changes of plant secondary metabolites during gall developmental. An early hypersensitive response within attacked buds that received eggs seems to be the most effective defensive trait of chestnut trees against the gall wasp.

Impact of active human complement on trascriptome and microbiota of Ae. aegypti and Ae. albopictus

Authors: Londono Berlin[2], Calle Arley[1], [1]Universidad de Antioquia Kansas State University, Colombia, [2]Vector Biology Laboratory, Dept. of Entomology, Kansas State University, Manhattan, KS, United States

Abstract: Our analysis shows that feeding Aedes mosquitoes induced significant changes in the expression of antimicrobial peptides in both Ae. aegypti and albopictus with significant differences in the expression of cecropins between the two species. Also, we observed an increase in Wolbachia replication in Ae. albopictus mosquitoes feed with normal human blood. Our studies suggest that activation of human complement in Aedes mosquito midguts may have a significant impact on the physiology and immune responses influencing the potential for transmission of arboviruses.

Spatial-temporal analyses of Glossina fuscipes fuscipes abundance in the West Nile region of Uganda

Authors: Longbottom Joshua[1], Stanton Michelle[2] and Torr Steve[2], [1]1Department of Vector Biology, Liverpool School of Tropical Medicine, Liverpool, UK 2Centre for Health Informatics, Computing and Statistics, Lancaster Medical, [2]Liverpool School of Tropical Medicine, United Kingdom

Abstract: Concentrated screening, accessible treatment, and vector control have resulted in a dramatic decline in the number of reported Gambiense human African trypanosomiasis (g-HAT) cases within Northern Uganda over the last two decades (average 877.6 cases per year during 1997-2001; 3.6 cases per year, 2014-2018) (World Health Organisation, 2020). Tiny targets, small pieces of impregnated fabric, are used to control tsetse within Northern Uganda, and play a vital role in suppressing tsetse populations to insufficient numbers to sustain transmission. In addition to vector control, other factors may be influencing tsetse population dynamics within the area such as land use change, climate change and urbanisation. The aim of this work was to analyse the spatio-temporal distribution of tsetse within a geostatistical modelling framework, and subsequently to investigate the influence of these factors on tsetse dynamics.

Between 2010 and 2019, pre- and post-intervention monthly tsetse abundance data were obtained from monitoring sites located in seven districts within the West Nile region of Uganda. Abundance data was collected through longitudinal monitoring (301 sites), or by exploratory surveys consisting of between one and three sampling days (310 sites). Such data were used to inform a spatio-temporal model exploring factors influencing tsetse abundance across the West Nile region. Firstly, remotely sensed data were combined with pre-intervention data (collected in the absence of vector control) within a species distribution-modelling framework to produce annual surfaces detailing habitat suitability. The species distribution model was informed by covariates describing several vegetation indices and environmental conditions believed to influence the distribution of riverine tsetse (Glossina fuscipes fuscipes). Spatial-temporal trends in monthly abundance were then characterised through the construction of a geostatistical model incorporating covariates detailing intervention coverage and associated metrics, temporal trends and habitat suitability outputs. Surfaces predicting spatial variation in tsetse abundance across the region were produced. Utilising the described model the relative contribution of each factor on the observed decline in tsetse abundance was assessed.

The generated results identify areas of tsetse persistence over time, providing information on the relative abundance of tsetse at previously un-sampled locations. The outputs described have the potential to guide further monitoring and control efforts within the West Nile Region of Uganda.

World Health Organisation. 2020. Global Health Observatory (GHO) data: Human African trypanosomiasis. https://www.who.int/gho/neglected_diseases/human_african_trypanosomiasis/en/ Accessed 10th February 2020.

Every Generalist Requires a Special Risk Assessment

Authors: Loomans Antoon, independent, Netherlands

Abstract: In an Environmental Risk Analysis benefits and risks of biological control agents and other beneficial organisms are assessed using criteria based on ecological determinants like the potential and impact of establishment and dispersal, on known and new hosts (host range vs specificity) and recorded direct and indirect non-target effects. There is a wide variety of natural enemies used for biological control, each of which has its specific biological and ecological requirements. Establishing the potential of its potential host range in its new area is one of the most challenging issues to be assessed prior to its introduction and release. Classical Biological Control programs of pest species nowadays mainly focuses on natural enemies specific for the target pest. In the regulatory requirements for regulation and the registration of non-native Invertebrate Biological Control Agents, assessment of host specificity is one of the main criteria in evaluating the risks, thus often excluding generalist predators and parasitoids a priori from being licensed. Here we will present and discuss several examples of different taxa with a generalist host range, and show that each of them have specific requirements and as a result require a specific risk assessment on their own.

What do environmental risk assessments tell us about non-target effects of omnivorous predators?

Authors: Loomans Antoon, independent, Netherlands

Abstract: The release of biological control agents (BCA's) is an important means to control plant pests worldwide in a sustainable and economic way. Prior to introduction and release of a natural enemy as a biological control agent, an assessment is necessary of both efficacy on the target pest as well as safety for the environment. In an Environmental Risk Analysis (ERA) information on a specific BCA or other beneficial is analyzed whether it is 'safe' to release, or not. Information on taxonomic identity, impact on human and animal health as well as the ecological impact are essential requirements. Main criteria to assess the environmental impact are the potential and impact of establishment and dispersal, impact on known and new hosts or prey (host range vs specificity) and recorded and potential direct and indirect non-target effects.

There is a wide variety of natural enemies used for biocontrol, each of which has its own specific biological, ecological and climatic requirements. Classical Biological Control programs of pest species traditionally mainly focuses on natural enemies which are specific for the invasive target pest. In Augmentative Biological Control programs in greenhouses and crops, a shift has taken place over time from the inoculative and inundative releases of monophagous or oligophagous natural enemies (parasitoids, predators) to the release of polyphagous or generalist predators (mainly predatory mites and predatory bugs). Omnivorous predators feed on more than one host or target species, but also on plants or fruits during the same life stage to survive and reproduce. Mirid bugs are an excellent example of this guild of predators, with a wide array of feeding strategies amongst species, varying from obligate carnivory to facultative or obligate herbivory. Establishing the potential of the potential host range of such an omnivorous BCA in a new area is one of the most challenging issues to be assessed prior to its introduction and release. Here we will discuss several examples of different taxa with an omnivorous prey range, and show that each of these BCA's has specific requirements on their own and as a result in specific non-target effects.

Separated at induction? Experiments with host plant associations and taxonomic boundaries of Diplolepis in western North America

Authors: Looney Chris, Washington State Department of Agriculture, United States

Abstract: The genus Diplolepis induces galls on rose species throughout the Northern Hemisphere. Most named species are described from the United States, but recent molecular analyses suggest that many currently accepted species are synonyms. Four of these species occur in the Pacific Northwest of the United States and Canada, in two distinct groups. In the Diplolepis bassetti and D. polita group the wasps induce round, unilocular galls on Rosa woodsii and R. nutkana, respectively. D. bassetti galls are covered by long dense hairs, while those of D. polita are covered by abundant thin spines. The molecular data raise questions about whether there are in fact two distinct species, or if one species induces galls that vary with host plant. To test these hypotheses, wasps of D. bassetti and D. polita were caged on both host plants in 2019-2022, and resulting galls examined. In all cases galls were only induced on the expected host, suggesting that they are distinct species. The experiment was repeated in 2020 and 2021 with another "problem" group that shares host plants but gall different plant tissues. Results and limitations of these experiments will be presented in light of the current taxonomy, and known distribution and host plants.

Interpopulation variation and intrapopulation plasticity of the thermal reaction norms for development in insects by an example of the linden bug, Pyrrhocoris apterus

Authors: Lopatina Elena, Saint Petersburg State University, Russia

Abstract: The degree and limits of phenotypic plasticity in insect development should adaptively change under the influence of natural selection in accordance with local climate characteristics and other environmental factors. As a result, geographic, interpopulation, seasonal, and other forms of variability of temperature and photoperiodic developmental norms arise.

Seventeen populations of the linden bug were studied at five constant temperatures (from 20 to 28°C) in the range from 32° to 58° of North latitude. Assuming a linear relationship between developmental rate and temperature we have demonstrated that the thermal sensitivity of egg and larval development shows a tendency to increase from the South to the North. Clinal variability of the thermal reaction norms for development (TRND) is more pronounced in larvae where the developmental time increases at 20°C and decreases at 28°C from the South to the North. As a consequence, there is a marked increase in both temperature thresholds and thermal sensitivity coefficient of development in northern populations.

The linden bug has an imaginal diapause, and so the larvae have to finish their development before winter falls. We found seasonal changes in TRND of larvae. In five studied European populations, larval developmental rate becomes gradually less dependent on temperature and proceeds faster at relatively low temperatures (below 24°C) and longer at relatively high temperatures, when the day length is reduced. A gradual decrease in the temperature threshold and the coefficient of the thermal sensitivity of development takes place. This allows the bugs to successfully reach the wintering stage before the winter onset. A peculiar change in TRND under the influence of photoperiodic conditions is observed in the linden bug population from Tel Aviv (Israel, 32°N), which lives in an arid Mediterranean climate. Here, the acceleration of larval development is induced by long-day conditions (16 hours) in the entire range of selected temperatures (from 20 to 28°C). In this case, the temperature threshold is lower than that under short day conditions (10 hours), and the thermal sensitivity of larval development is similar in both photoperiodic regimes. In Tel Aviv, linden bugs of the first generation have to complete development in the spring and early summer before the onset of summer drought. The development of the second generation takes place in the autumn. Slower development under short day conditions leads to the emergence of larger individuals that are able to successfully tolerate the lack of food in the winter in Israel at fairly high daytime temperatures.

The existence of the latitudinal variability of the thermal reaction norms for development in the linden bug and the presence of geographic differences in their photoperiodic plasticity allows P. apterus to maintain bivoltinism up to the northern boundary of its distribution.

The work is supported by the grant of Russian Foundation for Basic Research (RFBR N 20-04-00185a).

Colour preference in western flower thrips varies intraspecifically

Authors: Lopez Reyes Karla[1], Armstrong Karen[2], Teulon David[3], Butler Ruth[3], van Dooremalen Coby[5], Roher Monika[4] and van Tol Robert[5], [1]Bio-Protection Research Centre, Lincoln University, New Zealand, [2]Lincoln University, [3]The New Zealand Institute for Plant and Food Research Limited, [4]University of Zagreb, [5]Wageningen University and Research

Abstract: Discrepancies in literature regarding the response of the economically important pest western flower thrips (WFT) to different colours confounds extrapolation to the field to optimise traps for their management. To clarify whether differing experimental conditions of independent studies was a factor, or if intrinsic differences occur, we examined the colour responses of two WFT laboratory populations from Germany and The Netherlands that had independently shown different blue/yellow colour preference. To account for potential differences in host-rearing regime, both populations were established on bean for ~20 weeks, then on yellow chrysanthemum for 4–8 and 12–14 weeks. In blue/yellow LED lamp choice bioassays, country of origin, irrespective of rearing regime, remained a significant effect ($p<0.001$) with 65% of the Netherlands WFT landing on yellow compared to blue (35%), while 66% of the German WFT landed on blue compared to yellow (33%). There was also a significant host plant effect ($p<0.001$), with increased response to yellow, independent of country, after rearing on chrysanthemum for 12–14 weeks. Results suggest that original differing responses of WFT populations to colour is, in this case, a result of intrinsic differences and independent of experimental situation. Implications and underlying reasons for these results are discussed.

Mountain forest die-back and its impacts on terrestrial and aquatic insect diversity

Authors: Lopez Vaamonde Carlos[6], Sire Lucas[1], Schmidt Yáñez Paul[5], Zizka Vera[3], Rohe Erik[2], Müller Jörg[7] and Monaghan Michael[4], [1]IRBI, UMR 7261, CNRS – University of Tours – Tours, France, [2]Leibnitz-Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, [3]Leibniz Institute for the Analysis of Biodiversity Change , Germany, [4]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) – Berlin, Germany, [5]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) – Berlin, Germany, [6]National Institut of Agronomic Research (INRA)-Centre Val de Loire, Unité de Zoologie Forestière, 2163 Avenue de la Pomme de Pin CS 40001 Ardon, 45075 Orléans, France, [7]University of Würzburg, Germany

Abstract: Mountain forest ecosystems are under strong anthropogenic pressure. Increased mortality of key tree species due to rising global temperatures is a serious issue and is exacerbated through increased frequency of droughts and pathogen outbreaks, which results in drastic changes in forest structure and composition. Malaise trap sampling, to assess arthropod biodiversity, is gaining momentum as the method of choice for routine biomonitoring and the increased urgency induced by governments and the general public generates a favourable research environment. As passive devices malaise traps are perfectly suited for long-term, large-scale, nation-wide insect biomonitoring; however, morphological identification of the large numbers of collected insects is not feasible. We developed and applied DNA metabarcoding methods in an effort to identify insect taxa within Malaise trap samples.

This study was conducted in collaboration with the Bavarian Forest National Park, which has ample experience and a long tradition of research on mountain forests, in particular on Norway spruce (Picea abies), as well as an ongoing insect monitoring program.

From May to October 2017, we collected insects using malaise traps on 10 forest plots within each of three different forest habitats (intact, naturally disturbed, salvage-logged) for a total of 240 samples. Malaise traps were emptied every 2 weeks. We also collected kick-net samples in May 2018 from 10 streams within each of the same 3 habitat classifications to complement the terrestrial samples. After minimal handling, DNA was extracted from bulk subsamples and DNA metabarcodes were generated using Leray-Geller primers (313 bp mitochondrial COI) and Illumina MiSeq sequencing. PCR replicates, twin-tagging, a mock community and negative controls were used to ensure quality for subsequent sequencing and bioinformatics. Terrestrial samples were filtered using the DAMe pipeline with modifications, and a custom R script was employed to obtain OTU assignments from the BOLD database.

A total of 63% of ~4000 OTUs could be identified to species with a confidence of > 97%. Species richness differed only slightly between habitats but species composition was significantly different between habitats, showing high temporal and moderate spatial turnover. Plots within the intact forest communities had the fewest shared species compared to disturbed and salvage-logged forests. We expect the aquatic invertebrates to also respond to the effects of climate change on forests, although it is difficult to predict the patterns. Stream invertebrates are more dependent on abiotic factors such as sedimentation and direct solar irradiation leading to potentially different responses. The methods developed and knowledge gained is intended to help practitioners and policy-makers improve current biomonitoring programs for both terrestrial and aquatic communities facing alterations due to climate change.

How new knowledge on the pathology of baculoviruses modify their use as biological control agents

Authors: Lopez-Ferber Miguel[3], Graillot Benoit[1] and Blachère-Lopez Christine[2], [1]Bioline Agrosciences, Pôle R&D, Valbonne, France, [2]LGEI, IMT Mines Alès, France and SPE, INRAE 400, France, [3]LGEI, IMT Mines Alès, France

Abstract: Baculoviruses are known to regulate many insect populations in nature. They are host-specific and usually restricted to a single or a few closely related insect species, and it has been shown that they have no, or negligible, effects on non-target organisms (beneficial insects, plants and vertebrates). Accordingly, baculovirus-based pesticides are one of the safest existing pesticides. They can be used in integrated pest management strategies and contribute reducing the use of synthetic chemical insecticides and the risks associated. To date, they have been used for 30 years with success and with some issues; most of them due to the lack of knowledge on the relationships between baculoviruses and hosts. The new researches on baculovirus infections in insects and the problems encountered in field treatment have brought new hints to increase their effectiveness as biocontrol agent (resistances, directed evolution, better comprehension, gene regulation, IPM utilization…). This paper is a review of what is currently known about baculovirus pathology and how it influences its utilization as a biological control agent.

Tips and Tricks for Developing Genomic Tools for Hemipterans

Authors: Lorenzen Marce[1], Whitfield Anna[1], Rotenberg Dorith[1], Grubbs Nathaniel[1], Huot Ordom[1] and Klobasa William[1], [1]North Carolina State University, United States

Abstract: Despite the power of CRISPR/Cas9-based genome editing, published reports of confirmed genome editing in hemipteran species are rare. Here we add a new hemipteran species to the list, the corn planthopper, Peregrinus maidis. While we had an excellent "guidebook" to follow – CRISPR/Cas9-based genome editing of the brown planthopper, Nilaparvata lugens – the process of deploying this technology in a new planthopper species was far from easy. Therefore to aid others working with hemipteran species, we plan to offer a number of tips and tricks we wish we had known. We will start from the first step, that of developing genomic and transcriptomic resources for P. maidis. The next steps involved developing protocols for harvesting and microinjecting precellular embryos, which are critical for Cas9-based genome editing, since DNA and proteins cannot easily cross cell membranes. The later steps cover Cas9-based genome editing itself, including selection of target genes. For example, drawing on the work performed in N. lugens, we initially targeted the pivotal eye-color gene, white (w), which results in white eyes when disrupted in the brown planthopper. However, while Cas9-mediated knockout of w was successful in generating P. maidis embryos that lacked eye-spot pigmentation, only embryos that still possessed eye-spot pigmentation hatched. Since this suggests that w may play a vital role in P. maidis development, we tested another eye-color gene, cinnabar (cn). Unlike w, loss-of-function mutations in cn had no apparent impact on development, allowing us to establish a red-eyed P. maidis colony. Our current work focuses on a more difficult challenge, that of editing the genome of the bird cherry-oat aphid, Rhopalosiphum padi, during clonal reproduction. Importantly, these are merely the first steps towards a much boarder goal: bringing game-changing genomic tools to bear on understanding and controlling these important agricultural pests.

Male sexual communication in a vector of Chagas disease requires robust expression of the ionotropic co-receptor IR8a

Authors: Lorenzo Marcelo[2], Barcelos Pontes Gina[3] and Manuel Latorre Estivalis Jose[1], [1]CREG-CONICET, UNLP, Argentina, [2]CVIP, IRR-FIOCRUZ, Brazil, [3]FCEyN-UBA, Argentina

Abstract: The ionotropic receptor co-receptor IR8a has been reported to have multiple roles in arthropod chemosensory processes. This co-receptor seems critical for both mosquito host seeking, while it has been reported to have significantly higher expression in the antennae of a male copepod. We recently reported increased expression of IR8a in the antennae of male Rhodnius prolixus, a main vector of Chagas disease. In this study, we will present results showing that lack of robust expression of RproIR8a induces limited male performance in the mating context of the latter species. The RNAi technique was used to significantly knock-down the expression of RproIR8a. Insects having been exposed to knock-down of this genes were used for two behavioral experiments to test male sexual performance. In a first experiment, RproIR8a knocked-down males failed to leave shelters in the presence of females in the arena, when compared to mock (non-specific dsRNA injected) or intact males. In the same experiment, a lower proportion of knocked-down males approached females when compared to both control conditions. In a second experiment, a significantly lower proportion of RproIR8a knocked-down males mated up to 20 minutes when compared to males exposed to the two control conditions. To our knowledge, our report is the first to incriminate an IR co-receptor in the sexual behavior of an insect. Further experiments are necessary to establish details about sensory processes underlying these negative effects on male sexual performance.

Global decline in ladybird diversity: Causes and consequences

Authors: Losey John E.[1], Haelewaters Danny[2] and Gill Harsimran E.[1], [1]Cornell University, [2]Ghent University, Czech Republic

Abstract: The last several decades have seen a major shift in the global complex of ladybird beetles (Coccinellidae) from a diverse assemblage of "native" species to one of reduced diversity and dominated by a few cosmopolitan species, especially Harmonia axyridis. The extremely rapid decline and current rarity of several native species presents challenges for determining species distribution and collecting specimens to initiate laboratory colonies to allow further testing. These challenges have been addressed through several citizen-science projects across the world that educate non-specialists and recruit them to become ladybird beetle "spotters". Combining these submitted observations with directed experiments using captive populations, and comparing to published studies we have begun to test the potential role of introduced coccinellids in the decline of native species. All results point to increasing domination of H. axyridis and corresponding loss of coccinellid diversity at a global level. Modelling these trends will aid in predicting the ability of the coccinellid complex to aid in pest suppression in the future and facilitate the development of international strategies to restore and maintain coccinellid diversity.

Forecasting biological control efficiency of grapevine pest under climate change by using fine-grain climatic modelling and a multi-trait approach

Authors: Louâpre Philippe[2], Iltis Corentin[3], Thiéry Denis[1] and Moreau Jérôme[2], [1]INRA - UMR Health and Agroecology of vineyards, France, [2]University of Burgundy UMR CNRS 6282 Biogéosciences, France, [3]University of Burgundy, France

Abstract: Because of their key position in trophic webs, the ability of insects – as hosts or natural enemies – to respond to climate change may determine the evolution of trophic system's structure and dynamic. For instance, the way phytophagous insects modify their physiology and their behavior with raising temperature may force natural enemies to evolve in order to maintain in natural or agricultural systems.

Based on in situ climatic data and projections from climate models, we tracked the variation in individual performance of a major grapevine pest, the European grapevine moth (Lobesia botrana), and the associated consequences for interactions involving this phytophagous insect and adjacent trophic levels, more specifically parasitoids. The experiments to be presented here combined both an increase in mean temperature, and an alteration of daily thermal range, as two local facets of climate change captured by climate models.

Results highlight an impact of temperatures on defensive traits of the grapevine moth (at egg and larval stages) and adult reproductive success, with repercussions for the interaction between this pest and their associated larval and egg parasitoids. Furthermore, our results reveal an important variability of thermal responses occurring among several traits. The ability of the grapevine moth to deal with pressures exerted by natural enemies for the coming century should be constrained by several trade-offs between immune function, defensive behaviors, and reproduction. Hence, predicting life history trait evolution in host-parasitoids interactions under climate change requires adopting an integrative perspective of the biology of the focal species (here the host) while considering the complexity of changes occurring in insect direct thermal environment.

#SciComm at the interface of disciplines

Authors: Lovett Brian, University of Maryland, Department of Entomology, United States

Abstract: Interdisciplinary science is best positioned to address challenges facing the modern world, and innovative technology, tools, and apps facilitate international collaborations across disciplines, allowing researchers to answer increasingly complex questions. Researchers working at the interface of multiple disciplines face unique challenges when communicating their results. For example, mycologists who study fungal groups that are pathogenic or (ecto-) parasitic on insects must learn the terminology for each discipline relevant to their work, which can present barriers for communicating with audiences that are familiar with field-specific jargon. Though this may be prohibitive initially, this issue can prime interdisciplinary scientists to be effective communicators. Communicating science at the interface of disciplines requires scientists to constantly assess who their audience is, what they already know, and what they value. Additionally, it encourages scientists to move away from using jargon. This increased audience awareness is a gateway for effective science communication, as understanding your audience enables a tailored, high-impact message. Bridging the gap between disciplines at a professional level effectively prepares interdisciplinary scientists for bridging communication gaps with the public. This is a profound benefit to practicing interdisciplinary science, which should be considered when evaluating and training scientists as effective communicators in academia and outside. Here we discuss some of the challenges related to interdisciplinary research from personal experience, present suggestions for improved communication, and make a case for tying the skill of interdisciplinary science communication to the academic hiring process and (tenure-track) promotions.

Using public education to reduce household insecticide use

Authors: Lowe Lizzy, Macquarie University, Australia

Abstract: Insecticide use in urban areas has a detrimental impact on both public and environmental health. Overuse of chemical pest control products by residents is common, with people often applying pesticides even when there is no threat to health or property. The problem of excessive insecticide use is driven by attitudes and management practices, therefore it requires an approach that integrates the social and ecological sciences. To understand household pest control practices, I conducted an online survey asking people about their attitudes towards insects, why they do/don't use insecticides and which products they use.

My survey received 1878 responses, mostly from the Sydney area. We found that 83% of respondents use insecticides of one kind or another, the most popular of which were broad spectrum insect sprays and cockroach baits. Attitudes towards insects were more moderate than expected, with most people choosing to ignore or conserve insects (with the exception of mosquitoes and termites), especially in their gardens. Promisingly, of those who use sprays, the majority (68%) of people prefer to use a small amount over a restricted area, rather than small or large amounts over a large area.

I am using this new understanding of public attitudes to develop targeted community education materials and provide guidance to local governments to help reduce insecticide use. Examples of public education initiatives include: public talks, school yard biodiversity surveys, pamphlets distributed by local councils, and pesticide free pledges for local community gardens.

Does infection of endosymbiotic bacteria Wolbachia cause the high female-biased population of coffee berry borer Hypothenemus hampei?

Authors: Lu Hsiao-Ling, Department of Biotechnology, National Formosa University, Taiwan

Abstract: Coffee berry borer (CBB) is an important economic pest, which was invaded Taiwan in 2007 and caused injury. Previous studies on CBB have shown that they coexist with endosymbiotic bacteria Wolbachia and display a characteristic of a female-biased sex ratio in the population. Due to its encrypted life cycle, female-biased population, and a handful of basic biological information, current strategies cannot suppress pest population efficiently. We aim to promote CBB as a model for studying the mechanisms of insect sex determination, symbiosis, embryonic development and to develop pest-control strategies for those pests that spend most of their life cycle inside of plant host. To explore whether the female-biased population is caused by Wolbachia and the mechanism of sex determination for producing more female offspring, we adopted a polymerase chain reaction protocol to detect the maternally inherited cytoplasmic proteobacteria Wolbachia in total genomic DNA from CBB collected from 42 sample sites in southern and central Taiwan. Our preliminary results show that only one sample yields positive detection. The low Wolbachia infection rate of coffee berry borer highlights that the female-biased sex ratio may be regulated by other mechanisms.

Current situation and trend for red imported fire ant in mainland China

Authors: Lu Yongyue, Red Imported Fire Ant Research Center, South China Agricultural University, China

Abstract: Red imported fire ant Solenopsis invicta Buren is one of the 100 most threatening alien species in the world. Originally distributed in parts of South America, it has invaded 24 other countries and regions now. Because of its ferocious habits, rapid reproduction and strong competitiveness, it is easy to outbreaks and cause disaster in a short period of time after the invasion, and will endanger agriculture and forestry, human health, biodiversity and public safety. The fire ant was found in Taoyuan, Taiwan in Sept., 2003, and Guangdong, mainland China on Sept., 23, 2004. As a new invasive species in China, although it was paid serious attention by the governments, institutions, the public and scientists, but the fire ant still has kept spreading fast after its invasion.

In order to delay its expansion and control its infestation, many Action Plans, and science and technology programs on the fire ant had been carried out and completed in China. The National Fire Ant Detection and Management Union, and Advisory Committee were found in 2005. Red Imported Fire Ant Research Center, South China Agricultural University was built up in July, 2005. And then, work plans, technical plans for quarantine and extermination, and technical training plans at the national and provincial levels were presented, and implemented in the infected areas with the fire ants. National and provincial emergency management plans for plant quarantine pests was proposed and implemented firstly in mainland China. Standard framework and procedure for the fire ant management was also put forward, and 6 national, industrial and local standards were promulgated before 2009. Since finding the fire ant invasion, more than 4 million USD was invested in R&D, and more than 150 million USD in recent 5 years were used in the fire ant management in mainland China. The infestation degree of the fire ant at most of the infected area decreased below the middle level, and the fire ants had been eradicated successfully at 9 independent infected areas after the high intensity measures had been adopted.

According to its spreading speed with 27 county-level regions per year in the past 15 years, it was predicted that more than 400 county-level regions would be infected by the fire ant in the late 2019. There were already 15 provincial regions infested by the pest, including Hongkong, Macau, Taiwan, Guangdong, Guangxi, Hainan, Fujian, Zhejiang, Jiangxi, Hunan, Hubei, Guizhou, Chongqing, Sichuan, and Yunnan. The general trend was that the ant was expanding northward, and invading the Yangtze River Basin constantly. It was not ruled out that there may be sporadic invasion and occurrence in North China, Northeast China and Northwest China because of the extensive greenhouses in the future.

Bacteriocyte function and inheritance in the bacterial symbiosis of whiteflies

Authors: Luan Junbo[2] and Douglas Angela[1], [1]Cornell University, United States, [2]Shenyang Agricultural University, China

Abstract: Various insects require intracellular bacteria that are restricted to specialized cells (bacteriocytes) and are transmitted vertically via the female ovary. It is of great interest to investigate the function and inheritance of such novel host cells. We discovered that multiple horizontally acquired genes with bacteria origin are enriched in the bacteriocytes of the whitefly Bemisia tabaci. Each horizontally acquired gene can function with other genes in the pathway coded by the symbiont, while facilitating the decay of the symbiont gene coding the same reaction. We found that developmentally orchestrated remodelling of gene expression and correlated changes in cell behaviour underpin the capacity of bacteriocytes to mediate the vertical transmission and persistence of the symbiotic bacteria on which the insect host depends. We further demonstrated in the whitefly B. tabaci MEAM1 species, transmission is mediated by somatic inheritance of bacteriocytes, with a single bacteriocyte transferred to each oocyte and persisting through embryogenesis to the next generation. Then we investigate the mode of bacteriocyte transmission in two whitefly species, B. tabaci MED, the sister species of MEAM1, and the phylogenetically distant species Trialeurodes vaporariorum. We demonstrated that B. tabaci MED bacteriocytes are genetically different from other somatic cells and persist through embryogenesis, as for MEAM1, but T. vaporariorum bacteriocytes are genetically identical to other somatic cells of the insect, likely mediated by the degradation of maternal bacteriocytes in the embryo. These two alternative modes of transmission provide a first demonstration among insect symbioses that the cellular processes underlying vertical transmission of bacterial symbionts can diversify among related host species associated with a single lineage of symbiotic bacteria.

Pavement ants to population genomics: using citizen science to benefit invasion science

Authors: Lucky Andrea[4], Hulcr Jiri[2], Payton Adam[3], Storer Caroline[3], Dunn Rob[1], McDaniel Stuart[3], Vitone Tyler[3] and Zhang Yuanmeng[3], [1]North Carolina State University, United States, [2]School of Forest, Fisheries, and Geomatics Sciences, University of Florida, United States, [3]University of Florida, United States, [4]University of Florida, United States

Abstract: Clarifying the population structure and introduction history of non-native species is essential to preventing and mitigating effects of invasion, yet the invasion history of many long-established non-native species remain poorly understood. We characterized the population structure of one of the most commonly encountered urban ants in North America using public participant-collected specimens from the School of Ants citizen science project, in combination with double-digest restriction-site associated DNA sequencing (ddRADseq). Based on this genomic approach we confirm the identity of populations ranging across the continent as Tetramorium immigrans Santschi, and report low genetic diversity across its range, suggesting that this entire population resulted from the establishment of one single, or few closely related ant colonies, approximately two hundred years ago. The absence of strong population structure suggests that this ant's spread across North America has been repeatedly aided by human-assisted dispersal. We find no evidence of inbreeding in T. immigrans; this contrasts with the inbreeding and unicoloniality of many other invasive ants. These results demonstrate how collections-based public participatory science and emerging high-throughput sequencing techniques each have the potential to vastly improve the amount of data available to researchers; together, these techniques can be deployed to address ecological and evolutionary questions in non-model organisms, including invasion biology. We suggest that this model is particularly well suited for research on common taxa that are ecologically important but poorly understood.

Effect of Genetically modified Corn on non-target arthropods in Mexico

Authors: Luis A. Aguirre[1], Hernández-Juárez Agustín[1], Cerna Ernesto[1], Ochoa Yisa M.[1], Flores Mariano[1], Frias Gustavo[1] and Sánchez Victor M.[1], [1]Universidad Autonoma Agraria Antonio Narro

Abstract: Approval of genetically modified corn (GM) under controlled conditions in Mexico, allowed to evaluate corn hybrids AgrisureTM 3000 GT, Agrisure® VipteraTM 3110 and Agrisure® VipteraTM 3111 events, with several genes coding Cry1Ab, Vip3Aa20 and mCry3A proteins of Bacillus thuringiensis (Bt), in Sinaloa, Mexico Effect over non-target arthropods was evaluated determined by community attributes: number of families, arthropods abundance, diversity, richness, and population uniformity. A Kruskal-Wallis and U Mann Whitney test were used to estimate abundance to detect differences between populations of GM and conventional corn. Phytophagous and predators associated with maize were found more abundant in the GM events, whereas parasitoids and saprophagous were evenly distributed among hybrids, where the statistical analysis showed no significant differences between the GM and their respective conventional hybrids. Management of corn pests with GM hybrids is a control strategy to be incorporated into an integrated pest management program, increasing possibility to obtain better grain quality and yield. No adverse effects on abundance of non-target arthropods associated with corn was found; providing better opportunity to use this technology, which will reduce the use of chemical insecticides. Therefore, this technology can help preserve agroecosystem biodiversity in relation to other pest management options

Microbial symbioses as a critical aspect of insect community ecology

Authors: Lukasik Piotr[1], Kolasa Michal[1], Nowak Karol[1], Buczek Mateusz[1], Prus Monika[1], [1]Jagiellonian University, Poland

Abstract: Symbiotic microorganisms have played crucial roles in the ecology and evolution of insects. They have enabled major ecological transitions, and still influence their hosts' biology in multiple ways, often highly significant in heterogeneous and changing environments. With their ability to affect insect traits such as performance on different diets and susceptibility to natural enemies or abiotic stressors, and move within and across host populations or species, microbial symbionts can be viewed as an enormous genetic reservoir for their host's rapid adaptation to environmental challenges. However, our understanding of microbial diversity, distribution, and roles in natural populations and communities of insects has been limited.

Recent developments in high-throughput sequencing and bioinformatics have allowed studies of microbial associations across very large numbers of samples. My research group has devoted substantial efforts to the implementation and optimization of cost-effective and scalable approaches for quantitative amplification of host and microbial marker genes. We have successfully applied them to over ten thousand diverse wild insects. In this presentation, I will outline our methods and explain what we have learnt from looking at community-level host-microbiota datasets. I will also talk about the challenges, limitations, and possible applications of such approaches.

Not just nitrogen: Ancient, waste-recycling turtle ant symbionts encode complex carbohydrate catabolism

Authors: Lukasik Piotr[3], Russell Jacob[4], Bechade Benoit[2], Cabuslay Christian[2], Sanders Jon[1] and Hu Yi[2], [3]Drexel University, United States, Poland, [4]Drexel University, United States, [2]Drexel University, United States, [1]Cornell University, United States

Abstract: The work combines experimental and genomic inferences. We show directly that symbiont-recycled waste nitrogen is acquired by ants in large capacity. And we demonstrate the genetic mechanisms by which this occurs, and the symbionts responsible. We also show that ancient symbionts have retained capacities to break down plant cell wall biomass, suggesting an unforeseen capacity reminiscent of that seen for termite gut communities.

The digestive systems of many ants are sparsely colonized by microbial symbionts. But ants from several lineages with nitrogen-poor diets provide strong exceptions, harboring large masses of gut bacteria, which they transmit through trophallaxis. Turtle ants of the genus Cephalotes provide an intriguing example, engaging in ancient interactions with a diverse suite of specialized symbionts, which populate the midgut and ileum of adult workers. Using stable isotope labeling, and antibiotic manipulation, we show that gut bacteria recycle nitrogen-waste in adult turtle ants, and host ants acquire this recycled nitrogen in large quantities. Genomic analyses reveal specialized recycling roles for a subset of the bacteria, and that the majority can assimilate ammonia and synthesize amino acids. Further assessment of symbiont genomes reveal an unexpected feature - several specialized bacteria encode enzymes for the degradation of plant cell walls, including cellulases and xylanases. These enzymes are also encoded by the less specialized gut residents found in turtle ant larvae. We hypothesize that these conserved interactions function as multi-faceted, nutritional and digestive mutualisms, setting Cephalotes apart from most other ants. We also conclude that the use of nitrogen-limited diets have been facilitated by convergent acquisition of unrelated waste-recycling symbionts, but that unrelated herbivores derive idiosynchratic benefits from their unique symbioses.

DNA metabarcoding reveals host-specific communities of arthropods residing in fungal fruit bodies

Authors: Lunde Lisa, Norwegian University of Life Sciences (NMBU), Ås, Norway

Abstract: Many arthropods spend their immature life inside fruit bodies of wood-decay fungi. There is a succession of arthropod species within the fruit body as it ages, but earlier research has focused more on the fauna inside dead, rather than living, fruit bodies. Further, how fungal traits, like fruit body persistency and size, affect arthropod communities is poorly explored. Using DNA metabarcoding, we characterised the arthropod communities in living fruit bodies of eleven wood-decay fungi from boreal forests and investigated how they were affected by different fungal traits. Arthropod diversity was higher in fruit bodies with a larger surface area-to-volume ratio, suggesting that colonisation is crucial to maintain arthropod populations. Diversity was not higher in perennial fruit bodies, most likely because these fungi invest in defences against arthropods. Arthropod community composition was structured by fruit body size, thickness, surface area, morphology and toughness. Notably, we identified a community gradient where soft and annual fruit bodies harboured more dipterans, while tougher and perennial fruit bodies had more oribatid mites and beetles. Ultimately, close to 75% of the arthropods were specific to one or two fungal hosts. Our study has revealed surprisingly diverse and host-specific arthropod communities within living fungal fruit bodies.

Undersowing clovers in oats supports pollinators but does not benefit biological pest control

Authors: Lundin Ola[2], Boetzl Fabian[1], Douhan Sundahl Anna[1], Friberg Hanna[1], Viketoft Maria[1], Bergkvist Göran[1], [1]Swedish University of Agricultural Sciences, [2]Swedish University of Agricultural Sciences, Department of Ecology, Sweden

Abstract: A promising way of achieving more sustainable agricultural production is by replacing external inputs such as fertilisers and pesticides with yield-supporting ecosystem services generated by beneficial organisms within the agroecosystem. Increasing plant diversity within the field by intercropping with legumes has potential to achieve this but the effects on biodiversity and ecosystem services are so far not sufficiently understood. Using a design with paired plots in commercially cropped fields, we studied the effects of intercropping oats with a mixture of three annual undersown clovers on a total of 16 below-and above-ground ecosystem service indicators that included pollinator densities, insect pest damage, activity densities of natural enemies and predation rates. Intercropping promoted pollinators but had no effect on pest damage, predation rates, carabids or rove beetles, and a slightly negative effect on spiders. Additional benefits of intercropping included suppression of arable weeds and root-feeding nematodes, and a tendency of increased soil mineral nitrogen. Oat yield levels were not affected by intercropping, whereas oat yield nitrogen content unexpectedly decreased by ca. 4%. Undersowing annual clovers is a simple method to support pollinators without reducing cereal crop yields or taking land out of arable production. Intercropped plant mixtures should, however, be optimised to benefit natural enemies and biological pest control in order to support a higher level of overall cropping system multi-functionality.

Microplitis bicoloratus bracovirus modulates innate immune suppression through the eIF4E-eIF4A axis in the insect Spodoptera litura

Authors: Luo Kaijun, School of life Sciences,Yunnan University, China

Abstract: Eukaryotic initiation factor 4E (eIF4E) is regulated during the innate immune response. However, its translational regulation under innate immune suppression remains largely unexplored. Microplitis bicoloratus bracovirus (MbBV), a symbiotic virus harbored by the parasitoid wasp, Microplitis bicoloratus, suppresses innate immunity in parasitized Spodoptera litura. Here, we generated eIF4E dsRNA and used it to silence the eIF4E gene of S. litura, resulting in a hallmark immunosuppressive phenotype characterized by increased apoptosis of hemocytes and retardation of head capsule width development. In response to natural parasitism, loss of eIF4E function was associated with similar immunosuppression, and we detected no significant differences between the response to parasitism and treatment with eIF4E RNAi. Under MbBV infection, eIF4E overexpression significantly suppressed MbBV-induced increase in apoptosis and suppressed apoptosis to the same extent as co-expression of both eIF4E and eIF4A. There were no significant differences between MbBV-infected and uninfected larvae in which eIF4E was overexpressed. More importantly, in the eIF4E RNAi strain, eIF4A RNAi did not increase apoptosis. Collectively, our results indicate that eIF4E plays a nodal role in the MbBV-suppressed innate immune response via the eIF4E-eIF4A axis.

Plant–Pathogen Interactions under Herbivore Influence: Applying Evidence from the Coexistence of Wheat Spikes Colonizers

Authors: Luo Kun, Shaanxi Key Laboratory of Chinese Jujube, Yanan University, China

Abstract: The English grain aphid Sitobion avenae Fabricius (Hemiptera: Aphididae) and the fungus Fusarium graminearum Schwabe (Hypocreales: Nectriaceae) are two economically important pests residing on wheat spikes, a ‘synergistic’ relationship between the coexistence of S. avenae and F. graminearum on wheat spikes resulting in devastating damage to grain yield and quality was detected. However, the biological and ecological reasons why herbivore pre-exposure positively influence the plant–pathogen interactions have been understudied. In recent decades, extensive studies typically focused on unravelling more detail on the relationship between wheat–aphids and wheat–pathogens, which have greatly contributed to our understanding of this tripartite interactions at ecology level. Here we synthesize recent advances related to the tripartite interaction S. avenae–cereal–F. graminearum from the aspects of environmental nutrients and hormonal signals. We propose that the aphid honeydew excreted by S. avenae and their endosymbionts provide ready-to-use nutrients accelerating infection by the pathogen F. graminearum. Furthermore, F. graminearum infection is associated with accumulation of the growth phytohormone auxin, possibly interfering with hormone-dependent defense responses and stimulating the infected plants to release more nutrients. The findings highlights the relevance of herbivore S. avenae pre-exposure to trigger the accumulation of mycotoxins production, which stimulates the infection process of F. graminearum and epidemic of Fusarium head blight in natural ecosystems.

Chemical defense responses of Douglas fir seedlings to bark beetle associated blue stain fungi

Authors: Lusebrink Inka, Georg-August-University, Göttingen, Germany

Abstract: Douglas-fir is considered as a great hope for European forests in the face of climate change, however it is non-native. ... In Central Europe a few native bark beetles are pests in Douglas fir, including the fir bark beetle (Pityophthorus pityographus), the six-toothed spruce bark beetle (Pityogenes chalcographus), the larch bark beetle (Ips cembrae) and the European spruce bark beetle (Ips typographus). However, they have not caused major damage so far, but it is likely that the adaptation process of native bark beetles to Douglas-fir will continue and that increasingly successful attacks will occur on Douglas-fir in the future. Most bark beetles carry blue stain fungi that are considered critical to overcome tree defenses and to cause host tree mortality, additionally they lead to a reduction in the value of timber. In order to assess if the blue stain fungi associated with the above-mentioned bark beetles (1) are able to establish in or kill Douglas fir; and (2) induce different chemical defense responses, a seedling experiment was conducted. ... full abstract see attachment

Ultra-low fruit fly populations in mosaic landscapes: behavior, development, establishment and detection.

Authors: Lux Slawomir A., inSilco-IPM 05-510 Konstancin-Jeziorna insilico-ipm.eu, Poland

Abstract: Periodic detections of medfly in areas recognized as fly-free raises a lot of theoretical and regulatory controversy. The latter can be largely reduced to the question: “how long can local populations survive in the cryptic ultra-low-density phase and remain undetected by the surveillance network”.

To answer this question in the absence of empirical options, a series of stochastic simulations were carried out, emulating the behavior, development and fate of individual members of the residual / initial medfly populations. For this purpose, the PESTonFARM model was used, parameterized according to current knowledge about medfly biology and its behavior in the field conditions. The simulations were carried out for a specific area where medfly was recently detected, taking into account the key features of local topography, historical weather patterns and a surveillance system.

The projections generated by the model support the hypothesis about the possibility of the prolonged existence of cryptic populations fluctuating at very low densities, which may slip out of the surveillance grids and remain undetected for longer periods of time. Analysis of various scenarios emulated by the model has revealed a number of specific environmental factors that, acting simultaneously, are able to maintain fly populations at low densities. The application of the model also allowed estimating the chances of detection for various scenarios of terrain topography, host and weather patterns.

The theoretical and practical implications of the proposed approach and methodology, its key merits and limitations, were also discussed.

Methods for studying insects on carcasses for the use of data in determining postmortem interval. Cases from practice.

Authors: Lyabzina Svetlana[3], Basalaev Kosta[3], Prichod’ko Andrey[1] and Sikkelia Natalia[2], [1]Bureau of Forensic Medical Inspection, Russia, [2]independent researcher, Finland, [3]Petrozavodsk State University, Russia

Abstract: Carrion insects have recently been often used in criminal investigation. From large species of them, information on the biological characteristics of Diptera and Coleoptera is used. These insects, with good access to the corpse, in very quickly of time colonize it and lay eggs or give birth to larvae, and give high accuracy in establishing the postmortem interval (PMI). During experiments of the decomposition of pig carrion (Sus scrofa domesticus), the species spectrum and analyzed the chronological succession colonized a corpse by insects. During studies four stages of decomposition of carcasses was recognized. In Russia, the practice of using knowledge of invertebrate fauna to solve in establishing the postmortem interval (PMI) under unclear circumstances are increasingly being introduced. Most often Diptera use from the families blowflies (Calliphora vicina, Protophormia terraenovae, Cynomyia mortuorum), flesh flies (Sarcophaga) and houseflies (Hydrotaea dentipes). In cases where large species of necrophilic beetles, such as carrion beetles of the genus Necrodes, it accelerates tissue decay. This is facilitated by severe damage to the skin and deep internal holes caused by beetles. A complication for diagnosis can be caused by the presence of ants or the presence of corpse near an anthill.

Influence of lipopolysaccharide from bacteria on the expression of BmToll9-2 gene in larval silkworm

Authors: Lyu Xin[1], Liu Jisheng[2], [1]Guangdong Institute of Applied Biological Resources, China, [2]Guangzhou University, China

Abstract: Toll-like receptors in Toll signaling pathway in insects play an important role in activating the innate immune response to invading pathogenic microorganisms. This study aims to explore the influence of lipopolysaccharide (LPS) on the expression of the Toll-like receptor gene BmToll9-2 in larvae of the silkworm, Bombyx mori. LPS and Escherichia coli were respectively injected into the body cavity of the 5th instar larvae to induce their immune response, and the expression levels of BmToll9-2 after injection were detected by real-time quantitative PCR. The real-time quantitative PCR results showed that injection of LPS could induce the expression of BmToll9-2 in the midgut of the 5th instar larvae. Injection of E. coli could also induce the expression of BmToll9-2 in the midgut of the 5th instar larvae. Expression of BmToll9-2 in B. mori larvae is up-regulated after injection of LPS and E. coli, suggesting that BmToll9-2 receptor may be involved in the recognition process of Toll-like receptors to LPS and E. coli in insects.

Phylogenomic species delimitation of the twisted winged parasite genus Stylops (Strepsiptera)

Authors: Lähteenaro Meri[1] and Nylander Johan[2], [1]Stockholm University, [2]Swedish Museum of Natural History

Abstract: The advancements both in sequencing technologies and in statistical models used to analyse genomic datasets have provided new tools to resolve taxonomical controversies in many historically problematic groups. Stylops is the most species rich genus of the insect order twisted winged parasites (Strepsiptera) and has been the subject of alternating species concepts based on their host specialization, with vast implications for species diversity estimates. The concept of a single supergeneralist species in Europe (Stylops melittae Kirby, 1802), has been challenged by studies based on single molecular markers. In our study, we aim to resolve the controversies around the species delimitation of Stylops with adequate molecular data and species delimitation analyses. We generate whole-genome sequence data for over 200 samples, with a focus on European taxa, representing a large selection of the candidate species presented in a recent preliminary world checklist of Stylops. These include both freshly collected material and museum samples from 94 different host species. We use BPP which allows analysing multi-locus genomic sequence data under the multispecies coalescent model, to test the species limits. Here we present preliminary results of the phylogenomic species delimitation analyses and discuss their implications for the taxonomy and diversity of Stylops.

Relationship between the thermal tolerance of cereal aphids and their bacterial symbionts

Authors: Ma Chun-Sen[3], Zeeshan Majeed Muhammad[1], Zhang Bo[2], [1]1 Department of Entomology, College of Agriculture, University of Sargodha, Pakistan 2 Climate Change Biology Research Group, State Key Laboratory, [2]Climate Change Biology Research Group, State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences of Agricultural Sciences, [3]Climate Change Biology Research Group, State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: High temperature events influence the demographic parameters and population performances of insects such as aphids. This could be due to the complete or partial disturbance of their gut-associated symbionts during the physiological acclimation of host insect species to extreme high temperature events. This study aimed to determine if there was any effect of heat acclimation and chronic heat exposures on the density and community structure of symbiotic bacteria of cereal aphids Rhopalosiphum padi (L.) and Sitobion avenae (F.). Aphid clones were randomly collected from the wheat fields and were reared in the laboratory at 20±1 °C and 50-65 % RH with 16L:8D h photoperiod. Thermal tolerance indices (chronic, basal and acclimated CTmax) were determined for five-day old female aphids from parental, F1, F2 and F3 generations. Quantification of total (16S) and aphid-specific bacterial symbiont gene copy numbers was done by real-time q-PCR. Results revealed that thermal thresholds (both basal and acclimated) gradually increased from parental to F3 generation. On average, thermal threshold values of R. padi were 1.0°C higher than those of S. avenae. Although average total bacterial (16S) density was found higher in S. avenae than R. padi, average density of symbiont genes per aphid was almost similar for both aphid species. Temperature-tolerant aphid individuals harboured significantly higher symbiont genes than susceptible ones for both species. Moreover, thermal tolerance indices of both aphid species were found significantly correlated with gene densities of total symbionts (16S), Buchnera aphidicola, Serratia symbiotica, Hamiltonella defensa, Regiella insecticola and Spiroplasma spp, suggesting their role in thermal tolerance of host aphids.

Night warming on predator–prey interactions: Implications for biological control

Authors: Ma Gang[2], Ma Chun-Sen[1] and Bai Chun-Ming[2], [1]Climate Change Biology Research Group, State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [2]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: Most previous research concerning climate warming on interspecific interactions mainly focus on changes in temperature means, with a rise in both daytime and nighttime temperatures or a rise just in daytime temperatures. However, it has been found that the rise of global mean surface air temperatures has resulted from daily minimum temperatures increasing at a faster rate than daily maximum temperatures. Importantly, daytime and nighttime warming may lead to different thermal effects on organisms, indicating that night warming may have different effects on species and interspecific interactions from that of daytime warming. Thus, although many studies have reported the ecological consequences of warming in mean temperatures, nighttime warming are often omitted. Here we used the lady beetle Propylaea japonica and the English grain aphid Sitobion avenae as a predator–prey model system to study the effect of night warming on interspecific interactions. We examined how night warming would affect the demographic parameters, stage structure and population growth of the lady beetle. We also compared the different effects of night warming and mean temperature increase.

Compared with mean temperature increase, nighttime warming accelerated the growth rate of the lady beetle while reduced the reproduction, but had no significant effect on life span. The lifetime predation and energy efficiency of the lady beetle decreased with temperature under constant conditions while changed little with temperature under night warming, which indicated that the energy efficiency of the lady beetle was stable under realistic nighttime warming. Both nighttime warming and mean temperature increase altered population structure of the lady beetle, with the proportion of adults increased with temperature whereas the proportion of larvae decreased with temperature. The proportion of adults was higher than that of constant temperature warming. Importantly, the population growth rate of the lady beetle decreased with temperature under mean temperature increase while increased with nighttime warming, which indicated an opposite result of warming effect on predator–prey interspecific interactions between nighttime warming and mean temperature increase. These results and conclusions have important significance for the study of warming effects on insects and interspecific interactions. Our study thus has potential implications for biological control in the context of ongoing climate change.

Thermoregulation-mediated predator-prey interaction under climate warming

Authors: Ma Gang[3], Ma Chun-Sen[1] and Bai Xue[2], [3]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [1]Climate Change Biology Research Group, State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [2]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: Previous studies concerning climate warming on insects mainly focus on the direct effects of temperature increase. However, the indirect effects through interspecific interactions are often overlooked. Behavioral thermoregulation is an important strategy to cope with climate warming in insects. Therefore, under climate change, the changes in interspecific interactions may be indirectly caused by insect thermoregulation behavior due to the differences in thermal tolerance between species. Small insects like sap-sucking aphids can avoid thermal extremes such as heat stress either by walking away or dropping-off form their host plant to seek for cooler places. Here, by using the English grain aphid Sitobion avenae and the lady beetle Propylaea japonica as a model predator-prey model, we aimed at revealing the interspecific interaction between the aphid and its natural enemy mediated by the thermoregulatory behavior of the aphid under climate warming. We tested the hypothesis that the fitness related life history traits of the lady beetles can be altered by the thermoregulatory behavior of the aphids. Our results showed that behavioral thermoregulation can increase aphid survival under warming while lead to changes in body size, development and reproduction. Such changes in fitness related parameters of the aphid altered the life history traits of the lady beetle and thus support our hypothesis. Therefore, the effects of climate warming on species mediated by thermoregulation behavior highlight the indirect effects of climate change on trophic cascades. Insect behavioral thermoregulation should be taken into account when predicting the changes in interspecific interactions as well as biological control and ecosystem functioning under climate change.

Thermal resilience of Prostephanus truncatus (Horn): Can we derive optimum temperature-time combinations for commodity treatment?

Authors: Machekano Honest[3], Nyamukondiwa Casper[1], D Singano Charles,[2], Chidawanyika Frank[4], Mutamiswa Reyard[5] and Joseph Virgil[3], [1]Botswana International University of Science and Technology, Botswana, [2]Chitedze Agricultural Research Station, Department of Agricultural Research Services, Malawi, [3]Department of Biological Sciences and Biotechnology, Botswana International University of Science and Technology (BIUST), Botswana, [4]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [5]University of the Free State, South Africa

Abstract: Prostephanus truncatus (Horn) (Coleoptera: Bostrichidae), is a wood-boring, destructive quarantine insect pest of stored cereal grains and tuber crops. Current disinfestation methods against this pest mainly include fumigants, whose usage in some countries has been contested and discontinued owing to increasing pesticide resistance, public health risks and environmental hazards. Grain temperature treatments thus, offer a sustainable non-chemical and near universally acceptable form of disinfestation for international commodity movement. Currently, blanket temperature treatments are applied regardless of as-yet-unknown P. truncatus developmental stage thermal mortality thresholds that simultaneously optimise grain quality. Here, we used established static and dynamic protocols to determine the low and high thermal profile of P. truncatus larvae and adults measured as critical thermal minima (CTmin), lower lethal temperatures (LLT0), chill coma recovery time (CCRT), supercooling points (SCPs), critical thermal maxima (CTmax), upper lethal temperatures (ULT0) and heat knock-down time (HKDT). We tested the adult ULT-time matrices on maize and sorghum grain quality (germination %) to determine the most effective temperature-time combination retaining optimum grain germination quality. Our results showed adults had higher basal heat (CTmax and HKDT), cold (CTmin, CCRT and SCP) and potential thermal plasticity than larvae ($P < 0.05$). The LLTs and ULTs ranged -1 to -15°C and 41 to 49°C respectively. Using LLT0 and ULT0, our results showed that for heat treatment, moderate temperature × long duration matrix; i.e. either 45.5°C × 4 h or 47°C x 2h were more efficacious while retaining commodity quality. Similarly, for cold treatment; -9°C × 4 h, -11°C × 2 h, -13°C × 1 h and -15°C × 0.5 h were effective for complete mortality. These temperature-time combinations may be a sustainable alternative to fumigants in phytosanitary grain disinfestation against P. truncatus or related pests. Such pest- and commodity- specific thermal profiling is critical for development of effective standardised grain disinfestation protocols.

It’s raining species: Rainwash eDNA metabarcoding as a minimally invasive method to assess tree canopy invertebrate diversity

Authors: Macher Till-Hendrik[1], Schütz Robin[1], Hörren Thomas[1], Beermann Arne[1] and Leese Florian[1], [1]University of Duisburg-Essen, Germany

Abstract: Forest canopies are highly diverse ecosystems, but despite decades of intense research, substantial knowledge gaps of their biodiversity remain. The limited accessibility of these ecosystems is a fundamental challenge. Here, time- and cost-efficient, ideally minimally invasive yet comprehensive applications are required to help close this knowledge gap. A solution could be provided by metabarcoding of environmental DNA (eDNA). This minimally invasive method has been proven as efficient monitoring tool in various ecosystems, yet its potential for canopy monitoring remains unexplored. Thus, we conducted metabarcoding on eDNA collected from rainwater that fell through tree canopies to explore its monitoring potential. We placed four 1 m² rain samplers beneath the canopies of four different tree taxa prior to a major rain event, filtered eDNA from the collected rainwater, and performed eDNA metabarcoding to profile the invertebrate community. We detected 50 invertebrate species by eDNA metabarcoding, of which 43 were representing true canopy biodiversity signals. Furthermore, we observed clear species occurrence patterns corresponding to the four tree taxa, suggesting that ecological patterns can be assessed using the method. In conclusion, our study provides a proof of concept that rainwash eDNA metabarcoding offers a minimally invasive and comprehensive method for tree canopy diversity monitoring.

Dissecting physiological cause and effect at the limits of insect thermal performance

Authors: MacMillan Heath, Carleton University, Canada

Abstract: The limits of environmental stress are increasingly appreciated as important predictors and determinants of insect biogeography. Unfortunately, complexity and variation at multiple levels of biological organization create a formidable barrier to determining what physiological and molecular mechanisms set the limits of environmental stress tolerance. Progress in our understanding of these limits (and thus our ability to make sound predictions) will require systematic approaches that embrace this complexity and allow us to separate the causes of failure from the physiological consequences that can quickly follow. In this talk, I will give an overview of the ionoregulatory collapse model of insect chill susceptibility. Using this model as an example, I will attempt to convince you that integrative models that explain cause and effect links among multiple organ systems will allow us to quickly arrive at a holistic understanding of the many and varied challenges facing animals under environmental stress.

Consistency in provision of nutrients in dung beetles: Seasonal changes in nutrient levels.

Authors: Macphee Madzivhe Fhulufhedzani[1], Tocco Claudia[1], Harrison James[1] and Byrne Marcus[1], [1]School of Animal, Plant and Environmental Sciences University of the Witwatersrand Johannesburg, South Africa

Abstract: The nutrient content of animal dung is important for the growth, development and activity of dung beetles. The dung itself is a metabolic end product. It is made up of partially digested, undigested and undecomposed food particles such as plant cell walls, bacteria, fungi and gut epithelial cells. This leads to dung having a high carbohydrate content and very little protein. The nitrogen source is important for growth and reproduction. Protein, measured as nitrogen, changes with the seasons because of forage, temperature and moisture content fluctuations, and can affect factors such as dung beetle activity and egg production.

In this experiment we investigated how dung beetles manipulate nitrogen in the dung when feeding and nesting, and also how they respond to changes in dung nutrients across the seasons when nesting and feeding. The maternal gift from the brood balls of Euoniticellus intermedius and the foregut contents of Kheper nigroaeneus and Scarabaeus goryi (all Coleoptera: Scarabaeinea) were compared monthly with that of the raw dung. The maternal gift is a maternal addition to the broodball.

Relative to raw dung the nitrogen content of the foregut and maternal gift increased, and carbon content remained the same, while the C:N ratio decreased during ingestion. In contrast the nitrogen and carbon content, and the C:N ratio of the raw dung changed with the seasons throughout the year. The nitrogen content of the maternal gift and the foregut content of each species increased throughout the seasons by a percentage, while the carbon content changed little compared to the raw dung. Furthermore, the C:N ratio of the raw dung corresponded with the nitrogen and carbon content throughout the seasons while that of the foregut and maternal gift remained the same. Dung beetle nutrient provision appears not to be driven by nitrogen alone but both the carbon and nitrogen content. Despite seasonal changes in C:N ratios of the raw dung (driven presumably by changes in herbivore forage quality), selective feeding by adult dung beetles enables them to maintain a sufficiently nutritious intake and provide a nutritious maternal gift, “starter” diet for the newly hatched larva.

Edible Insects and the Collection of the Natural History Museum Bulawayo (NHMB), Zimbabwe

Authors: Madamba Dorothy C[1] and Musundire Robert[2], [1]Curator of Entomology Natural History Museum, Bulawayo, Zimbabwe, [2]Department of Crop Science and Post harvest Technology, Zimbabwe

Abstract: A report on research attempting fully to document available data and specimens of edible insects in the natural history museum of Zimbabwe and to raise awareness on the role of museum collections in taxonomy and monitoring of species distributions. The project also highlights the museum's role in gathering information on indigenous knowledge systems that have sustained the practice of Entomophagy and disseminating knowledge to relevant stakeholders. The Zimbabwean story tell of entomophagy as a fairly commonly accepted practice in the country. We wish to contribute to consolidating answers on how much knowledge of the practice still exists, what the extent of entomophagy is as well as the number of species still known and available in Zimbabwe, and to give an account of efforts made thus far in testing farming methods for these insects in the country. Micro-livestock have been proven to offer more nutrition per gram compared to the conventional livestock, with the added advantage of ease of rearing. Exploring already existing information will count towards making strides to deliberately rear insects to improve livelihoods and show museums as central to gathering and disseminating information on edible insects.

The three insulin receptors of cockroaches

Authors: Maestro Jose L.[1], Belles Xavier[1] and Escudero Jorge[1], [1]Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: The insulin receptor pathway, remarkably conserved throughout Metazoan evolution, regulates such important processes as cell growth and proliferation, sugar levels, longevity, stress resistance, and reproduction. Insects generally have two insulin receptors (InR) as a result of an ancestral gene duplication. However, in the lineage that gave rise to the Polyneoptera branch that includes stick insects, termites, and cockroaches some 250 million years ago, a further duplication occurred that increased InR number to three. There are three outcomes in the evolution of duplicated genes. One is that one copy is functionally redundant (nonfunctionalization). Another is that one copy acquires a novel function, while the other retains the original one (neofunctionalization). A third possibility is that both copies may become partially compromised to the point at which their total capacity is reduced to the level of the single-copy ancestral gene (subfunctionalization). Using the cockroach Blattella germanica as a model, we are seeking to determine the function of its three InRs, and the evolutionary fate of the new duplication. Until now, the results show that InR2 is the most abundantly expressed gene in all tissues examined, and its depletion produces the most dramatic effects in relation to the female reproductive processes.

The life-table parameters of Perilla Seed bugs (Nysius Spp.) (Heteroptera: Lygaeidae: Orsillinae) in different radiofrequency fields

Authors: Maharjan Rameswor[1], Song Dukyoung[1], Yi Hwijong[2], Jung Tae-Wook[1], Yoon Youngnam[1] and Jang Yunwoo[2], [1]Department of Southern Area Crop Science, National Institute of Crop Science, Rural Development Administration, South Korea

Abstract: The genus Nysius is polyphagous pests, and it can cause a serious damage to seeds, foliage and flowers of various plants. In this study, we investigated the oviposition preference, development, and adult performances of Nysius plebeius and Nysius hidakai at five Radiofrequencies of 0 (control), 5, 10, 20, and 30 kHz on perilla seeds. In addition, the effects were also studied in four generations (Parent, F1-, F2-, and F3-generation) of each species. The results showed that radiofrequency application had significant effects on the life-table parameters of Nysius species. Radiofrequency exposures on species not only affected developmental period, adult weight and longevity, but also negatively affected the fecundity of subsequent generations. The total developmental period from egg to adult emergence was longer and adult longevity was shorter in the radiofrequency treatments than in the untreated control. Reduced the radiofrequency level further affected the life-parameters of Nysius species. The lowest rate of adult emergence and the shortest adult longevity both occurred at 5 kHz. The outcomes of this study are discussed in terms of targeting susceptibilities to radiofrequency as an alternative to chemical treatments.

Revising the phylogenetic position of the genera Ablattaria, Phosphuga and Silpha

Authors: Mahlerová Karolina[1] and Ruzicka Jan[2], [1]Department of Ecology, Faculty of Environmental Sciences, Czech University of Life Sciences Prague, Czech Republic, [2]Faculty of Environmental Sciences, Czech University of Life Sciences Prague, Czech Republic

Abstract: The phylogenetic position of the genera Ablattaria Reitter, 1884, Phosphuga Leach, 1817 and Silpha Linnaeus, 1758 of the subfamily Silphinae (Coleoptera: Silphidae) is unclear and variable in different classifications. The genus Ablattaria is either classified as a sister lineage to Phosphuga and Silpha, or all three taxa are treated as subgenera of broadly defined Silpha. The genus Ablattaria contains four extant species, the genus Phosphuga two species and the genus Silpha has 22 species (with 18 species in the Palaearctic region). The genera have diverse food strategies. The genera Ablattaria and Phosphuga are specialized gastropod predators, and the species belonging to the genus Silpha are either necrophagous, scavengers or predaceous. The centre of the distribution of all genera is through Palaearctic Region, Trans-Palaearctic in Phosphuga and Silpha (with highest diversity and high endemism of the later in Nepal and China) and Western Palaearctic in Ablattaria. The relationship of the three genera was carried on collected specimens belonging to six species (P. atrata Linnaeus 1758, S. carinata Herbst 1783, A. laevigata Fabricius 1775, S. obscura Linnaeus 1758, S. olivieri Bedel 1887 and S. tristis Illiger 1798) stored in 96% ethanol in -25 °C and additional sequences available from NCBI. Three genes (two mitochondrial – 16S and COI and one nuclear – 28S) were used to uncover the phylogenetic relationship of the genera within the crown lineage of the subfamily Silphinae.

Semiochemical-based management of stored product insects: Mating disruption and mating delays

Authors: Mahroof Rizana, Department of Biological and Physical Sciences South Carolina State University Orangeburg, United States

Abstract: Current research have focused on non-chemical alternatives for the control of stored product insects with the ban of methyl bromide and the many problems associated with the use of other synthetic chemicals. Mating disruption either using synthetic sex pheromones in storage environments along with laboratory manipulated mating delays are some of the techniques investigated in this study. The effect of age at mating on the reproductive rate and longevity of the cigarette beetle, Lasioderma serricorne (Coleoptera: Anobiidae) was determined. The mating approach was disrupted by delaying the insects from mating for different time periods in days. Same age virgin male and female cigarette beetles were paired to mate soon after emergence (0 day old), or delayed from mating for 1–14 days. In another experiment, we maintained the age of the male at 0 day old and varied the age of the female from 0¬–14 days old and vice versa. Insects were observed daily for longevity and F1 progeny was recorded 7–10 weeks after set up. Progeny production generally decreased with age of adults at mating. Average developmental time, adult body size and adult dry weight for F1 and F2 generations were estimated. The number of F1 progeny produced by same age adults varied from 59 per female to 10 per female. Similarly the number of progeny decreased the longer one of the sex was delayed from mating. Findings from this study may provide biological insights on mating disruption techniques and how it may be effective in keeping populations of L. serricorne below levels that would warrant a control action.

BMSB management strategies on tree fruits in Italy

Authors: Maistrello Lara, Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy

Abstract: The brown marmorated stink bug (BMSB) is an invasive hitchhiker and a plant pest, which primarily threatens fruit and vegetable crops. Since its first discovery in Italy in 2012, it has rapidly spread throughout the country and in Europe. Recognized as a key pest of orchards since 2015, a dramatic situation occurred in 2019, when fruit production losses in northern Italy were estimated at € 588 million. Biological parameters obtained in an outdoor life table study showed it has two generations/year and high reproduction rates for both generations. Field and laboratory investigations indicate that the potential for biocontrol by native antagonists is currently quite limited. The establishment of BMSB has brought about a radical transformation of the management of the orchards, causing an impressive reversal of the trend towards sustainability. Currently BMSB control is mainly based on broad-spectrum insecticides and the maximum number of treatments allowed has doubled since 2014, resulting in disruption of existing Integrated Pest Management (IPM) programs, with an increasing negative environmental impact. The management of BMSB is particularly challenging, and chemical control has proved ineffective due to the general robustness, as well as to the high polyphagy combined with the high mobility of all instars, which result in continuous movements of insects between different host plants. More sustainable approaches to manage BMSB in fruit orchards include the use of exclusion netting systems and behaviour-based strategies such as “attract and kill” and IPM-Crop Perimeter Restructuring (IPM-CPR). However, none of these strategies proved to be both fully successful and easily applicable in different contexts.

Long-term and more sustainable management strategies include inundative and classical biological control with native and exotic antagonists, respectively. However, in European countries the use of exotic biocontrol agents is restricted by the ‘Habitats directive’. Although Anastatus bifasciatus (Hymenoptera, Eupelmidae) is the most successful native species in parasitizing BMSB eggs, augmentative field releases with this species did not lead to an effective reduction of the BMSB population.

Field surveys on naturally laid BMSB egg masses revealed a widespread presence of adventive populations of the non-native parasitoids Trissolcus japonicus and T. mitsukurii (Hymenoptera, Scelionidae) in northern Italy, Switzerland and Slovenia in 2018-2020. In 2020, in Italy, following the high negative economic impact caused by BMSB on fruit production, a decree of the Italian Ministry of Environment and of Land and Sea Protection finally authorized the use T. japonicus for the BMSB biocontrol, leading to one of the largest biological control projects ever attempted in Italy and Europe.

Reduction of unpleasant odours from HO.RE.CA. leftovers used for black soldier fly rearing

Authors: Maistrello Lara[1], Antonelli Andrea[1], Masino Francesca[1], Montevecchi Giuseppe[1], I. Macavei Laura[1], Gammaitoni Marco[1] and D'Arco Sara[1], [1]Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy

Abstract: The larvae of the black soldier fly Hermetia illucens (Diptera, Stratiomyidae) can be reared on a wide variety of organic substrates, such as HO.RE.CA. (Hotel-Restaurant-Catering) leftovers that include heterogeneous foods: pasta, pizza, bread, rice, meat and fish scrapes, vegetables, fruits, eggshells, bivalve shells, oily condiments, spices, etc. However, during the rearing process, strong and unpleasant smells are released from the growth substrate. The present study aims at improving this undesirable aspect through the addition of materials with adsorbent properties to the feeding substrate. Finely ground grape stalks (212-500 µm), coarsely ground grape stalks (500-850 µm), activated charcoal, and zeolitite were selected for the investigation, due to their adsorbent properties.

The rearing methodology consisted in providing 300 g of HO.RE.CA. substrate to 100 young larvae and the addition of the specific adsorbent material (6% w/w). To evaluate the volatiles released by the system (consisting of: substrate, larvae and their excretion products, outcome from microbial metabolism, and adsorbent material), sampling was performed at 2, 5, 7, 9, 12, 14, 16, 19 days after larvae inoculation. The volatiles were determined using through solid phase microextraction (SPME) of head space over substrate aliquots using 27 cm3 vials, sealed with a rubber septum and a metal ring. The samples were oven conditioned at 35 °C (15 min), after which the needle of the SPME holder was introduced through the septum and the fibre exposed for 15 min.

A gas chromatograph (GC) coupled with a mass spectrometer (MS), equipped with a carbowax-like column, was used to carry out a semi-quantitative analysis of volatiles. Peak identification was performed by comparing mass spectra with those of pure reference standards and those present in software libraries (Nist 14 and Wiley).

The volatile compounds were grouped into four categories: malodorous volatile compounds (short and medium chain fatty acids, phenolic substances, and thioethers), low boiling liquids (solvents), aromatic compounds already present in HO.RE.CA. leftovers, and products deriving from various fermentation processes.

All the adsorbent materials tested showed similar aptitude to retain many of the volatile compounds responsible for unpleasant smells. Furthermore, no inhibitory effects on the larval growth were detected by adding any of the adsorbent materials, although finely ground grape stalks ensured a higher larval growth compared to the other substrates. However, this material needs to be dried, grinded, and sieved, thus worsening the life cycle assessment of the process. The actual possibility of employment therefore remains to be assessed.

Results incorporated in this publication originate from the SCALIBUR project, which received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 817788.

Evaluation of different feeding strategies of Black Soldier Fly larvae for scale-up purposes

Authors: Maistrello Lara[1], Antonelli Andrea[1], Montevecchi Giuseppe[1], I. Macavei Laura[1], D'Arco Sara[1] and Marchesini Tommaso[1], [1]Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy

Abstract: The black soldier fly Hermetia illucens (L.) constitutes a particular interest for the feed, food or industry sector. Its larvae have the capacity to convert quickly and efficiently large quantities of organic waste into a protein biomass rich in fats.

This work represents a part of a European project (SCALIBUR) wherein the purpose is to obtain high quality bio-products from black soldier fly larvae (BSFL) reared on organic urban waste, in particular HO.RE.CA. (hotel-restaurant-catering) leftovers, which include: pasta, pizza, bread, rice, meat and fish scrapes, vegetables, fruits, eggshell, bivalve shells, oily condiments, spices, salt, etc. The aim of this study was to assess the best feeding strategy using HO.RE.CA. leftovers as substrate for BSFL in order to obtain heavier larvae, suitable for a scale-up perspective. Moreover, we aimed at establishing correlations between the main nutrimental components within HO.RE.CA. fresh substrates, the chemical composition of mature larvae and the content of residual substrate (frass), in comparisons with the control substrate (Gainesville housefly diet).

Three replicates were performed for each rearing strategy for both type of substrates. Therefore, for each container, 300 g of feeding substrate were provided to 100 young larvae as follows: i) all at once at the beginning of experiment, considered as day 0; ii) in two tranches, half on day 0 and half on day 3; iii) four equal tranches in day 0, 2, 4, and 6. Experiments were performed in a climatic chamber at 27.0 ± 0.5 °C and 70 ± 10% HR. Daily for 12 days, a sample of 15 larvae was collected from each container, weighed and reintroduced into the specific rearing container.

The samples of initial and residual feeding substrate were subjected to the following analytical determinations: i) ash content; ii) crude protein content (Kjeldahl); and iii) lipid content (Soxhlet), after being oven dried at 60 °C and then grinded and homogenized. The content of ashes, proteins, and lipids of mature larvae was also evaluated.

Results indicate that feeding strategy did not significantly affect larvae fed on HO.RE.CA., whereas using the control diet, the heaviest larvae were obtained by administering the substrate in four tranches. Moreover, regardless of the feeding strategy applied, the trend for larval growth followed different patterns for the two tested diets. Larvae fed on HO.RE.CA. leftovers showed a high growth between days 7-10, while larvae fed on control diet had a constant growth all over the period. Detailed results will show the chemical composition of the larvae and related substrates. The results allowed the identification of the optimal conditions for BSF larvae rearing on HO.RE.CA. leftovers.

Results incorporated in this publication originate from the SCALIBUR project, which received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 817788.

Augmentative releases of the native egg parasitoid Anastatus bifasciatus for the control of the invasive Halyomorpha halys in northern Italy

Authors: Maistrello Lara[5], Haye Tim[2], Costi Elena[5], Butturini Alda[6], Moretti Christian[1], Di Bella Emanuele[5], Bombardini Enea[1], Vaccari Giacomo[3], Casoli Luca[3], Grazia Tommasini Maria[5], Bariselli Massimo[6], Landi Matteo[1], Preti Michele[1] and Caruso Stefano[3], [1]ASTRA Innovation and Development Test Facility, Italy, [2]CABI, Delémont, Switzerland, [3]Consorzio Fitosanitario Provinciale di Modena - Plant Protection Service, Italy, [4]CRPV, Cesena, Italy, [5]Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy, [6]Plant Protection Service of Emilia-Romagna Region, Italy

Abstract: The invasive Brown Marmorated Stink Bug (BMSB) Halyomorpha halys (Heteroptera, Pentatomidae) is currently the most serious pest of fruit crops in northern Italy, where it caused €588 million damage in 2019. Management of BMSB is very challenging, due to its mobility and very high polyphagy. To face this threat, farmers doubled the number of treatments with broad-spectrum insecticides, seriously disrupting previous IPM programs. Biological control is the most sustainable alternative to manage invasive pests; however, legal restrictions prevented the use of exotic biocontrol agents in Italy until 2019. The generalist Anastatus bifasciatus (Hymenoptera: Eupelmidae) is the predominant species of native egg parasitoids attacking BMSB in Europe, and it is able to successfully develop on viable BMSB eggs. In order to verify the potential of this parasitoid as a biocontrol agent for augmentative releases, a first field trial was carried out at the end of July 2018, releasing 600 A. bifasciatus females at once in 0.5 ha organic pear orchard in Emilia-Romagna. Results showed an average parasitization of 16% on frozen BMSB eggs and up to 48.5% on naturally laid eggs (Stahl et al. 2019). In 2019, further trials were performed in the same region releasing the parasitoids in woody areas near IPM fruit orchards and verifying parasitization on both, fresh and frozen sentinel egg masses. Releases were performed once a week at the beginning of the BMSB oviposition period(from mid-June to early July) reaching a density of 1 female per m2. In trial 'A' (in Modena province), a total 20,000 A. bifasciatus females were released in a wooded area of 2 ha adjacent to an IPM pear orchard. In trial 'B' (in Ravenna province), 1,300 A. bifasciatus females were released in a wooden area of 0.13 ha surrounded by tree fruit crops, including an IPM pear orchard. Both trials included a control area in which no parasitoid release was performed.

In trial "A", where 11,312 eggs were exposed, average parasitism was 6% on naturally laid eggs (obtained in sleeve cages) and 1.5% on frozen sentinel eggs, with no differences between control and release areas. In trial 'B', where 7,712 sentinel eggs were exposed, in the release area average parasitism was 1.4% on the fresh egg masses (laid on Vicia faba potted seedlings) and 0% on frozen eggs; in the control area parasitism was 1.1% on fresh eggs and 2.0% on frozen ones.

Results from 2019 indicated that mass releases of A. bifasciatus were not efficient for biocontrol of BMSB under the current test conditions.

Cooperative or not? Big groups of foundresses in a quasisocial parasitoid

Authors: Malabusini Serena[2], Hardy Ian[1], Jucker Costanza[2], Lupi Daniela[2], Savoldelli Sara[2], [1]Uni. Helsinki, Finland, [2]University of Milan, Italy,

Abstract: In the parasitoid genus Sclerodermus, multiple foundresses communally produce and care for broods. When hosts are large, group members have greater reproductive success than when attempting to reproduce alone. Prior studies evaluated groups of ≤10 foundresses but the natural range of group sizes is undocumented. We create groups of up to 55 foundresses and explore the consequences for the success and timing of cooperative brooding and on brood sex ratios. As group size increases, brood failures increase and per capita success decreases. Most broods fail at the early developmental stages. Foundresses competition for oviposition sites is likely as is determined by reproductive dominance and ovicide. While most foundresses likely produce some progeny, many foundresses do not produce any adult sons. Sex ratios are very biased: 10% of offspring are males. Based on this result, and a recent finding that larger and earlier-arriving females within smaller foundress groups produce most male offspring, we suggest that Sclerodermus brood sex ratios are the result of a combination of local mate competition and the dominance (via suppression or infanticide) of male production by some foundresses within what initially appeared to be cooperatively reproducing groups.

Insect-plant-soil microbial tug of war: which is the major force structuring insect- and plant-associated microbiomes?

Authors: Malacrinò Antonino[2], Bennett Alison[3] and Karley Alison[1], [1]The James Hutton Institute, Dundee, Scotland, United Kingdom, [2]The Ohio State University, Columbus (OH), United States, [3]The Ohio State University, United States

Abstract: Insect herbivores are a driving force in shaping plant communities and their relationship with the surrounding environment. Microorganisms are key partners of both insects and plants, influencing their development and physiology, and can modulate the outcome of plant-herbivore interactions. In this plant-microbe-insect system, a question is still open: which is the major force structuring insect- and plant-associated microbial communities? Answering this question will increase our ability to predict the effects of the environment on plant and insect microbiomes and, in turn, their influence on plant-insect relationship. Here, we tested whether soil microbiome, plant species and herbivory are able to influence insect- and plant-associated microbiomes. Using a microcosm setup, we manipulated the herbivore, plant species and soil microbial diversity, and we characterized the microbiota at different compartments: rhizosphere, roots, leaves and herbivore. We showed that herbivores drive a top-down effect shaping the microbiota of leaves, roots and rhizosphere. Furthermore soil microbiome and plant species drive a bottom-up effect that influences the microbial communities at rhizosphere, roots, leaves and, eventually, the microbiota of the herbivore. The soil-drive effect not only influenced insect microbiota, but also the insect fitness.

Effects of genetic diversity, inbreeding and outbreeding investigated in six reared biocontrol agents

Authors: Malausa Thibau[2], Quaglietti Bastien[2], Mathé-Hubert Hugo[2] and Martinez Rodriguez Paloma[1], [1]Bioline Agrosciences, France, [3] [2]Institut Sophia Agrobiotech, INRA, CNRS, France

Abstract: Genetics are expected to impact phenotypic traits of biocontrol agents, and as a consequence our capacity to produce them or use them in the field. Here, we report the results of studies that investigated the effects of population characteristics (genetic diversity) or genetic processes (inbreeding, outbreeding) on phenotypic traits or population establishment in six biocontrol agents (Allotropa burrelli, Chrysoperla comanche, Cryptolaemus montrouzieri, Macrolophus pygmaeus, Psyttalia lounsburyi, Trichogramma brassicae). Sensitivity to inbreeding was studied in A. burrelli, M. pygmaeus, C. nr comanche and C. montrouzieri by comparing phenotypic traits between individuals coming from sibling crossings (inbred) or non-sibling crossings (outbred). Inbred C. montrouzieri males displayed a 7% reduced longevity. Prey consumption of C. inbred nr comanche larvae was 39% higher. Outbred M. pygmaeus individuals displayed 30% higher reproduction success. Impacts of outbreeding (intraspecific hybridization) were investigated in C. nr comanche and M. pygmaeus. Field populations were sampled and crossing experiments were carried out, with crossings within or between populations. In Chrysoperla sp., the occurrence of cryptic taxa within populations prevented from producing enough biological material to perform the experiments. In M. pygmaeus, genotyping-by-sequencing data revealed three genetic clusters mixed in the field-sampled populations. Between genetic clusters, partial reproductive isolation was observed. Within genetic clusters, female heterozygosity rates were positively correlated to the number of offspring produced. Impacts of initial genetic diversity on population establishment in controlled conditions were studied in P. lounsburyi and A. burrelli. For P. lounsburyi, population samples were imported from South-Africa and Kenya, introduced in the laboratory and monitored over several generations. A positive relationship between the population initial microsatellite allelic richness and the time before population extinction was observed. An impact of the initial Wolbachia infection status in the populations was also detected. For A. burrelli, populations were created and introduced in laboratory conditions. Extinction rates and population densities over three generations were monitored and compared between two treatments: (i) populations created from a unique isogenic line vs (ii) populations created from a mix of five isogenic lines. Although differences were observed among isogenic lines, the average growth rate of all populations started from one line was not different to that of populations started from a mix of lines. These results motivated the start of public-private projects on the management of biocontrol agent genetics. Among them, one demonstrated that isogenic lines of Trichogramma brassicae can be efficiently produced and enable higher biocontrol efficacy than previously commercially available populations.

Bio-ecology and Over Seasoning Strategy/Alternate Host Plants of the Cotton Stainer bug, Dysdercus volkeri F. [Heteroptera: Pyrrhocoridae] on Cotton in North-Eastern Nigeria

Authors: Malgwi Anna[2], Dunuwel Danzaria[2] and Onu Isa[1], [1]Department of Crop protection, Faculty of Agriculture/ Institute for Agricultural Research, Ahmadu Bello University, Samaru-Zaria, Nigeria, [2]Department of Crop protection, School of Agriculture and Agricultural Technology, Modibbo Adama University of Technology, Yola, Nigeria

Abstract: Field trials and survey were conducted in two cropping seasons and two locations at the Teaching and Research Farm of the Department of Crop Protection, Modibbo Adama University of Technology Yola and at the College Farm of Government Girls Secondary School Kaltungo, in Adamawa and Gombe states in 2017 and 2018 respectively. The study was carried out to determine the bio-ecology and over seasoning strategy/alternate host plants of the cotton stainer bug, Dysdercus volkeri F. (Heteroptera: Pyrrhocoridae) on cotton in the Eastern cotton of Nigeria. The week that haboured the highest population of D. volkeri in a combined analysis was at 18WAS with a number of 66.30 in 2017 and at 16WAS with 20.70 in 2018 per 10 cotton plants sampled population. The least population in both locations was recorded at 12WAS had 27.70 and 2.83 in 2017 and 2018 per 10 cotton plants respectively. Boll maturation stage supported the highest population of D. volkeri at Yola and Kaltungo in 2017 and 2018 cropping season with 89.23and the least at the beginning of boll formation with 48.34/10plants. During the survey while the cotton plants were sprayed, some crop plants and weeds were observed with high relative number of D. volkeri as an alternate host plants. This include: roselle, Hibiscus sabdariffa L.; kenaf, Hibiscus cannabinus L.; okra, Abelmoschus esculentus; rice, Oryza sativum; maize, Zea mays; pig weed, Commelina compresus; Detarium microcarpum; Jew telteria, Corchorus oliotorius Linn. and on dried leaves of groundnut, Arachis hypogeae L. as well as on the debris after harvesting cotton which encouraged the survival and spread of D. volkeri to the next cropping season. This results will give farmers an idea of some of the plants that should not be inter cropped with cotton or Malvaceae because it will increase the incidence of the pest on the cotton farms. This is a key factor that will lead towards developing an Integrated Pest Management of cotton.

Efficacy of biopesticides against cotton pests under field conditions in South Africa

Authors: Malinga Lawrence, South Africa

Abstract: Cotton is a major fibre crop grown in South Africa; and is subjected to pest attacks, which reduce its yield and profitability for farmers. Field trials were conducted in 2017 and 2018 to evaluate three biopesticides, namely, Eco-Bb®, Bb endophyte, and Metarhizium rileyi in comparison with the insecticides Chlorpyrifos® 480 EC, Karate® EC, and Bandit® 350 SC. The objective was to determine their efficacy against sucking pests, leafhoppers Jacobiella facialis, aphids Aphis gossypii, thrips Thrips tabaci, whiteflies Bemisia tabaci, red spider mite Tetranychus urticae, and cotton stainers Dysdercus spp. Karate® significantly reduced the leafhopper population and outperformed all the other treatments. Eco-Bb® and Bb endophyte did not control the aphids in 2017. However, in 2018 the best aphid control resulted from the biopesticides used. In 2017 plots treated with Eco-Bb® had the lowest number of thrips, while in 2018 plots treated with Bandit® had the least thrips, followed by treatments with M. rileyi and Karate®. There were no significant differences in the populations of whiteflies, however, insecticides were more effective than the biopesticides. All the treatments, except for Bandit®, significantly reduced the number of spider mites compared in 2017. Applications of Eco-Bb® and Bb endophyte significantly reduced spider mites in 2017, while in 2018 plots treated with Karate®, followed by M. rileyi, resulted in the lowest number of spider mites. Application of Bb endophyte, Chlorpyrifos®, and Karate® resulted in the lowest number of cotton stainers. The highest mean cottonseed yields of 6 395 kg/ ha, 6 295 kg/ha, and 6 141 kg/ha were recorded in plots sprayed with Bandit®, Bb endophyte, and Eco-Bb®, respectively. Biopesticides and chemical insecticides can be combined or alternated for future IPM programmes to control cotton pests.

Global biogeography of non-native Lepidoptera

Authors: Mally Richard[1], Turner Rebecca, Blake Rachael, Fenn-Moltu Gyda, Bertelsmeier Cleo, Brockerhoff Eckehard, Hoare Robert, Nahrung Helen, Roques Alain, Pureswaran Deepa, Yamanaka Takehiko and Liebhold Andrew, [1]Czech University of Life Sciences Prague

Abstract: Lepidoptera is a highly diverse, predominantly herbivorous insect order, with species transported to outside their native range largely facilitated by the global trade of plants and plant-based goods. Analogous to island disharmony, we examine invasion disharmony, where species filtering during invasions increases systematic compositional differences between native and non-native species assemblages, and test whether some families are more successful at establishing in non-native regions than others. We compared numbers of non-native Lepidoptera species with the land area of 11 regions worldwide. Differences among native and non-native assemblages in the distribution of species among families were investigated using ordination analysis. We tested whether invasion disharmony is explained by propagule pressure (proxied by species richness in border interceptions) and if families were associated with specific trade commodities. Much of the variation in species numbers in the native, and less so in the non-native assemblages could be attributed to land area. Although native assemblages were similar among nearby regions, non-native assemblages were not, suggesting geography had little effect on invasion disharmony. Macromoth families were generally under-represented in establishments, whereas several micromoth families were under-represented in interceptions. Invasion disharmony in Lepidoptera appears to be driven by processes unrelated to the success of native assemblages.

Early sex, short lives: effects of nutrition and selection for age of female reproduction on oxidative damage, antioxidant protection and nutrient reserves in a tephritid fruit fly

Authors: Malod Kevin[1], Weldon Chris[3], E. du Rand Esther[1], Archer Ruth[2] and W. Nicolson Susan[1], [1]Department of Zoology and Entomology University of Pretoria, South Africa, [2]Institute for Evolutionary Ecology and Conservation Genomics University of Ulm, Germany, [3]University of Pretoria, South Africa

Abstract: Life-history traits, such as lifespan or reproductive effort, are tightly correlated with the amount and blend of ingested macronutrients. In herbivorous insects, high protein to carbohydrate ratios (P:C) consistently decrease life expectancy, whereas such ratios promote female egg-laying. The physiological mechanisms behind shortened lifespan due to macronutrient intake are yet to be elucidated. The Free Radical Theory of Ageing (FRTA) was one of the most popular theories attempting to explain ageing mechanisms. The keystone of the FRTA is the equilibrium between reactive oxygen species (ROS) and antioxidant protection: if ROS exceed antioxidant protection it induces oxidative damage to cellular components, which ultimately leads to death. Although the FRTA is controversial and now considered simplistic, evolutionary biologists have shown interest in the relationship between ROS and antioxidant protection to explain trade-offs such as that between lifespan and reproduction. Because this trade-off is diet mediated, and there is evidence that oxidative damage and antioxidant protection change with dietary manipulation, all may be interconnected. In this study, we tested how dietary manipulation modulates oxidative stress balance, and whether this relationship is conserved across selection lines of the marula fly, Ceratitis cosyra (Diptera: Tephritidae) that differ in lifespan and reproductive traits. In addition, nutrient storage by flies was also assessed because it is linked with survival and reproductive performance. Flies selected for early reproduction and shorter lifespan had more oxidative damage than laboratory adapted (i.e. control flies), but also had more total antioxidant capacity than wild flies. Lipid storage, which is associated with longer lifespan, was lower in flies selected for early age of female egg-laying and similar between laboratory adapted and wild flies. Flies fed the diet promoting female fecundity suffered more oxidative damage to protein than flies fed the worst diet for lifespan, or the best diet for lifespan. Total antioxidant capacity matched the change in oxidative damage due to diet and was lowest in flies fed the diet promoting lifespan. In brief, selection for early age of reproduction increased oxidative damage and antioxidant protection, but decreased lipid reserves. Dietary related increases in oxidative damage and antioxidant protection depended on the reproductive outputs associated with the diet fed to the flies.

Wolbachia prevalence in Russian populations of Loxostege sticticalis (Pyraloidea: Crambidae)

Authors: Malysh Julia[1], Malysh Svetlana[1], Kononchuk Anastasia[1], Kireeva Daria[1] and Tokarev Yury[1], [1]All-Russian Institute of Plant Protection, Russia

Abstract: Beet webworm Loxostege sticticalis L. is a notorious pest of numerous crops of European and Asian parts of Russia, as well as Northern China. L. sticticalis L. has an eruptive type of population dynamics and high migratory activity. The outbreaks are therefore difficult to predict, and the pest belongs to the category of highly dangerous pests. However, during periods of depressions this insect is not observed within the most of its range and is very susceptible to infection by pathogens, including various species of microsporidia, some of which are not specific parasites of the order Lepidoptera. Screening of insect populations for naturally occurring parasites and pathogens is inevitable for understanding the dynamics of pest populations. In particular, obligate intracellular parasites, such as Microsporidia, play an essential role in L. sticticalis density dynamics. Withal, other intracellular symbionts in populations of L. sticticalis have not been reported yet.

Bacteria of the Wolbachia genus are widespread endocytobionts of arthropods. In certain species of Lepidoptera, Wolbachia may contribute to population biology of the hosts, as it regulates reproductive processes (including sex determination) and influence host vitality and fertility in direct or indirect ways. The knowledge of Wolbachia distribution in populations of insect pests is therefore of great interest. Here, we report the first results of screening Wolbachia infection in L. sticticalis populations.

PCR with primers specific for wsp gene fragment of Wolbachia yielded amplicons with the expected size of ~600 bp in 23 % of analyzed samples. In a single sample set collected in 2005 from Rostov Region, Wolbachia infection was detected at the prevalence rate of 8.3 %. Larvae collected in Saratov Region were Wolbachia free in 2006, but about 47 % were Wolbachia-positive in 2013. In the Asian part of Russia Wolbachia prevalence ranged from 16.7 to 40 %.

Prevalence rates of Wolbachia in insect hosts may significantly vary over time and space. For example, in pyraloid moths of the genus Ostrinia, Wolbachia was found in all examined populations in the European part of Russia, and the prevalence rates were dependent upon the species and the forage plant. We found only one strain of Wolbachia for Ostrinia and several strains for L. sticticalis. Some strains of Wolbachia from L. sticticalis are most similar to the strains from different species of Ostrinia, and others are similar to Wolbachia from beetles. Long-distance migrations are likely to provide symbiont exchange between local populations of beet webworm, and various ecological factors may also affect the diversity and dynamics of Wolbachia infection.

Sticky LED trap for pest monitoring: the European corn borer, Ostrinia nubilalis hbn. (Lepidoptera: Crambidae) as an example

Authors: Malysh Svetlana[1], Kononchuk Anastasia[1], Andrey Frolov[1], Inna Grushevaya[1] and Alexandr Miltsyn[1], [1]All-Russian Institute of Plant Protection, Russia

Abstract: Phytosanitary monitoring is one of the most important elements of integrated pest management (IPM). In recent years, LEDs have begun to be widely used in lighting technology, which are characterized by high efficiency, small size and long life (Schubert, 2006). Although the possibilities of using LEDs in IPM have been actively discussed for several years (e.g. Shimoda, Honda, 2013), there are few examples of their practical use in pest phytosanitary monitoring. Despite the obvious advantages of pheromone traps used for the European corn borer (ECB), Ostrinia nubilalis (Hbn.) monitoring, more and more data are accumulating that testify to certain problems that arise when using them (Cizej, Persolja, 2013; Frolov, Ryabchinskaya, 2018; Frolov, Grushevaya, 2018, etc.). Original sticky LED trap with an electronic control unit developed in the VIZR Agricultural Entomology Lab. (Miltsyn et al., 2019) was used in trials for monitoring of the ECB carried out in 2019 on maize sowings in three geographical points located at the Krasnodar Territory, namely vil. Botanika (Gulkevichi Region), vil. Kurchanskaya (Temryuk Region) and huthor Slobodka (Slaviansk Region). Pheromone traps manufactured by JSC “Shchelkovo Agrokhim” were used as standard. The number of the moths caught per one LED trap exceeded 3.7 to 12.1 times the number caught by set of three pheromone traps supplied with Z (97% of Z11-: 3% of E11-14:OAc), E (1% of Z11-: 99% of E11-14:OAc) and ZE (35% of Z11-: 65% of E11-14:OAc) pheromones of the ECB races. Unlike pheromone traps catching only males, LED traps attracted also females: their percentage ranged from 7 (Kurchanskaya) up to 49% (vil. Botanika) of the total number of moths caught. Trials in the vil. Botanika showed that though LED and pheromone traps registered the beginning of the ECB flight in the same date, the peak of moth catching by LED traps was strongly displaced by the beginning of flying period, for a week preceding the beginning of oviposition by females. The peak of male capture by pheromone traps was noted a week later after achievement of a maximum of egg-laying activity by females. Provided that LED traps installed inside the maize planting, they caught a small number of entomophages. In 2020 we are going to conduct extensive trials of LED traps for monitoring the pest in various ecological zones of the country. The research is supported by RFBR No 19-016-00128.

Overview of vibratory communication applications for pest management

Authors: Mankin Richard, USDA Agricultural Research Service, United States

Abstract: Detection of mechanical vibrations is one of the oldest, most widely used of the insect senses, and more insects employ vibrational communication for courtship and for predator avoidance or prey detection more than they employ acoustic, chemosensory, or visual communication. We consider several examples in Hemiptera, Coleoptera, Lepidoptera, Termitidae, and Hymenoptera where detection of pest insects or disruption of courtship has been used for pest management applications.

Acoustic Detection of Hidden Invasive Pests: Progress on Development of Inexpensive, User-friendly Detection Systems

Authors: Mankin Richard[2] and Rohde Barukh[1], [1]University of Florida, United States, [2]USDA Agricultural Research Service, United States

Abstract: Early, rapid detection methods are important to amplify the effectiveness of management programs against invasive species attacking food crops, ornamental crops, and forests. Hidden infestations of pest insects in stored products, trees, and soil are particularly difficult to detect. Red palm weevils, for example, spend most of their lives inside the trunks or crowns of palm trees and typically cause extensive harm to trees before they are discovered; consequently, infested trees often are transported to uninfested areas. Acoustic detection is a useful method for early detection of red palm weevil infestations and has also been applied against stored product and soil dwelling insect pests. The cost and user-friendliness of acoustic insect detection systems has limited its usage, but new detection systems and interfaces are being developed. Here we present an overview of some of new systems under development that may come into more general use for early detection of invasive insects over the next decade.

Over and over (again): Repeated evolution of co-obligate symbioses across aphids

Authors: Manzano Marín Alejandro[1], Emmanuelle Jousselin[2], Clamens Anne-Laure[2], Coeur d'acier Armelle[2], [1]Centre for Microbiology and Environmental Systems Science, University of Vienna, Austria, [2]UMR 1062 CBGP, INRAE

Abstract: Aphids are a large group of animals comprising 4,000+ currently described species. This group of sap-sucking insects depend on the Gammaproteobacteria Buchnera aphidicola for the provision of essential amino acids and some B vitamins. However, recent evidence has demonstrated that in some cases, the typical aphid-Buchnera association has evolved to incorporate yet another obligate symbiotic partner. These new associates complement their Buchnera partner, which have lost the capacity to synthesise compounds essential for their nutritional complementation role. These multi-partner associations occur not only in aphids, but also in several other insect taxa. However, we still know little about the way these associations evolve and which role, if any, they might play in the adaptation of their hosts. Through the use of high throughput NGS, we have explored the existence and nutritional roles of such multi-partner associations across aphids. We have explored tissue tropism in selected species and revealed repeated patterns of symbiont localisation across species. In addition, these explorations have revealed that these associations are more common than previously thought, and that, based on a newly resolved phylogeny for Aphidinae based on Buchnera sequences, they have evolved not once, but multiple times throughout the evolutionary history of their aphid hosts.

Molecular Study on field evolved Resistance of Red Palm Weevil (Rhynchophorus ferruginous) and Its Management through RNAi

Authors: Manzoor Mujahid, Institute of Agricultural Sciences, University of the Punjab, Lahore, Pakistan, Pakistan

Abstract: Molecular and proteomic study was conducted on field evolved resistance of Red Palm Weevil (Rhynchophorus ferruginous) against Parathyroid group of insecticide (Cypermethrin). Cytochrome P450 genes have been associated with insecticides resistance. Field collected population of R. ferruginous from different provinces of Pakistan was investigated for insecticides resistance development against P450 gene. Insect bioassay indicated highly significant level of LC50 values among laboratory reared and field collected population against Cypermethrin. The laboratory reared resistant population, Sindh and South Punjab collected population showed high LC50 values as compared to susceptible, Baluchistan and KPK population. The expression of P450 gene through PCR showed enhanced level of P450 gene in different Instars as well as collected population. The dsRNA specific for CYP450 gene was designed and

targeted through dsRNA in thoracic region of R. ferruginous through micro-injection. Gene expression and proteomic study confirmed the down regulation of P450 gene and associated protein in dsRNA treated

population. The application of ds RNA specific for CYP450 also reduced insecticide resistance in R. ferruginous. The developmental parameters were highly affected in RPW treated with dsRNA as compared to control samples treated with water or dsGFP. These results support the RNAi application as a suitable tool for the management of insecticide resistance and control of R. ferruginous.

Intensity Prediction for Aerial Animal Migration Based on Weather Radar Network

Authors: Mao Huafeng[2], Hu Cheng[1] and Wang Rui[1], [2]Beijing Institute of Technology, China, [1]Beijing Institute of Technology, China

Abstract: Weather radar networks now enter an exciting stage for monitoring large-scale aerial animal migration with rapid developments of bio-echo extraction, biomass quantification, scientific researches, etc. For migration intensity prediction problem, we propose a novel method for weather radar network by taking spatial and temporal correlations of migration intensity into account. The weather radar network is modeled as a graph, and the graph convolution is applied to utilize the spatial correlation among different radars. Then recurrent neural network extracts the temporal correlation along the time axis and predicts the bio-echo. Our method is evaluated by the dataset collected from 40 weather radars in China, and achieves the coefficient of determination with 0.77.

Generic approach for the development of genetic sexing strains of the codling moth for SIT applications

Authors: Marec František[1], Pospíšilová Kristýna[1], van't Hof Arjen E.[1], Yoshido Atsuo[1], Visser Sander[2], Kružíková Renata[3], Dalíková Martina[3] and Nguyen Petr[3], [1]Institute of Entomology, Biology Centre CAS, České Budějovice, Czech Republic, [2]University of Groningen, The Netherlands, [3]University of South Bohemia, České Budějovice, Czech Republic

Abstract: Sterile Insect Technique (SIT) has become an important component of area-wide integrated programs to control several major lepidopteran pests, including codling moth (Cydia pomonella). One of the most successful SIT applications is the Okanagan-Kootenay Sterile Insect Release (OKSIR) program to suppress codling moth populations in the Okanagan Valley, British Columbia, Canada. Currently, this program, like other lepidopteran pest control programs using SIT, relies on bisexual releases. Male-only releases could significantly reduce costs and increase efficiency of SIT. However, a suitable genetic sexing system for producing male-only offspring is not yet available for any lepidopteran pest. We develop generic strategies for the construction of genetic sexing strains in codling moth using two approaches: (1) inserting a dominant conditional lethal mutation into the female-specific W sex chromosome using the CRISPR/Cas9 method to abort the development of female embryos, and (2) identifying genes involved in sex determination with the aim to find new possibilities for genetic sexing. Here we present the results obtained so far and our progress in achieving the objectives in both approaches.

Large scale drivers of bark beetle population outbreaks across Europe

Authors: Marini Lorenzo[1] and Schroeder Martin[2], [1]Department of Agronomy, Food, Natural Resources, Animals and the Environment. University of Padua, Italy, [2]Department of Ecology, Swedish University of Agricultural Sciences, Sweden

Abstract: Bark beetles are among the most destructive biotic agents affecting forests globally and population dynamics of several species are expected to be boosted by climate change. Given the potential interactions of bark beetle outbreaks with multiple biotic and abiotic disturbances, and the potentially strong impact of changing disturbance regimes on forest resources, investigating climatic drivers of destructive bark beetle outbreaks is becoming of paramount importance. Here, we analysed 17 time-series of the amount of forest damaged by the European spruce bark beetle (Ips typographus L.) collected across Europe in the last three decades. We aimed to quantify the relative importance of key climate drivers in driving population outbreak dynamics testing whether abiotic disturbance such as wind or snow storms synergistically enhanced outbreak propensity when coupled with drought and temperature warming. We found that regional outbreaks shared the same drivers, including increasing summer rainfall deficit and warm temperatures. Large availability of storm-felled trees in the previous year increased spruce bark beetle damage, likely by providing an alternative source of suitable breeding material. We did not find any positive synergy among outbreak drivers. On the contrary, the occurrence of large storms cancelled the effect of warming temperatures and rainfall deficit, suggesting that the large surplus of breeding material likely boosted bark beetle population size above the density threshold required to colonize and kill healthy trees irrespective of the climatic conditions. Across Europe, we found a strong direct negative density dependence that lead the population to decline after demographic outbreaks. The generality in the effects of the abiotic drivers observed across different geographical areas suggests that the large-scale drivers can be used as early warning indicators of increasing local outbreak probability. In conclusion, European spruce forests are expected to become increasingly susceptible to bark beetle outbreaks under global change with important economic and ecological consequences for forest ecosystems. However, in most of the situations the negative density feedback seems to be a natural regulating mechanism that impedes a long-term propagation of the outbreaks.

Edge lineages in Orthoptera (Xyronotidae and Tanaoceridae): current status and challenges

Authors: Marino-Perez Ricardo, University of Michigan, United States

Abstract: Family Xyronotidae consists of four species, they are unique and relict lineage (its closer relative is endemic to Southeast Asia) found in cloud forest in the states of Veracruz, Oaxaca and Chiapas, Mexico.

Family Tanaoceridae consists of three species, they are unusual and relict lineage with a very restricted distribution in desert habitats in southwestern USA (California and Nevada) and northern Mexico (Baja California). They are small, wingless and are unique in all grasshoppers in having long and filiform antennae (longer than the entire body itself).

Both families are relict lineages, evolutionary distinct from their closest relatives, possess unique stridulatory structures and have very narrow distributions threatened by land conversion. Both taxa are priorities (targets) of the Grasshopper Specialist Group and here we discuss new and valuable information from recent expeditions sponsored by a SSC EDGE Internal Grant. Now, we will be able to provide precise IUCN assessments that will help stakeholders to take decisions to protect their habitats. People from Mexico and USA will be benefit as well as humanity in general because two EDGE lineages will be better understood.

Lathiceridae, Lithidiidae and Schizodactylidae in Southern Africa: current status and challenges

Authors: Marino-Perez Ricardo, University of Michigan, United States

Abstract: We present the status of these three enigmatic groups from literature and recent field trips to arid regions in South Africa and Namibia.

Trade in ornamental plants - Which associated species may become significant pests of Nordic coniferous forests?

Authors: Marinova-Todorova Mariela[1], Tuomola Juha[1], Boberg Johanna[2], Björklund Niklas[2], Flø Daniel[3], Wendell Micael[3] and Hannunen Salla[1], [1]Finnish Food Authority, [2]Swedish University of Agricultural Sciences (SLU), [3]The Norwegian Scientific Committee for Food and Environment (VKM)

Abstract: In a recently published study we screened plant pests potentially associated with the trade of ornamental plants to identify pests that could pose a high risk to the coniferous forests of Finland, Sweden and Norway. Specifically, our aim was to find pests that potentially could fulfil the criteria to become regulated as quarantine pests. We used an approach developed by EPPO for commodity studies, which includes several steps of screening. From an initial list of 1062 pests, 65 pests were identified and ranked using the FinnPRIO pest risk ranking model and the hypervolume approach, which resulted in a top list of 14 pests namely Chionaspis pinifoliae, Coleosporium asterum s.l., Cytospora kunzei, Dactylonectria macrodidyma, Gnathotrichus retusus, Heterobasidion irregulare, Lambdina fiscellaria, Orgyia leucostigma, Orthotomicus erosus, Pseudocoremia suavis, Tetropium gracilicorne, Toumeyella parvicornis, Truncatella hartigii and Xylosandrus germanus. In the next step we, jointly with EPPO, conducted full pest risk assessments according to the International Standards for Phytosanitary Measures for two of the pests in the top list, namely white-marked tussock moth (Orgyia leucostigma) and pine needle scale (Chionaspis pinifoliae). The results of these assessments provide support for decisions within the EPPO-region on whether the assessed pests should be regulated as quarantine pests.

Host plant condition determines the abundance and composition of herbivorous insect communities on urban maple trees (Acer spp.)

Authors: Markó Viktor[2] and Korányi Dávid[1], [1]"Lendület" Landscape and Conservation Ecology, Centre for Ecological Research, [2]Institute of Plant Protection, Hungarian University of Agriculture and Life Science

Abstract: Maple species (Acer spp.) are among the most common urban trees throughout North America and Europe. Sycamore (Acer pseudoplatanus), Norway (A. platanoides) and field (A. campestre) maple are native to Central Europe and commonly planted in urban areas. On the one hand, all the three maple species support large diversity of herbivorous insect species with different degrees of host plant specialization. On the other hand, the ecological requirements of the three maple species are different, and therefore they tolerate urban stress to varying degrees. In this study, we examined how these two factors (host plant identity and condition) affect the abundance of insect pests and composition of herbivorous insect community in the canopy of maple trees, and how the studied maple species support urban biodiversity.

The study was carried out in the city of Budapest, Hungary. We selected four study sites in urban environment (Arboretum of Buda, Gellért Hill, streets around the Buda Campus of Hungarian University of Agriculture and Life Sciences, and Alkotás street), each with sycamore, Norway, and field maple trees of roughly the same age and in close proximity to each other. Insects were collected from the canopy of the trees by the beating method for two years. We also examined the stress level [expressed as peroxidase (POD) enzyme activity], and physiological condition (expressed as degree of leaf necrosis and leaf fall) of the maple trees, and their relationship to herbivore abundance. We found that in urban environment field maple trees were in the best and Norway maple trees in the worst condition. The abundance of the herbivorous insect community was similar in the canopy of field maple and sycamore and was significantly lower in the canopy of Norway maple. Most herbivorous insect species were associated with field maple, sycamore had the highest aphid densities, while Norway maple not only had the lowest abundance but also the harboured the least specific herbivorous insect community. The super-abundant planthopper species, Metcalfa pruinosa positively affected the POD activity of trees, but did not influence their condition. On the contrary, M. pruinosa abundance was driven by tree condition, with higher numbers on healthier trees.

Our findings suggest that the abundance of phytophagous insects in the canopy of maple trees is highly determined by tree condition, and in this study field maple had the highest and Norway maple the lowest tolerance for urban stress.

This research was supported by the NKFIH (K-129311).

RNAi studies with stink bugs: from basic science to agricultural losses

Authors: Marques-Souza Henrique, University of Campinas - Unicamp, Brazil

Abstract: Brazil is the second largest producer of soybean, Glycine max (L.) in the world. However, $ 6 billion is lost each year due to the action of pests. From this amount, about one third is caused by true bugs, and Euschistus heros (F.) (Hemiptera: Pentatomidae) plays a central role in this financial impact. Traditional methods based on pesticides generate annual expenses of R $ 8.5 billion and still E. heros is one of the main causes of agricultural losses in soybean. In addition, constant applications of pesticides can cause environmental contaminations and the emergence of pest resistance to insecticides. RNAi technique is one of the best molecular tools to reduce the function of genes in eucaryotes. The beetle Tribolium castaneum (L.) has been deeply studied using RNAi to understand its embryology, metamorphosis, behavior, etc. In model organisms such as this beetle and nematode, RNAi has proven to be highly efficient and specific to knock down virtually any gene. By choosing a gene with essential function for the organism, RNAi can be used to induce mortality of the target organism and has become a valuable alternative for agricultural pest control. The present work identifies silencing molecules capable of inducing mortality in E. heros, by targeting genes essential for the insect survival. The tests were carried out by means of microinjections in the ventral region of the animal, using different concentrations and combinations of target genes. Insect mortality was checked every 24 hours and the level of gene expression was evaluated by qPCR 12 and 24 hours after microinjections. We showed that mortality rates of up to 78% can be obtained 72 hours after injections and the effect was dose-dependent. Also, combining silencing molecules resulted in an increment of the mortality rate to about 85% after three days. These mortality rates happen concomitantly to reductions of expression of the target genes of about 86%, for the individual assays, and up to 98% when silencing molecules are combined. These results highlight the high efficiency of the RNAi technique by means of a gene pool in the control of this major pest of soybean in a sustainable, specific, and innovative way.

History, Status and Future of Bioprotection (Biocontrol)

Authors: Marrone Pamela, Marrone Bio Innovations, United States

Abstract: There is a long history of using microorganisms, pant extracts, biochemicals and other natural substances as the basis for creating new pesticides, but there is still a relatively low percentage of naturally-derived pesticides relative to the percentage of pharmaceuticals derived from natural sources (>50% vs 11% for pesticides). Biologicals for pest management, called biopesticides, biocontrol or bioprotection have been around for seventy years, starting with there bioinsecticide from Bacillus thuringiensis (Bt). They are now experiencing rapid growth as the products have better efficacy, are more science-based and there are more restrictions on synthetic chemical pesticides driven by consumers' requirements for sustainability and transparency of our food supply. Still, biopesticides are still a small percentage (approximately US $3-4 billion) of the US $60 billion chemical pesticide market. Growth of biopesticides is projected to outpace that of chemical pesticides, with compounded annual growth rates of between 15-20%. When integrated into crop production and pest management programs, biopesticides can offer the potential for higher crop yields and quality than chemical-only programs. Added benefits include reduction or elimination of chemical residues, therefore easing export, delay in the development of resistance by pests and pathogens to chemicals, shorter field re-entry, biodegradability lower carbon footprint, and low risk to non-target organisms, including pollinators. Challenges to the adoption of biopesticides include lack of awareness and education in how to deploy their unique modes of action in integrated programs, testing products alone versus in integrated programs, and lingering perceptions of cost and efficacy.

Towards a macroecology of "the little things that run the world"

Authors: Marshall Katie[2], Siler Cameron[5], Blair Jarrett[4], Miller Matthew[5], D. Weiser Michael[1] and Kaspari Michael[3], [1]Department of Biology University of Oklahoma, United States, [2]Department of Zoology, University of British Columbia, Canada, [3]Geographical Ecology Group University of Oklahoma, United States, [4]University of British Columbia, Canada, [5]University of Oklahoma, United States

Abstract: A key aim of macroecology is to quantify and predict how Earth's great abiotic drivers--temperature, precipitation, and biogeochemistry--govern how ecological communities of individuals and species vary from place to place. Community data at continental extents are sparse and restricted to a few taxa. They vastly underrepresent the terrestrial arthropods--perhaps the most diverse and abundant animal group--in part due to the immense effort required to count, size, and identify ground-dwelling arthropod taxa. Here we present a project that aims to address this gap by the analysis of samples from the NEON pitfall network (arrays of traps, sunk in the soil, that capture and store biweekly samples of arthropods in ethanol). We are developing two complementary methods to do so. First, we are developing an environmental barcoding pipeline to identify pitfall taxa from extracts of ethanol. Secondly, we are developing an image analysis pipeline that uses machine learning to count, size, and classify arthropods in a sample. Pitfall samples containing key orders of Earth's arthropods will be analyzed from NEON's 47 sites throughout the United States. Here we present our current work on the image analysis pipeline, including a framework and working machine learning models for insect identification. This project represents an opportunity to collect standardized field data from entire communities of ground dwelling arthropods, and to test macroecological theory at continental scale.

Overcoming the barriers: the case study of Bagrada stinkbug and its egg parasitoid for biocontrol purposes

Authors: Martel Guillaume[1] and FH Sforza René[2], [1]USDA-ARS-EBCL Montpellier SupAgro, France, [2]USDA-ARS-EBCL, France

Abstract: For any egg parasitoid that aims to find host eggs in the environment, synchronized climatic suitability, foraging time allocation, and egg availability are the main issues for achieving success. These three components can be considered as barriers that only coevolved parasitoids can overcome. Among invasive stinkbugs in North America, Bagrada hilaris Burmeister (Hem.: Pentatomidae) possesses specific biological and behavioral traits, including high thermal development requirements, strong population variations in the field, and a unique oviposition behavior among the Pentatomidae. The objectives of the current study were to evaluate the capacity of a Pakistanis' biocontrol parasitoid candidate, Gryon gonikopalense Sharma (Hym.: Scelionidae), to cope with the different above mentioned bagrada behavioral and biological parameters. Originating from Asia and Africa, B. hilaris was first reported to be invasive in California in 2008. Since this time, this severe invasive pest of crucifer crops has expanded its range into several southern U.S. states and South America. Within the context of a biocontrol program, we examined the life history traits of G. gonikopalense, with focus on its suitability as a potential candidate for a field-based B. hilaris biological control. The first barrier to overcome for G. gonikopalense was for it to develop, reproduce and survive within the same climatic range as B. hilaris, or even beyond. Laboratory studies showed G. gonikopalense's ability to complete its life cycle between 15 and 35°C, which is perfectly consistent with bagrada thermal development requirements. The second barrier was to ascertain that G. gonikopalense was able to live long enough for successful parasitization of B. hilaris after an extended period of host deprivation. Our results showed that G. gonikopalense could easily live more than 2 months and still be able to parasitize B. hilaris eggs. These data indicate that adult parasitoids could survive when host populations decrease in the field (winter and summer periods in California's coastal regions) and still be able to parasitize eggs once bagrada start to build up field populations (late winter and autumn periods in California). Finally, we tested the response of G. gonikopalense to the unique bagrada oviposition behavior, as females lay eggs individually and naturally bury them in the soil. This oviposition strategy theoretically limits access to natural enemies. After showing that more than 80% of B. hilaris were buried in the soil, with either broccoli or mustard host plants, we exposed G. gonikopalense females to naturally buried eggs in a quarantine laboratory. Results showed up to 90% successful parasitism of buried eggs. Collectively, these results on the biology and behavior of G. gonikopalense supported a strong co-evolution and synchronization with B. hilaris, and are therefore promising for its use within the framework of an importation biocontrol program in California, and beyond.

On size, time and hormones: Control of postembryonic development by the metamorphic gene network

Authors: Martin David[3], Cruz Josefa [1], Chafino Silvia[3] and Franch-Marro Xavier[2], [1]IBE (CSIC-UPF), [2]Iinstitute of Evolutionary Biology CSIC-UPF, Spain, [3]Institute of Evolutionary Biology (CSIC-University Pompeu Fabra)

Abstract: Stage identity and progression in hemimetabolous and holometabolous insects is controlled by the regulatory activity of the temporal identity factors Krüppel-homolog 1 (Kr-h1), Ecdysone inducible protein 93F (E93), and Broad-complex (Br-C; also known as broad), which conform what we have called as the "Metamorphic Gene Network" (MGN). The sequential expression of these three factors during development is controlled by the interplay between ecdysteroids -20-hydroxyecdysone (20E) being the most active form- and juvenile hormones (JH), produced by the prothoracic glands and the corpora allata glands, respectively. Whereas the anti-metamorphic component of the MGN is exerted by Kr-h1, E93 acts as the metamorphosis-triggering factor as well as the adult specifier, and Br-C functions as the pupal specifier in holometabolous insects. However, the occurrence of important changes in the MGN functioning in the highly derived D. melanogaster reveals the degree of plasticity that the MGN can provide to the developmental program. Here, we present our new data on the regulation and function of these key temporal identity genes during the metamorphosis of D. melanogaster, thus contributing to a better understanding of the molecular basis of insect development and the evolution of insect metamorphosis.

Genotype influence in potato aphid (Macrosiphum euphorbiae) response to an aphid parasitoid

Authors: Martinez Chavez Laura Marcela[2], Karley Alison J[3], Pope Tom W[1], Roberts Joe M[1] and Shaw Bethan[2], [1]Harper Adams University, [2]NIAB EMR, [3]The James Hutton Institute

Abstract: The potato aphid (Macrosiphum euphorbiae) is an economically important pest of strawberry crops. The withdrawal of insecticides and incompatibility of others to pollinators and biological controls of pests found within strawberry crops has increased reliance on aphid parasitoids and predators for the management of this pest. However, the recent description of innate resistance to a parasitic wasp (Aphidius ervi) in some populations of M. euphorbiae feeding on potato could reduce the effectiveness of biological control programmes used for this pest in strawberry crops. As it is not yet known if the parasitoid-resistant genotype of M. euphorbiae also infests strawberry crops, experiments have been developed to identify the different genotypes of potato aphid present in strawberry crops. This work uses aphids sampled from different geographical locations in the UK and microsatellite information is used to genotype these aphid populations. The susceptibility of these populations to A. ervi is then recorded using laboratory bioassays. Together this information informs on the likely effectiveness of biological control programmes based on releases of A. ervi for control of potato aphids in strawberry crops.

Health status of Eucalyptus nurseries in Uruguay

Authors: Martínez Gonzalo[1], Lozano Juan[1], Alonso Raquel[2] and Lupo Sandra[2], [1]Instituto Nacional de Investigacion Agropecuaria. Forestry programme. Laboratory of Entomology, Uruguay, [2]Universidad de la Republica. Faculty of Sciences. Laboratory of Mycology, Uruguay

Abstract: Nurseries are the source of seedlings and clones for the growing Eucalyptus- based pulp and timber industry in Uruguay. Annual production reaches 100 million Eucalyptus plants and it is conducted by 30 nurseries, although three of them account for more than 70% of the plant production. In the nursery, plants may exhibit health issues derived from the particular environment provided by the greenhouses, which differ from the conditions they will experience later in the plantation. The optimal temperature range, water supply, and light that benefit plant growth also promote the occurrence of several organisms that inflict damage to the plants and poses health risks to the future plantations. Herbivorous arthropods also benefit from a constant supply of fresh plant tissue, which may lead to outbreaks in certain moments of the year. Apart from this health issues directly derived from the conditions of the nurseries, several eucalypt pests can start multiplying inside the nursery and from there they can disperse into the plantations, such as the blue gum chalcid or different species of psyllids.

We started a seasonal survey on eucalypt nurseries in Uruguay aimed at assessing the main sanitary problems affecting plants in the early stages of development. Eleven nurseries were selected, accounting for the variation in size, production and geographical situation. All of them were visited each three months for two years. Plants were assessed for disease or insect attack randomly along transects inside greenhouses. Insect and plants exhibiting disease symptoms were collected for diagnosis in the laboratory. A set of five yellow and five blue sticky traps was hung in the rearing and in the hardening sector for 15 day on each visit. Additional insect collection was made by sweep net sampling. Collected insects were preserved dried or in 70% ethanol solution. Voucher specimens were additionally preserved in absolute ethanol for further DNA analysis. All specimens were identified to species level.

We share results from the first sampling year. Mites were the most frequent problem related to arthropods in the clonal gardens, followed by the greenhouse whitefly and caterpillars from several species. Although diseases were more frequent than insect-related issues in the rearing and hardening areas, we found several species of psyllids, aphids, and lepidopterans attacking plants; the attacks showed seasonal and geographical variability. The incidence of the blue gum chalcid or psyllids inside the nurseries was lower than expected. Several dipteran species occurred in the greenhouses; we are currently assessing the role of the different species of flies in the dispersion of pathogens within greenhouses. Beneficial insect fauna was also recorded in the different nursery sectors.

These preliminary results allow us to sectorise and prioritise health problems in eucalypt nurseries, as well as to improve current pest management strategies or to tailor new ones.

Root mutualistic microbes drive plant-insect interactions at multiple trophic levels

Authors: Martinez Medina Ainhoa, IRNASA-CSIC, Spain

Abstract: Trichoderma and arbuscular mycorrhizal (AM) fungi are widespread soil inhabitants that establish symbiotic interactions with the vast majority of terrestrial plants conferring positive effects on growth and fitness. Several studies indicate that they can affect plant-insect interactions, still the mechanisms involved remain obscure. In our lab, we used a systems biology approach, integrating transcriptomics and metabolomics data with performance and behavioral studies, and functional analyses, to identify novel key molecular traits driving the impact of Trichoderma and AM fungi on the interaction of tomato plants with the insect herbivores Manduca sexta and Spodoptera exigua. Bioinformatic analyses with the integrated data sets highlighted the differential regulation of networks of components related to antiherbivory responses triggered by the mutualistic fungi. Accordingly, root inoculation with the microbial symbionts strongly altered the dynamics of the plant-herbivore interaction by negatively affecting the insect performance. Moreover, the fungal symbionts increased the performance and host preference by the parasitic wasp Cotesia congregata, by affecting the blend of volatiles released by the plants, indicating that the effect of root symbionts on herbivores escalates up to further trophic levels.

Bird-biting Culicoides: host location, feeding patterns and avian blood parasite transmission

Authors: Martínez-de la Puente Josué[3], Figuerola Jordi[2] and C. Soriguer Ramón[1], [1]Doñana Biological Station (EBD-CSIC) and Biomedical Research Center Network for Epidemiology and Public Health, Spain, [2]Doñana Biological Station (EBD-CSIC), Seville, Spain. Biomedical Research Center Network for Epidemiology and Public Health, Spain, [3]University of Granada, Network for Epidemiology and Public Health, Spain

Abstract: Biting midges of the genus Culicoides are one of the most important insect vectors involved in the transmission of a number of pathogens affecting humans, livestock and wildlife. Nowadays, most studies have been focused on the role of Culicoides species for the transmission of pathogens affecting livestock such as bluetongue virus, while their role in the transmission of parasites affecting wildlife have been comparatively poorly studied. In this talk, we present results from our field studies on the feeding patterns and host location of Culicoides species in southern Europe. In addition, we identify the role of bird-biting species including Culicoides circumscriptus and C. paolae for the transmission of blood parasites affecting wild birds, as is the case of avian malaria-like parasites of the genus Haemoproteus.

Controlling silverleaf whitefly (Bemisia tabaci) using kaolin: an integrated IPM approach

Authors: Martini Xavier[1], Johnston Nicholas, University of Florida, United States

Abstract: The silverleaf whitefly, Bemisia tabaci (Gennadius), has become a major pest in Florida, causing serious losses to many specialty crops including tomatoes and cucurbits. These whiteflies damage plants directly by phloem-feeding on crop foliage but also indirectly by transmitting at least 50 types of geminiviruses. Despite intensive control efforts, whiteflies remain a difficult pest to manage due to their wide host range and ability to easily switch feeding between vegetable hosts and surrounding weed hosts. In order to develop more economic management strategies, kaolin clay was tested as a whitefly repellent in association with limonene, a natural plant-based repellent. Both nymph and adult populations were surveyed in both a tomato and watermelon field trials conducted during the fall 2019 season in Quincy and Live Oak, Florida, respectively. The field trials were arranged using a randomized block design which included a limonene only treatment, kaolin only treatment, mixed limonene/kaolin treatment, and a control. It was found that tomatoes and watermelon treated with a kaolin/limonene mixture had a three to four-fold reduction in B. tabaci adult populations compared to controls and a two to three-fold reduction compared to both kaolin and limonene only treatments. Total quality weight of tomatoes harvested from kaolin/limonene treatments was also higher by two-fold compared to controls. Whitefly repellency to kaolin depends on its varying synergistic effects with additional repellents and demonstrates the potential for use in an integrated IPM strategy by lowering both the amount of conventional insecticides used and frequency of spraying for effective whitefly control.

Use of semiochemical and visual cues to control ambrosia beetles and laurel wilt spread.

Authors: Martini Xavier[3], Stelinski Lukasz[1] and Mizell Russ[2], [3]University of Florida, United States, [1]University of Florida Citrus Research and Education Center, United States, [2]University of Florida North Florida Research and Education Center, United States

Abstract: Laurel wilt disease is a devastating vascular disease of plants within the family Lauraceae that includes redbay (Persea borbonia) and avocado (Persea americana). The redbay ambrosia beetle, Xyleborus glabratus is the vector of the pathogenic fungus Raffaelea lauricola that causes laurel wilt. Currently, the vector and the disease are spreading rapidly westward throughout the southeastern United States. Laurel wilt has killed over 1 million trees throughout the region and has caused significant loss to avocado production in southern Florida. If X. glabratus is the main vector of the laurel wilt pathogen in redbay, X. glabratus is rarely found in Florida avocado groves with Laurel wilt. Multiple exotic and native ambrosia beetle species found in Florida avocado groves have been found carrying R. lauricola and some species shown to be capable of transmitting the disease to avocado.

We first tested verbenone as a potential repellent for Xyleborus glabratus and ambrosia beetles found in avocado groves. The results of the field trials on avocado and redbay demonstrated that trunk application of verbenone reduces landing rates of ambrosia beetles. Subsequently, our team developed a trap using visual and odor to capture ambrosia beetles. Our trap associates visual and odor cues used by ambrosia beetles to locate their host. Ambrosia beetles use both host volatiles and bark reflectance characteristics to discriminate against non-host trees. Visual cues used in our trap are based on previous study demonstrating that ambrosia beetles are attracted toward the silhouette of trees. The trap was tested with three different colors and two odor sources. Our trap has been tested successfully in forest and avocado groves in north and south Florida, respectively. Visual traps and verbonene lures have been combined in a push-pull system in forest that significantly reduced the number of ambrosia beetles landing on redbay. Using a combination of visual and odor cues may allow for a better control of Laurel wilt and its vector.

Specificity of Pathogen-Induced Plant Volatiles from Two Viruses to Vectoring and Non-vectoring species of Flower Thrips

Authors: Martini Xavier[3], Strzyzewski Iris[3], Funderburk Joseph[2], Freeman Joshua[2] and Renkema Justin[1], [1]Agriculture and Agri-Food Canada Government of Canada, Canada, [2]University of Florida, United States, [3]University of Florida, United States

Abstract: Insect-vectored plant pathogens are known to alter host-plant quality and associated cues, which subsequently affect the frequency of interactions with the vector and can influence pathogen transmission. Following infection, pathogen-induced changes in the host plant may result in direct effects on the vector such as increased survivability, fecundity, and altering feeding behaviors or indirect effects through host-mediated cues including plant nutrients, changes in plant morphology, and release of pathogen-induced plant volatiles (PIPVs). It is unknown if these PIPVs deliver information highly specific to the vector and have evolved as a result of host manipulation, or if they are a more generalist indicator of plant status. We investigated the response of two thrips species, the western flower thrips, Frankliniella occidentalis Pergande, the vector of the tospovirus tomato spotted wilt virus (TSWV) and a non-vectoring species, the eastern flower thrips, F. tritici Fitch. Both species compete within the same flower in tomatoes and may respond differently to PIPVs. Additionally, both species were exposed to PIPVs of the Begomovirus tomato yellow leaf curl virus (TYLCV) transmitted by the sweet potato whitefly, Bemisia tabaci Gennadius, to determine how specific these responses may be. Frankliniella tritici did not respond to pathogen-induced volatiles. F. occidentalis; however, was attracted to both TSWV and TYLCV-infected plants. Volatiles from TSWV- and TYLCV-infected plants were collected, and plant volatiles were identified using GC-MS. Principal component analysis of the volatiles showed a clear differentiation between the volatiles of the uninfected and infected tomatoes. There was, however, no differentiation in volatiles between the two virus-infected tomatoes, suggesting that PIPVs from both viruses elicit a generalist response in F. occidentalis absent in the non-vectoring species and are likely not the result of host manipulation.

Leaf-mining moths (Lepidoptera: Gracillariidae) as important invasive pests of deciduous trees in urban and suburban areas in Russia

Authors: Martirova Maria[1], Mamaev Nikita[1], Selikhovkin Andrey[1], [1]Saint Petersburg State Forest Technical University, St. Petersburg, Russia

Abstract: Gracillariidae might be considered as unique example of a case when several species from one family simultaneously and during a relatively short period (late 20th and early 21st centuries) increased their invasiveness.
In Russia, the following species expanded their ranges and became pests: Parectopa robiniella (Clemens, 1863), Macrosaccus robiniella (Clemens, 1859), Caloptilia roscipennella (Hubner, 1796), Cameraria ohridella (Deshka et Dimic, 1986), Phyllonorycter issikii (Kumata, 1963), Phyllocnistis citrella (Stainton, 1856), and Acrocercops brongniardella (F., 1798). Secondary ranges of P. robiniella, M. robiniella, C. roscipennella, and Ph. citrella are relatively small in Russia because these species feed on thermophilic tree species common only in southern Russia: P. robiniella, M. robiniella develop on Robinia pseudoacacia L., C. roscipennella – on Juglans regia L., and Ph. citrella – on citrus.
Phyllonorycter issikii and C. ohridella quickly formed wide secondary ranges in Russia. Phyllonorycter issikii is currently distributed over almost the entire range of lime Tilia spp. in Russia. In St. Petersburg and Leningrad Region (the northern border of the lime range), it was noted for the first time in 2000. A slight increase in population density of this species was observed in 2002, 2008, and 2013 and 2018. Tilia × europaea L. and T. cordata Mill. are the most severely damaged hosts of this species in the region. In Russia, C. ohridella, an invasive pest of Aesculus hippocastanum L., was first recorded in 2013 in St. Petersburg. Already in 2014, damage caused by this pest became noticeable in St. Petersburg. Its secondary range is rapidly expanding east- and northward. In 2019, the species was recorded in Vyborg (north of the Karelian Isthmus) and, apparently, reached the range limit of A. hippocastanum.
Acrocercops brongniardella was first recorded in St. Petersburg and its environs in 2018. In 2019, single mines of this species on the leaves of Quercus robur L. were found in all parts of the city and its environs. It should be noted that the northern limit of the oak range lies in St. Petersburg.
Phyllonorycter populifoliella (Treitschke, 1833) (Lepidoptera: Gracillariidae), started to appear on poplars in St. Petersburg only in the second half of 20th century. First large-scale breeding outbreak of this species began in 1991, and the second in 2017.
The successful development of the third generation of C. ohridella and the second of Ph. populifoliella was recorder for the first time in 2021 due to extremely high temperatures in June and July.
Thus, at the beginning of the 20th century at least six species of Gracillariidae became significant invasive species in Russia. The invasive ranges of three species (P. issikii, C. ohridella, and A. brongniardella) have reached the northern range limits of their host plants.
The research was funded by the Russian Science Foundation, project № 21-16-00065

Bioefficacy of powder and ash of Carica papaya seed against Sitophilus zeamais

Authors: Mary Atere Bukola[1] and Ejemen Idoko Joy[1], [1]Department of Crop, Soil and Pest Management, Federal University of Technology Akure, Nigeria

Abstract: The study investigates the efficacy of powder and ash of Carica papaya seed on Sitophilus zeamais regarding mortality, adult emergence, seed weight loss, weevil perofration index and seed viability. C. papaya seeds were air-dried and ground to obtain the powder. Pulverized C. papaya seeds were heated in a muffle furnace and maintained at 5500C for four hours to obtain the ash. Doses of the powder and ash were applied solely at 0.2, 0.4, 0.6, 0.8 and 1.0g rates per 20g of maize grains and the untreated grains served as the control. Each experiment was replicated thrice. Insect mortality increased at higher concentrations of the powder. C. papaya seed ash and powder at 1g application rate were most effective at controlling S. zeamais evoking 56.7% and 66.7% mortality respectively after 96hrs of exposure and significantly reduced the number of emerged weevils in stored maize grain. The Weevil Perforation Index of maize grains treated with C. papaya seed ash ranges between 6.9 and 29.8 when compared to the control experiment. The effectiveness of the powder and ash of C. papaya seed in reducing damage caused by S. zeamais infestation during storage was proved in this work. Therefore powder and ash of C. papaya seed could be used as a substitute to synthetic insecticides.

Mosquito-borne arbovirus survey at hospitals and livestock markets: Concurrent detection of sindbis virus and insect-specific flaviviruses in culicine mosquitoes

Authors: Masiga Daniel[1], Chiuya Tatenda[2], Bastos Armanda[3], Fevre Eric[2], Villinger Jandouwe[1], [1]International Centre of Insect Ecology and Physiology (ICIPE), Kenya, [2]International livestock Research Institute (ILRI), Kenya, [3]University of Pretoria, South Africa

Abstract: Aedes aegypti and Culex pipiens complex mosquitoes are prolific vectors of the major arboviruses presenting a global threat to human and animal health. Due to increased globalisation and travel these viruses have been able to propagate across country borders causing epidemics. Vector control is therefore an important in mitigating the effects of arboviral diseases and recently research focus has been on the use of insect-specific flavivirus (ISFs) that naturally infect Aedes and Culex mosquitoes as potential regulators against infection with pathogenic arboviruses. Surveillance efforts for arboviruses in Kenya have been mainly concentrated in the endemic coastal regions with minimal efforts in other regions such as western Kenya which borders Uganda where high arboviral activity has been documented. In this study we trapped mosquitoes using CDC light and BG sentinel traps in the long and short rainy season in 2018 and 2019 at two livestock markets and six hospitals in western Kenya. We assessed how man-made habitats may impact the mosquito diversity, abundance and at hospital, how in-patients can be exposed to nosocomial arboviral infections. Mosquitoes were screened for pathogenic arboviruses, ISFs and their blood-meal sources determined by reverse transcriptase PCR coupled with high resolution melting analysis. A total of 6848 mosquitoes were collected of which 89% were trapped during the long rainy season with Aedes aegypti (59%) and Culex pipiens (40%) being the most abundant. The majority of the blood-fed mosquitoes were Culex pipiens that took blood meals from humans, chicken and one from a sparrow (Passer sp.). A single Culex poicilipes pool was positive for sindbis virus while 30 pools were positive for Cell fusing agent virus (CFAV), 11 for Aedes flavivirus (AeFV), and eight for Culex flavivirus (CxFV). The overall infection rate of mosquitoes by ISF was 12.66 (8.74-17.82) for CFAV infection and 4.27 (2.26-7.39) for AeFV in Ae. aegypti. Our findings highlight the presence of sindbis virus which causes febrile illness, myalgia and arthralgia which can complicate the diagnosis and prognosis of already immunocompromised patients. The comparatively high infection rates by ISF may explain why there has not been a lot of outbreaks reported in the region given their transmission blocking potential.

Evaluating the transferability of Glossina pallidipes occurrence and abundance models from an intensively sampled livestock-wildlife interface area in Kenya to less sampled areas in the country

Authors: Masiga Daniel[3], Gachoki Stella[3], Skidmore Andrew[2], Vrieling Anton[1], Okal Michael[3] and Groen Thomas[2], [1]Faculty of Geo-Information and Earth Observation (ITC), University of Twente, Netherlands, [2]Faculty of Geo-information Science and Earth Observation (ITC), University of Twente, Netherlands, [2]Faculty of Geo-Information Science and Earth Observation (ITC), University of Twente, Netherlands, [3]International Centre of Insect Ecology and Physiology (ICIPE), Kenya

Abstract: Remote sensing of the environment provides the potential to transfer models to areas that are lacking ground sampling data, thus allowing surveillance over large areas. Successful transfer of Species Distribution Model has been reported in relation to the spread of invasive weed species, distribution of different butterfly species among others. However, sampling biases, dissimilarities in environmental conditions between the reference and target areas, species behaviors and biotic interactions are among the major challenges affecting the transfer of species distribution and abundance models. Also, the issue of spatial and temporal scale in terms of the data used to develop the model and the areas they are to be transferred to need to be addressed while performing the transfers. Additionally, to have confidence in the application of a model in other areas, we nonetheless require validation of its performance using ground data in those target areas. For the case of the different species of tsetse flies, the transfer of their occurrence and abundance model has not been attempted before. While occurrence models have been widely applied in areas where presence or absence tsetse fly data is available, abundance models are very limited. Since there are limited funds that allow the actual surveillance of tsetse flies in all the areas they occur, contriving methods that can allow their monitoring on a large scale while maintaining the data quality is paramount. Therefore, this study will focus on answering if;
1) the tsetse fly occurrence and abundance models from an intensely sampled area accurately predict and explain 80% of the variation in tsetse fly distribution and numbers in less sampled areas? 2) how precise and reliable are the resulting transferred occurrence and abundance models in these less sampled areas? The research hypothesizes that application of the occurrence and abundance tsetse flies (Glossina pallidipes) models from Shimba Hills to an area that has similar (Bray-Curtis < 0.4) environmental conditions will result in comparable Kappa accuracies and Root Mean Square Errors (RMSE), while a dissimilar area will have lower Kappa accuracies and higher RMSE. The study design will apply the resulting seasonal formulae of the occurrence and abundance models developed in Shimba Hills, a study site that has been intensely monitored between 2017 and 2019 by the International Centre of Insect Physiology and Ecology (ICIPE), to the rest of Kwale county, Arabuko Sokoke Forest Reserve and Ruma National Park. Ground validation data set will be collected for two months for accuracy assessment and model sensitivity analysis.

Integrative taxonomy of African stingless bees: Using Nest architecture, Morphology, Genetics and Chemistry

Authors: Masiga Daniel[3], Ndungu Nelly[1], Yusuf Abdullahi[4], Pirk Christian[4], Nkoba Kiatoko[2], [3]International Centre of Insect Ecology and Physiology (ICIPE), Kenya, [1]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [4]University of Pretoria, South Africa, [2]International Centre for Insect Physiology and Ecology, icipe, Kenya

Abstract: Stingless bees are important pollinators contributing significantly to biodiversity and food security. Stingless bees produce honey that has high medicinal value that fetches higher prices compared to the honey produced by honey bees (Apis mellifera). However, identification and classification of Afrotropical stingless bees, which is key and important for their domestication, still remains ambiguous and solely reliant on the use of morphological features. Colonies of the three Hypotrigona species from Kakamega forest and Mwingi, Kenya were nested at meliponary on the campus of icipe in Nairobi, Kenya. Nest sites and nest architecture were recorded. It was found that nest sites are specific with Hypotrigona gribodoi nesting mostly in crevices of mud walls in homesteads, while H. ruspolii and H. araujoi nest in specific indigenous tree species found in Kakamega forest. Using veins on the right forewing and hind leg for morphometrics analysis, H. gribodoi and H. ruspolii were separated from H. araujoi. On the other hand, using mitochondrial DNA, COI gene, the three Hypotrigona species were clearly separated. A lower genetic distance exists between H. araujoi and H. gribodoi from Kakamega (1.4%) than between H. gribodoi collected from Kakamega and H. gribodoi from Mwingi (4.3%). Lastly, using gas chromatography and mass spectrometry, workers were successfully grouped into their respective species and colonies. In conclusion, integrative taxonomy tools applied in this study provides a valuable alternative to identify African stingless bee species. In addition, this study indicates the need for a thorough revision of Hypotrigona species.

Improving access to biological control genetic resources

Authors: Mason Peter[1] and Silvestri Luciana[2], [1]Agriculture and Agri-Food Canada, Canada, [2]National Council for Scientific and Technical Research, Argentina

Abstract: The third objective of the Convention on Biological Diversity (CBD), adopted in 1992 seeks the fair and equitable distribution of the benefits derived from the utilization of genetic resources (GR). The access and benefit-sharing (ABS) regime aims to contribute to the conservation of biological diversity and to bridge the biotechnological gap between developed countries and developing countries, amongst other objectives. Since 1992, several countries have adopted national ABS regimes. Some of them turned out to be highly restrictive; as a result, they even limited access to GR for purely scientific research purpose. Such was the case of the Philippines. This drawback, added to the lack of enforcement of compliance measures in user countries brought about the need to negotiate a new ABS international regime. The Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization (NP), adopted in 2010, further develops the third objective of the CBD. Particularly, the NP establishes that Parties shall create conditions that promote research that contributes to the conservation and sustainable use of biological diversity, including through simplified measures on access for non-commercial research purposes (article 8.a). Since 2010, several countries have updated or even developed national ABS regimes in accordance to the NP. Biological control (BC) is by definition a not for commercial purposes research activity. Based on previous experiences, researchers and practitioners working in the field of BC warn that new national ABS regimes might hinder effective and efficient access to GR. Considering that the symposium will discuss whether national post-Nagoya ABS regimes satisfy Nagoya's requirements; particularly article 8.a, the approaches ABS legal frameworks have taken in relation non-commercial research, and the impacts they are likely to have on activities related to BC. This presentation focuses on the cases of Argentina and Brazil, two important suppliers of BC agents, which had highly restrictive regulations for access to their GR, and which have adopted new legislation to better enable access to GR for scientific research including BC.

Mosquito Monitoring Smart Trap European (Species, Genus and Age) Brazil and Global - field tests and results

Authors: Maspero Renato[2], Njaime Fabio Castelo[1], [1]Ministry of Health, General Coordination of Arbovirus Control, GDF, BR, [2]Technical Consultant - Ministry of Health, General Coordination of Arbovirus

Abstract: Process automation, generate surveillance data in real time, reduction of logistics costs, human resources, time optimization and correct prioritization of hot spots.

The VECTRACK project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 853758.

IoT sensor with Infra-Red optoelectronics that can generate spectral data related to the morphology and kinematics of the insects:

- Savings of 80% in field operations costs
- Remote and automatic classification of mosquitoes: species, sex and age.
- Provides real time information: each capture is tagged with time, coordinates, temperature and humidity.
- Machine Learning cloud server with API to share data with other platforms: Mosquito Alert and VECMAP
- Supported on standards based IoT framework: OGC-SWE, IEE1451
- Sensor capable of capturing data in adult traps with suction fans: mosquitoes detected in <50ms, in an air-flow of 3m/s

Lab results so far - Data analysis using machine learning techniques allow us to separate the different variables tested (species, sex and age) with a range accuracy from 61,3% to 99% .

Earth observation service for preventive control of insect disease vectors.

Assessing the effects of plant and pollinator traits, phylogenies and spatio-temporal distributions on the architecture of plant-pollinator networks

Authors: Massol Francois[2], Berquer Adrien[1], De Manincor Natasha[3] and Joffard Nina[4], [1]CNRS, UMR 7372 CEBC, France, [2]CNRS, UMR 9017 - CIIL, France, [3]University of California, Riverside, United States, [4]Uppsala University, Sweden

Abstract: Pollination is a critical ecosystem service affecting both biodiversity and agriculture through the control of breeding of many angiosperms. Therefore, it is an important concern for society and research. However, plant-pollinator networks are mostly studied from a descriptive point of view - despite considerable theoretical advances, existing methods mostly deal with summary statistics of networks, from connectance and modularity to motif and position counts. Assessing the effects of driving factors, such as insect and plant traits, phylogenies, or habitat preferences, on the structure of networks is still in its infancy. In this presentation, I propose to apply a novel method to assess the determinants of plant-pollinator interactions based on a decomposition of network matrix representations. The method is then applied to two datasets: (i) the network linking all Euro-Mediterranean orchids to their pollinators and (ii) six hoverfly-plant visitation networks sampled in French calcareous grasslands. Results obtained with these analyses pinpoint the leading roles of spatio-temporal variation of species occurrences (phenology and geography) in the determination of plant-pollinator networks. These examples illustrate how our understanding of plant-pollinator interactions might benefit from such large-scale statistical analyses and emphasize a need for more entomological studies aimed at assessing insect species traits and spatio-temporal distribution in order to understand the drivers of pollination.

Hoverflies use a time-compensated sun compass to orientate during autumn migration

Authors: Massy Richard, University of Exeter, United Kingdom

Abstract: The sun is the most reliable celestial cue for orientation available to daytime migrants. It is widely assumed that diurnal migratory insects utilise a ‘time-compensated sun compass’ to adjust for the changing position of the sun throughout the day, as demonstrated in some butterfly species. The mechanisms used by other groups of diurnal insect migrants remain to be elucidated. Migratory species of hoverflies (Diptera: Syrphidae) are one of the most abundant and beneficial groups of diurnal migrants, providing multiple ecosystem services and undergoing directed seasonal movements throughout much of the temperate zone. To identify the hoverfly navigational strategy, a flight simulator was used to measure orientation responses of the hoverflies Scaeva pyrastri and S. selenitica to celestial cues during their autumn migration. Hoverflies oriented southwards when they could see the sun, and shifted this orientation westward following a 6-hour advance of their circadian clocks. Our results demonstrate the use of a time-compensated sun compass as the primary navigational mechanism, consistent with field observations that hoverfly migration occurs predominately under clear and sunny conditions.

Distribution and status of important longhorned beetles (Coleoptera: Cerambycidae) of Croatia

Authors: Masten Milek Tatjana[1], Pintar Maja[2] and Šimala Mladen[2], [1]“Zeleni prsten” Public Institution of Zagreb County, Samobor, Croatia, Croatia, [2]Centre for plant protection - HAPIH, Zagreb, Croatia

Abstract: Family Cerambycidae (longhorn beetles) is one of the economically most important wood boring insect. On the other hand, some species from this family have been under strict legal protection in most European countries. Its high conserva¬tion status results from the global shrinking of its range and resulted in its placement on the IUCN world’s list of endangered species, with VU category.

In recent years, some alien species of longhorn beetles have arrived and spread rapidly through Europe. The most important are Anoplophora chinensis Forster, 1971 and A. glabripennis Motschulsky, 1853. Adult beetles feed on the leaves, bark of twigs and petioles of these hosts, and females chew pits into the bark where they lay their eggs. Larvae burrow into the sap and heartwood, forming galleries. Damage by the larvae can result in crown dieback and early senescence, and eventually the death of the tree. A. chinensis was registered for the first time in Croatia in 2007. Since 2008. Croatia is performing surveys of this quarantine pest. Till today, species have spread on 5 locations on the Croatian coast (Turanj, Sv. Filip and Jakov, Biograd, Cavtat and Vrana) and it is present on one location in the continental part of Croatia in Zagreb county (Rugvica). The important thing is that A. chinensis isn’t yet registered in forests. It is present in nurseries, parks and gardens.

The genus Monochamus Megerle, 1821 comprises of beetles that may become pests of economic importance in conifer stands in the Nearctic and Palearctic Regions. Besides direct damages due to the larval tunneling habits, they have also been recognized as main vectors of the phytoparasitic nematode Bursaphelenchus xylophilus (Steiner & Buhrer, 1934). So far, five European species of genus Monochamus are known. In Croatia two of them are registered; M. galloprovincialis (Olivier, 1795) and M. sutor (Linneus 1758).

Rosalia alpina (Linnaeus, 1758) and Cerambyx cerdo Linnaeus, 1758 are present in Croatia. These are threatened species which have been under strict legal protection and their status is “vulnerable” (VU). Species Morimus asper funereus Mulsant, 1862 are registered in Croatia as well, and even it is not under strict legal protection, it has VU status. All three species are saproxylic beetles, and widespread all over the country. Unlike R. alpine and M. asper funereus which are inhabiting dead woods and are of no economic importance, C. cerdo is primarily inhabiting healthy trees. Due to the damage C. cerdo causes to trees, especially oak communities, this species is considered as a serious pest in forests and orchards. Adults feed on the liquid that appears on the trees during mechanical injuries, as well as on ripe fruits rich with sugar. Larvae of C. cerdo also feed on the sap and heartwood, forming galleries. In some countries of Europe C. cerdo is near extinction, but in Croatia, it is still a quite common species.

Effects of an emergency sewage discharge into a large European river on the structure of Chironomidae larvae

Authors: Matela Mikołaj[1], Obolewski Krystian[1] and Mrozińska Natalia[1], [1]Kazimierz Wielki University, Poland

Abstract: The study was performed on the Vistula River in the urban area (Warsaw city) from December 2019 to May 2021. This period included analysis of the effects of the two failures of wastewater treatment plant (August 2019 and 2020). More than 10 mln m^3 of wastewater entered the lotic ecosystem during the accidents. Insect larvae of the family Chironomidae were selected for monitoring the effects of the accidents. Four study areas were established, including upstream of the urban area (reference point) and others corresponding to the impact of the sewage discharge at distances of 0.5, 2.5 and 4.5 km from the sewage discharge collector. Taxonomic studies identified the presence of 24 taxa of chironomid larvae, with total density was 3,347 individuals m^{-2}. Chironomus plumosus, Cryptochironomus borysthenicus and Polypedilum deletum formed the dominant group. They were accompanied by Cryptochironomus zabolotzkii and Paratendipes intermedius as subdominants. The highest density of larvae recorded during the whole study period was at the site nearest to the collector and the lowest at the distance of 2.5 km from it. However, there is a noticeable increase in the value of the Shannon index with the further distance from the place of sewage discharge into the river.

Chromosome-scale genome assemblies of aphids reveal long-term conservation of the X chromosome and extensively rearranged autosomes

Authors: Mathers Thomas[4], van Oosterhout Cock[5], Swarbreck David[2], Wouters Roland[3], Mugford Sam[1] and Hogenhout Saskia[3], [1]Department of Crop Genetics, John Innes Centre, Norwich Research Park, Norwich, United Kingdom, [2]Earlham Institute, United Kingdom, [3]John Innes Centre, United Kingdom, [4]John Innes Centre, United Kingdom, [5]University of East Anglia, United Kingdom

Abstract: Chromosomal rearrangement plays an important role in evolution. However, our understanding of chromosome dynamics at a sequence-level has been restricted to a relatively small number of model systems where multiple chromosome-scale genome assemblies have been generated. In insects, comparative genomics of Diptera and Lepidoptera has revealed high levels of chromosome conservation within these orders. However, across insects as a whole, chromosome number is highly variable, suggesting a more dynamic situation. In this talk I describe recent work investigating chromosome evolution across aphids, a fascinating group of sap-sucking plant pests belonging to the insect order Hemiptera. By comparing newly generated and published chromosome-scale assemblies of aphids and other Hemiptera we find that the aphid sex chromosome (X) has a highly conserved gene content, with negligible translocations having occurred over 60 million years of evolution. In contrast, aphid autosomes have been highly rearranged during this time, showing evidence of extensive translocations, fusions and fissions. The stability of X chromosome gene content contrasts with a dynamic evolutionary substrate – X linked genes are fast evolving, and the X chromosome is significantly more repetitive than the autosomes. I will discuss these findings in the context of aphid sex chromosome evolution and sex determination.

Exploring Genetic Determinants of Variation in Arboviral Competence in an Aedes aegypti population from Florida, USA

Authors: Mathias Derrick[1], Bozic Jovana[1], Stenn Tanise[1] and Wang Xiaodi[1], [1]Florida Medical Entomology Laboratory, Institute of Food and Agricultural Sciences, University of Florida, United States

Abstract: Since 2009 at least three Aedes aegypti-transmitted arboviruses non-endemic to the United States (chikungunya, dengue, and Zika viruses) have emerged or re-emerged in the state of Florida, illustrating their threat to public health. These emergence events have mostly remained localized, with the number of autochthonous cases reported per event ranging from 1 (dengue virus in 2015, 2018) to more than 200 (Zika virus in 2016). In Florida, local transmission of dengue virus (DENV) in particular has become more commonplace, as autochthonous cases were reported in 10 of 11 years from 2009 – 2019 with a maximum of 65 cases in 2010. A key factor governing the spread of emergent arboviruses is the vector competence (VC) of local mosquito populations. Conceptually, VC is defined as the ability of an arthropod to harbor a pathogen and transmit it horizontally to new hosts, and in mosquitoes VC can be estimated empirically as the proportion of females that produce virus in saliva following oral exposure in a bloodmeal and the extrinsic incubation period (EIP). During the EIP, arboviruses must negotiate physiological tissue barriers within the mosquito that include the apical and basal surfaces of midgut and salivary-gland epithelia. Data from the literature and reported here indicate that VC for a given arbovirus tends to vary within mosquito populations and that geographic origin of both the vector and virus strongly influences VC, demonstrating the importance of mosquito and virus genetics on VC phenotype. Although physiologically we have a basic understanding of the molecular pathways in mosquitoes (e.g., RNA interference, innate immunity, apoptosis, autophagy) that influence viral infection dynamics, what is less clear is how genetic variation in these pathways vary within natural populations and how such variation impacts VC. Data will be presented on variation in vector competence for dengue and Zika viruses in a population of Ae. aegypti from Florida, as well as efforts underway to characterize molecular-genetic variation segregating within this population and to investigate associations between mosquito genotype and VC phenotype.

De novo genome assembly combined with long-read RNA-seq reveal insights into early embryo development of an important agricultural insect

Authors: Mathiopoulos Kostas, Dept. of Biochemistry & Biotechnology, University of Thessaly, Greece

Abstract: Background
The olive fruit fly (Bactrocera oleae) is the most important pest of cultivated olive trees but poorly characterized at a genomics level.

Results
We assembled the 480 Mb B. oleae genome using short-, mate-pair-, long-, and linked-read sequencing technologies to generate a genome assembly (Genbank accession GCA_001188975.3) with a scaffold N50 of 4.69 Mb and L50 of 30 scaffolds. Using the chromosome quotient method enabled identification of Y-chromosome scaffolds which were extensively validated by PCR. Oxford Nanopore long-read RNA-seq of B. oleae embryos collected at hourly intervals for the first 6 hours of development yielded a median of 4.5 million total reads per timepoint. Through our custom pipeline, we generated a de novo long-read transcriptome assembly of the olive fly and identified 1768 novel genes and a total of 79,810 transcripts. We noticed sex specific isoforms some of which were found in genes related to sex development. Using internal ERCC RNA standards, we obtained absolute gene expression quantification and we were able to define a set of developmental stage-specific transcripts. On a global scale, the first six hours of embryo development were characterized by dramatic transcriptome changes with the total mRNA content per embryo dropping by half from the first hour to the second hour of embryo development.

Conclusions
These data provide the first insight into the transcriptome landscape of the developing olive fly embryos and provides avenues that can be used to identify new targets which can help suppress fly population in the field and prevent crop damage.

Role of Endophytes on Insect Induced Responses in Brassica juncea

Authors: Mathur Vartika[1] and Sharma Garima[2], [1]Department of Zoology, Sri Venkateswara College, University of Delhi, India, [2]Sri Venkateswara College, University of Delhi, India

Abstract: Endophytes are the most diverse and abundant colonizers of plants and share an intimate metabolic interaction with the host plant. In exchange of carbon and nitrogen resources, they contribute to the secondary metabolic profile of their host and play a crucial role in plant fitness and defence. However, the role of endophyte association in conferring resistance to the host upon insect attack is still unclear. Therefore, we studied early responses (superoxide dismutase, SOD; peroxidase, POD and protease inhibitor, PI) of Brassica juncea, with and without endophytes, against the damage by a generalist insect Spodoptera litura.
Plants with endophytes showed significantly elevated POD and PI after 24h of insect damage, compared to plants without endophytes. Although increased PI content upon insect damage was also observed in plants without endophytes, this change was considerably lesser compared to plants with endophytes. Furthermore, SOD increased upon insect damage irrespective of endophyte presence. These changes indicate an overall suppression in the early responses upon insect damage in plants without endophytes, suggesting their significance in insect resistance. Thus, the intimate association between endophytes and the host plant have the potential to offer an exclusive breakthrough for application in plant protection and biological control.

The use of whole-genome sequencing data to bridge macro- and micro-evolution in butterflies

Authors: Matos Maraví Pável[2] and Ribeiro Pedro[1], [1]Biology Centre CAS, [2]Biology Centre CAS, Czech Republic

Abstract: Short read whole genome re-sequencing (WGS) is a cost-effective approach to obtain genome wide nucleotide polymorphisms to study processes at the species and population levels. Although there is a growing number of high-quality reference genomes across butterfly families which can be used for read mapping, the characterization of genomic variation still relies on de novo contig assemblies for most lineages. We show that phylogenomic markers can be more efficiently mined from de novo assemblies that were generated using multi-kmer approaches and having at least 5X sequence coverage. We were able to produce more complete and informative alignments by merging data coming from low coverage WGS and sequence target capture, to produce a robust tribal-level phylogeny of the butterfly subfamily Eudaminae (Hesperiidae). Further, using gene tree-based methods, we estimated large-scale introgression events in Eudaminae clades where substantial phenotypic convergence has been estimated, which might indicate a possible correlation. Ongoing efforts are being made to characterize highly divergent genomic regions that potentially explain the genetic differentiation of phenotypically similar co-occurring sister species in the Neotropical genera Cecropterus and Spicauda (Eudaminae). Altogether, WGS is an efficient approach to understand the assembly of butterfly species and genetic diversity across evolutionary scales.

The challenge of managing an alien invasive forest insect pest-a successful case of classical biological control with introduced parasitoid Torymus sinensis

Authors: Matošević Dinka, Croatian Forest Research Institute, Croatia

Abstract: Dryocosmus kuriphilus (Hymenoptera, Cynipidae) is considered as one of the major pests of sweet chestnut (Castanea) worldwide and the only effective method of controlling the populations and damages of this invasive forest pest is biological control with introduced parasitoid Torymus sinensis. T. sinensis is a univoltine, host specific parasitoid, phenologically synchronized and morphologically adapted to D. kuriphilus. T. sinensis has good dispersal ability, builds up populations quickly and effectively controls the pest already few years after release. Ten years after first releases and natural dispersal in Croatia, we have evaluated the impact of this classical biocontrol agent on invasive population of D. kuriphilus. T. sinensis has shown traits of very effective biocontrol agent: the methods for raising and release are not difficult to apply, it disperses very quickly when released, it lowers the population of its host for more than 90% in only few years, suffers no bottleneck -induced founder effect phenomenon and leads to recovery of chestnut yield in natural sweet chestnut forests. This is first example of successful application of classical biocontrol agent in forests in Croatia, Slovenia and Hungary.

Increased voltinism and outbreak level of bark beetle Orthotomicus erosus populations in Mediterranean part of Croatia-high potential of a forest pest in changed ambient conditions

Authors: Matošević Dinka[1] and Pernek Milan[2], [1]Croatian Forest Research Institute, Croatia, [2]Department for forest protection Croatian Forest Research Institute, Croatia

Abstract: Bark beetles are important forest pests which have already been researched and discussed in relation to climate change, indicating that the predicted increase in temperature would lead to higher survival rates and faster development, thus directly influencing their population dynamics. Bark beetle Orthotomicus erosus is widely distributed across the Mediterranean and southern Europe, Asia and North Africa. It is considered as secondary pest found on recently dead or felled trees, but can also attack weakened living trees. In high population levels this species can attack healthy trees and cause their dieback. Severe outbreaks occur after dry periods, or after fire in adjoining stands in warmer parts of the Mediterranean region. Several locations in the Mediterranean part of Croatia (Marjan Forest Park in Split, islands of Lokrum and Korcula) had reported dieback of Aleppo pine from the year 2016. Visual examination of trunks, branches and bark showed symptoms of bark beetle infestation, and on-site examination of the observed adults and morphological identification pointed out to O. erosus. Population monitoring with pheromone traps in the years 2017, 2018 and 2019 showed 6 to 7 generations per year which has never been recorded in Croatia or in any other European country. O. erosus is native to Croatia and so far it has been considered only as a minor pest whose outbreaks have never been recorded. Drought intensity and frequency and aridification trends in the research area (Dalmatia, Croatia) cause cumulative stress to trees and have increased O. erosus occurrence. O. erosus has shown increased voltinism, better overwintering performance and earlier spring flights. Our first results confirm this epidemic stage of O. erosus with high abundances in Dalmatia. The population level and pest status of this bark beetle has been seriously altered probably due to climate change. High dispersal abilities of O. erosus through active flight and easy transportation with infested material (logs and branches with bark), O. erosus has the potential to become an important forest pest in Croatia and in other European Mediterranean countries.

Insecticides okaramines work as defense weapons for plants in nature

Authors: Matsuda Kazuhiko, Kindai University, Japan

Abstract: Indole alkaloids okaramines were discovered as insecticidal substances from fermentation products of fungus Penicillium simplicissimum in soy pulp okara. Testing the compounds on the silkworm larval neurons using patch-clamp electrophysiology led to a finding that okaramines selectively activate ligand-gated chloride channels. Hence, actions of okaramines were investigated on ?-aminobutyric acid receptors and glutamate-gated chloride (GluCls) channels expressed in Xenopus laevis oocytes. As a result, okaramines selectively activated GluCls expressed only in invertebrate nervous systems. Following the discovery of okaramines, many other insect-active compounds were isolated from fungal products in okara. They also modulated insect ion channels with high selectivity. It was therefore predicted that plants secret chemical signals that induce microorganisms to produce defense weapons for plants in the rhizosphere.

Understanding target site of actions of neonicotinoids for safer and environmentally benign crop protection

Authors: Matsuda Kazuhiko[1], Ihara Makoto[1], [1]Kindai University, Japan

Abstract: Neonicotinoids modulate insect nicotinic acetylcholine receptors to exhibit insecticidal actions. Neonicotinoids show high systemicity in plants, which enables seed treatment, and now make up >25% of insecticide sales in the world. However, recent studies suggest a potential risk of neonicotinoids to pollinator, notably to bees, and thus it is critical to understand neonicotinoid actions in detail. We have studied mechanisms of selectivity to insects as well as of diverse actions of neonicotinoids and found that 1) both a and non-a subunit possess structural features favorable for interacting with neonicotinoids; 2) Vertebrate a subunits possess glutamate residue in loop C, which plays a gate keeper role for repelling neonicotinoids; 3) Insect non-a subunits possess basic residues in loop D, which interact electrostatically with the nitro or cyano group of neonicotinoids to enhance the affinity. Further, we have recently found that basic residues in loops G and E may also contribute to the binding of neonicotinoids. With all these results, we discuss the future perspective of neonicotinoids.

Selectivity of okaramines, indole alkaloid insecticides targeting glutamate-gated chloride channels

Authors: Matsuda Kazuhiko[1], Ihara Makoto[1], Koizumi Wataru[1], Sattelle David[3], Furutani Shogo[2] and Buckingham Steve[3], [1]Kindai University, Japan, [2]National Institute of Infectious Diseases, Japan, [3]University College London, United Kingdom

Abstract: Indole alkaloids okaramines were found as insecticidal compounds against the silkworm larvae (Bombyx mori) from the fermentation products of Penicillium simplicissimum in soy pulps 'okara'. They exhibit rapid toxicity when applied not only by injection, but also by oral administration. We investigated the target of okaramines using patch clamp electrophysiology to show that they selectively activated glutamate gated chloride channels (GluCls). Since it was unclear whether they modulate the other ligand-gated chloride channels, we tested okaramine B, the most potent okaramine, on Bombyx RDL ?-aminobutyric acid (GABA) receptor as well as human a1ß2?2 GABAR and a1ß glycine receptor expressed in Xenopus laevis oocytes. Okaramine B was ineffective on these chloride channels, suggesting high selectivity to GluCls. We also tested okaramine B on GluCls from other insect species than the silkworm larvae and found that it also modulated GluCls with different affinity and efficacy.

Modulation of neonicotinoids of recombinant nicotinic acetylcholine receptors containing a pollinator a subunit

Authors: Matsuda Kazuhiko[1], Ihara Makoto[1], Yuma Komori[1] and Shigetou Sho[1], [1]Kindai University, Japan

Abstract: So far neonicotinoids have been used for crop protection relying on their high plant systemicity as well as on pest control efficacy. Meanwhile, there is evidence that some neonicotinoids may cause the decline of bees. Hence it is urgent to understand how neonicotinoids act on their targets, nicotinic acetylcholine receptors (nAChRs) in pollinators. While the difficulty of their functional expression has impeded the study of neonicotinoids, robust nAChRs formed by insect a subunits and vertebrate non-a subunits in cell lines and Xenopus laevis oocytes have been employed to understand the mode of action and selectivity of neonicotoids. Thus, we attempted to co-express a pollinator a subunits with chicken ß2 subunit, resulting in robust nAChRs. The recombinant nAChRs can be used to evaluate the mode of actions, not only of neonicotinoids, but also of pest-selective ligands underlying plant-microbe-insect interactions.

Role for serine221 in loop C in determining neonicotinoid actions on Drosophila Da1/chicken ß2 hybrid nicotinic acetylcholine receptors

Authors: Matsuda Kazuhiko[1], Ihara Makoto[1], Yuma Komori[1], Kamiya Masaki[1], Shigeto Sho[1] and Shimada Shota[1], [1]Kindai University, Japan

Abstract: Neonicotinoids selectively modulate insect nicotinic acetylcholine receptors (insect nAChRs). Studies have shown that serine with ability to form a hydrogen bond in loop C of some insect nAChR a subunits may contribute to enhancing the neonicotinoid actions. However, there is no clear evidence what loop C properties underpin the target site actions of neonicotinoids. Thus, we have investigated the effects of S221A and S221Q mutations in loop C of the Drosophila melanogaster Da1 subunit on the agonist activity of imidacloprid and thiacloprid for Da1/chicken ß2 nAChRs expressed in Xenopus laevis oocytes. The S221A mutation hardly affected either the affinity or efficacy for ACh and imidacloprid, whereas it slightly reduced the efficacy for thiacloprid on the nAChRs with a higher composition ratio of ß2 to Da1 subunits. The S221Q mutation markedly reduced their efficacy of the neonicotinoids for the nAChRs with a higher composition of the ß2 subunit lacking basic residues critical for binding neonicotinoids. Hence, we council caution of enhanced neonicotinoid resistance in pests by a mutation of the serine when it occurs in the R81T resistant populations lacking the basic residue in loop D and demonstrate needs of new chemical leads which may be found from chemical signals controlling insect behaviors.

Molecular basis of pyrethrum repellency in Aedes aegypti

Authors: Matsuda Kazuhiko[6], Dong Ke[9], Ihara Makoto[6], Coats Joel[4], Feng Bo[7], Bandason Elizabeth[8], Oliveira Eugenio[10], Andreazza Felipe[11], Liu Feng[8], Makamatsu Genki[5], Klimavicz James[3], Scott Jeffrey[1], Smith Leticia[2], Chen Mengli[12], Xu Peng[8], Wang Qiang[7], Yan Ru[12], Valbon Wilson[10] and Du Yuzhe[7], [1]Cornell Univ, United States, [2]Cornell Univ., United States, [3]Iowa State University, United States, [4]Iowa State University, United States, [5]Kindai University, Japan, [6]Kindai University, Japan, [7]Michigan State Univ, United States, [8]Michigan State Univ., United States, [9]Michigan State University, United States, [10]Universidade Federal de Viçosa, Brazil, [11]Universidade Federal de Viçosa, United States, [12]Zhejiang University, China

Abstract: Pyrethrins I and II, the principal components of pyrethrum, and pyrethroids target voltage-gated sodium channels for insecticidal action. However, the molecular basis of pyrethrum/pyrethroid repellency remains enigmatic. Here we discovered that pyrethrum elicited repellency through a multi-target mechanism in Aedes aegypti. Here we discovered that pyrethrum elicited repellency through a multi-target mechanism in Aedes aegypti. Pyrethrins I and II activated a specific type (sst-1A) of olfactory receptor neurons (ORNs) and elicited odorant receptor (Or)-mediated repellency. We also discovered that sesquiterpene (E)-ß-farnesene (EBF), a minor component of pyrethrum extracts, can elicit repellency by activating a specific Or expressed in another type (sbt-1A) of ORNs. Furthermore, two mutations in sodium channels that attenuate the potency of pyrethrins on sodium channels also reduced pyrethrum repellency. Collectively, our results suggest a synergistic Or- and sodium channel-mediated repellent action by multiple components in pyrethrum extracts. Discovery of this multi-target mechanism provides a conceptual framework for development of a new generation of broad-spectrum and durable insect repellents.

Silkworms suppress the release of green leaf volatiles by mulberry leaves with an enzyme from their spinnerets

Authors: Matsui Kenji, Yamaguchi University, Japan

Abstract: In response to herbivory, plants emit a blend of volatile organic compounds that includes green leaf volatiles (GLVs) among others. GLVs are known to attract natural enemies of herbivores and are therefore considered to function as an indirect defense. Selection should favor herbivores that are able to suppress these volatile emissions, and thereby make themselves less conspicuous to natural enemies. Silkworms leave secretions from their spinnerets while feeding on mulberry leaves. We ablated the spinnerets of silkworms to limit the secretions. The leaves infested by ablated silkworms emitted higher amounts of GLVs than those infested by intact silkworms while the amounts of other volatiles were similar, indicating that the spinneret secretion specifically suppressed GLV production. We found a novel enzyme that converted 13(S)-hydroperoxy-(9Z,11E,15Z)-octadecatrienoic acid, an intermediate in the biosynthetic pathway of GLVs, into its keto-derivative that cannot be used to form GLVs in leaves. Zenillia dolosa (Tachinidae), a parasitoid fly of silkworms, discriminated the difference in GLV emissions, and the flies laid fewer eggs when exposed to the volatiles from intact silkworm-infested leaves than when exposed to the volatiles from ablated silkworm-infested leaves. The genes orthologous to that encoding the enzyme were widespread among Lepidoptera. It is suggested that lepidopteran insects are able to feed on leaves in a stealthy manner by suppressing GLV production, as a countermeasure against induced indirect defense by plants.

The evolution of Zoraptera

Authors: Matsumura Yoko[1], Yao Izumi[4], A. Rafael Jose[5], T. Camara Josenir[2], Yoshizawa Kazunori[3], Beutel Rolf[6] and P. Lima Sheila[5], [1]Department of Functional Morphology and Biomechanics, Zoological Institute, Kiel University, Germany, [2]Federal University of Piaui, Brazil, [3]Hokkaido University, Japan, [4]Systematic Entomology, School of Agriculture, Hokkaido University, Japan, [5]The National Institute of Amazonian Research, Brazil, [6]University of Jena Jena, Germany

Abstract: Together with Dermaptera, Zoraptera is the first split among the polyneopteran orders. To understand the evolution of Polyneoptera, accumulating more knowledge on zorapteran species is essential. However in comparison to Phasmatodea and other related groups, there are still large gaps of information. Based on a broad taxon sampling from all continents where the group is known we conducted the first species level phylogeny, using partial sequences of 18S rRNA, Histone 3, 16S rRNA, and 12S rRNA genes. The resulting phylogenetic trees show that Zoraptera is divided into three major clades, and that two of them are composed of species distributed on different continents. The monophyly of these clades is at least partly supported by shared derived morphological features. The divergence age estimation and ancestral distribution area reconstruction unveiled an ancient origin and early radiation initiated in the Permian. The plate tectonics theory suggests that the present distribution of Zoraptera was mainly established by vicariance, rather than dispersal. The three major clades likely originated on the Pangaea supercontinent, or alternatively on the Gondwana and Laurasia supercontinents. Their ancient origin explains previously found conspicuous interspecific divergence variation of the spermatozoa morphology, genital apparatus, sperm structure, and mating behavior, in striking contrast to a highly conserved general body morphology. We also compiled data of available reproductive features and reconstructed the character evolution. Although homologies in the genital character system are not fully established yet, the analyses revealed repeated acquisitions and/or losses of a hyper-elongated intromittent organ, mating hooks, and tergal protuberances. We will discuss desiderates and introduce a part of our latest projects aiming at a better understanding of the evolution of Zoraptera.

Olfactory receptors tuned to volatile mustard oils in flies

Authors: Matsunaga Teruyuki[2], Goldman-Huertas Benjamin[3], Reisenman Carolina[4], Suzuki Hiromu[4], Miao Kevin[4], Whiteman Noah[1], Brand Philipp[5] and Ramirez Santiago[5], [1]Department of Integrative Biology, University of California, Berkeley, United States, [2]Department of Integrative Biology, University of California, Berkeley, United States, [3]University of Arizona, United States, [4]University of California, Berkeley, United States, [5]University of California, Davis, United States

Abstract: Plant toxins are effective defenses because they are aversive to most insects. The same molecules, however, are co-opted as host-finding cues by specialist herbivores. Although these behavioral shifts are central to our understanding of herbivorous insect diversification, it is not well understood how these behaviors evolve. We addressed this in Scaptomyza flava, a herbivorous drosophilid fly that shifted to toxic mustard plants (Brassicales) less than 10 million years ago and lost the ancestral attraction to yeast volatiles as well as the attendant chemoreceptors. We first found a gain-of-function behavior: S. flava, but not its close microbe-feeding relatives Drosophila melanogaster and S. pallida, is attracted to mustard host-plant odors, including volatile mustard oils (isothiocyanates or ITCs). Our genomic analysis then uncovered three S. flava paralogs of an olfactory receptor gene (Or67b) that likely experienced recent positive selection. We then tested whether these candidate chemoreceptors could underlie the observed attraction to volatile ITCs. Our in vivo recordings revealed that two of the S. flava Or67b proteins (Or67b1 and Or67b3) – but not the homologous Ors from microbe-feeding relatives - responded selectively to volatile ITCs. These Ors are the first ITC chemoreceptors other than TRP channel family (e.g., the TrpA1 ‘wasabi’ receptor) known from any animal. Remarkably, S. flava Or67b3 was sufficient to drive olfactory attraction toward butyl ITC when expressed in an attractive olfactory circuit. Our study illuminates that ancestrally aversive chemicals can be co-opted as attractants through gene duplication, leading to the origin of hedonic valence shifts in herbivorous insects.

Evolutionary relationship between endopolyploidy and fecundity in termite queens

Authors: Matsuura Kenji[2], Nozaki Tomonari[1], [1]Center for the Development of New Model Organisms, National Institute for Basic Biology, Japan, [2]Kyoto University, Japan

Abstract: Extreme reproductive specializations are exhibited in social insects under the reproductive division of labor. Female fertility of them ranges from sterility (workers or soldiers) to hyperfecundity (queens). In termites, queen fecundity varies greatly between lineages with different lifestyles: queens in species with foraging lifestyle, which is observed in the advanced clade show much higher fecundity than those in wood-dwelling lifestyle, which is considered phylogenetically basal type. Recently, we reported that in a termite, queens exhibited higher polyploid levels than the nonreproductives in their fat body, the organ producing a lot of yolk protein precursors, vitellogenin. Moreover, we found that the polyploidization was occurred along with ovarian development of the queens. In general, endopolyploidy or somatic polyploidy is often attributed to the increasing cellular size or gene expression owing to the increase in availability of DNA templates; therefore, the fat body endopolyploidy can accelerate egg production, via promoting vitellogenin synthesis.

In this study, in order to investigate the relationship between the fecundity and ploidy level in the fat body of the queens, we conducted ploidy analyses on three foragings and three wood-dwelling termites via flow cytometry. In all the species, the fat body of queens contained significantly more polyploid cells than that of other nonreproductive females, even considering their body size effect. On the other hand, the male fat body, which is not involved in yolk production, did not show consistency in the rate of polyploid cell among the species studied. Then, we compared the relative ploidy levels of queens, which is the standardized polyploid level of queens relative to the polyploid levels of conspecific female workers that represent nonreproductives, and found that highly fecund queens in foraging termites exhibit higher levels of endopolyploidy in their fat body than those with less fecundity in wood-dwelling termites. These results suggest not only that endopolyploidy in the fat body of termite queens can boost their egg production, but also the level of endopolyploidy in their fat body is linked to their fecundity. Our study provides a novel insight into the evolutionary relationship between endoreduplication and caste specialization in social insects. In this talk, we will also discuss about what the polyploid index actually means, or the physiological significance of fat body endopolyploidy such as the regulation of gene expression, cell size and cell differentiations.

Genomic imprinting and the origin of termite eusociality

Authors: Matsuura Kenji, Kyoto University, Japan

Abstract: The concept of epigenetic inheritance provides the keys to many unsolved puzzles in a wide range of biology. Recent empirical studies have revealed that the transfer of epigenetic marks from parents to offspring can influence offspring phenotype independently of DNA sequence. Reproductive division of labor is a hallmark of social insect societies where individuals follow different developmental pathways resulting in distinct morphological castes. There has been a long controversy over the factors determining caste fate of individuals in social insects. It has been known that parental phenotypes influence the caste fate of offspring in termites. For example, female offspring of sexually matured queens and worker-derived males develop exclusively into queens, as do parthenogenetically produced daughters. Such heritable effects on caste propensity has been recognized as an evidence of genetic caste determination. Recently, we demonstrated that parental phenotypes influence the social status of the offspring not through genetic inheritance but through genomic imprinting. We conducted extensive field survey and genetic analysis of the termite Reticulitermes speratus and concluded that the caste system of this species cannot be explained by genetic caste determination models. Alternatively, we documented a genomic imprinting caste determination system in termites, in which queen- and king-specific epigenetic marks antagonistically influence the sexual development of offspring and thus determine their caste fate. Our genomic imprinting model accounts for all known empirical data on caste differentiation in termites and explains the evolutionary processes underlying diverse reproductive systems. According to the genomic imprinting model, the worker caste is seen as a ‘neuter’ caste whose sexual development is suppressed due to counterbalanced maternal and paternal imprinting. Importantly, a wide variety of species including lower and higher termites share the genomic imprinting caste determination system. The most parsimonious idea to explain this background would be that genomic imprinting is involved in the origin of termite eusociality. Our model further demonstrates that genomic imprinting played an essential role in the origin of eusociality.

Gut microbial pulse provides nutrition for parental provisioning to larvae during colony foundation in a termite

Authors: Matsuura Kenji[2], INagaki Tatsuya[5], Igai Katsura[4], Yanagihara Saki[1], Fuchikawa Taro[3] and Hongoh Yuichi[4], [1]Kyoto University, Japan, [2]Kyoto University, Japan, [3]Osaka City University, Japan, [4]Tokyo Institute of Technology, Japan, [5]Tokyo Institute of Technology, Japan

Abstract: The success of aerial dispersal involves a tradeoff between propagule size and dispersal ability such that reducing weight may increase dispersal capability. Therefore, dispersing propagules such as plant seeds, fungal spores, and insect alates need to settle in new habitats with a very limited amount of resources. In termites, the time from alate dispersal to colony foundation is the most critical period in their life-cycle because a pair of males and females establish a new colony without any help from others. In addition, termites depend largely on gut microbes for their nutrition. However, little is known how termite founding pairs with limited resources manage to establish new colonies and raise first brood in association with their gut symbionts. Here we provide the integrated analysis of reproductive schedule, gut microbial fluctuation, and resource allocation of founding pairs in incipient colonies of subterranean termite, Reticulitermes speratus. We found a steep increase and rapid decrease of intestinal protozoa (hereafter gut microbial pulse) at the timing of larval hatching. Besides monogamous pairs same-sex (male-male and female-female) pairs found tentative colonies in this termite. A comparison of the patterns of changes in the amount of protein and lipid among different types of pairs revealed that the gut microbial pulse plays an essential role for parents to feed the first brood larvae. We also found that founders utilize the storage protein and lipid for brood production. Our study highlights the significant role of intestinal symbionts during the early stage of the termite life cycle.

Identification of an aggregation pheromone in a termite

Authors: Matsuura Kenji[3], Mitaka Yuki[4], Mizumoto Nobuaki[1], Matsuyama Shigeru[5] and Akino Toshiharu[2], [1]Arizona State University, United States, [2]Kyoto Institute of Technology, Japan, [3]Kyoto University, Japan, [4]Laboratory of Insect Ecology, Kyoto University, Japan, [5]University of Tsukuba, Japan

Abstract: Termites have developed a sophisticated chemical communication system that regulates various social activities. In most subterranean termites, workers forage for new wood resources to expand their nesting areas. When they discover a new edible wood, they gather and stay there, suggesting that an aggregation pheromone regulates this colonization process. Nevertheless, such a pheromone has never been discovered until today. This study successfully identified the aggregation pheromone that serves as the signal for the presence of nestmates and the place suitable for staying for a long time in the termite Reticulitermes speratus. Gas chromatography-mass spectrometry analysis combined with bioassays revealed that the workers utilize the mixture of an aromatic hydrocarbon, cuticular hydrocarbons, saturated and unsaturated fatty acids, and a steroid compound as the aggregation pheromone triggering long-term aggregation. Although the aromatic hydrocarbon can attract workers, all the other compounds enhanced the arrestment effects on the attracted workers when mixed. These results suggest that termite foraging workers produce the multicomponent aggregation pheromone by combining cuticular hydrocarbons with a volatile hydrocarbon and lipids, and that this pheromone enables the quick aggregation of the workers, contributing to efficiently feeding and dwelling in new dead wood. This work contributes to further understanding of the chemical communication underlying the social assembly in termites.

Royal homeostasis: the advanced maintenance systems exist in long-lived termite kings and queens

Authors: Matsuura Kenji[2], Tasaki Eisuke[3] and Iuchi Yoshihito[1], [1]Graduate School of Sciences and Technology for Innovation, Yamaguchi University, Japan, [2]Kyoto University, Japan, [3]Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto University, Japan

Abstract: The trade-off between reproduction and longevity is the bedrock of the evolutionary theory of aging. The evolution of eusociality in termites has been attended by an increase in the intrinsic longevity of the royals (kings and queens) without sacrificing high reproductive activity. The extraordinary longevity of the royals, which contradicts the trade-off, has attracted much attention because it implies the existence of an anti-senescence mechanism. We performed comparative analyses of molecular homeostasis between long-lived royals and short-lived non-reproductive individuals in the subterranean termite <i>Reticulitermes speratus</i>. In this investigation, we found that the royals have advanced antioxidant and DNA-repairing system, which are important for maintaining molecular homeostasis, in comparison to that of non-reproductive individuals. In addition, we focused on environmental factors that influence physiological state in organisms. Termite royals reproduce in royal chambers deep inside the wood, which expects hypoxic environment in the royal chamber. We tested whether hypoxia influences the development of royal characteristics and found that hypoxia enhances survival and reproductive activity in the royals of <i>R. speratus</i> compared with those in control conditions. This result suggested that adaptation to hypoxic habitats accompanied with the development of anaerobic energy-producing systems, which avoid oxidative metabolic stress, may contribute to lifespan extension in the termite royals. Our studies provide new insights to the maintenance system of molecular homeostasis in long-lived termite royals.

Suppressive effect of prohydrojasmon on the western flower thrips (Frankliniella occidentalis) on greenhouse tomato plants

Authors: Matsuura Shohei[1], Abe Hiroshi[5], Mitomi Masaaki[3], Ohya Takeshi[2] and Sakurai Tamito[4], [1]Hiroshima Prefectural Technology Research Institute, Agriculture Research Center, Japan, [2]Kanagawa Prefectural Agricultural Research Center, Japan, [3]Meiji Seika Pharma Co., Ltd., Japan, [4]NARO Agricultural Rresearch Center, Japan, [5]RIKEN BioResource Center, Japan

Abstract: Frankliniella occidentalis is an important pest that transmits tospoviruses such as Tomato spotted wilt virus. F. occidentalis feeds by piercing plant cells with their mouthparts and ingesting cell contents through their stylets. Resistance in plants including Solanaceae against herbivorous insects depends on wound-response signaling via phytohormone jasmonate (JA). Thus, JA and its derivatives are phytohormones with essential roles in plant defense against herbivorous arthropods. Using an Arabidopsis–thrips system, Abe et al. (2008) revealed that endogenous JA enhanced resistance against thrips feeding via a JA-regulated defense response. Based on this finding, Abe et al. (2009) also showed that application of JA to Arabidopsis plants enhanced plant resistance to thrips; thus, JA induces acquired resistance against thrips feeding in Arabidopsis. Prohydrjasmon (PDJ), which is JA derivative, is registered for use as a plant growth regulator for accelerating ripening of tree fruits. We investigated the suppressive effects of PDJ sprays on F. occidental infestation of greenhouse tomato plants and the influence of these sprays on tomato growth, yield, and quality of tomato fruit under commercial-like conditions to help develop a novel control measure based on PDJ's repellent action with respect to this pest. In experiments conducted over two consecutive years, we evaluated how spraying with PDJ affected F. occidentalis infestations of greenhouse-grown tomato plants. Single or consecutive sprayings of 400 nmol/ml PDJ in the early growth stage of tomato plants significantly suppressed thrips infestation and feeding damage as well as spraying with spinetoram. Although initial plant growth was slightly inhibited by spraying with PDJ, no deleterious effects on tomato yields or fruit quality were observed. These results suggest that PDJ could be practically used as a repellent to control F. occidentalis infestation and primary tospovirus infection in commercial tomato growing greenhouses.

Are arthropod head segmentation mechanisms evolutionarily conserved?

Authors: Matsuyama Ryo, Kyoto University, Japan

Abstract: Is the insect head segmented in the same way as the trunk? Studies using Drosophila have found differences in the expression of pair-rule genes and Hox genes between the head and trunk, suggesting different segmentation mechanisms between them. However, the insect head segmentation is poorly understood compared to the trunk, and the detailed mechanism-of head segmentation is unknown.

In other arthropods such as chelicerata, myriapoda and crustaceans, the head segment is formed by splitting of hedgehog (hh) stripes during embryonic development. Furthermore, it has recently been reported that msx1 is involved in splitting of the hh stripes in chelicerata.

In this study, we aim to understand whether the function of msx1 in splitting hh stripes is conserved outside od chelicerata. We performed functional analysis of msx1 and hh orthologs in the two-spotted cricket Gryllus bimaculatus, and found that these genes are involved in the segmentation of the anterior region of the head. This work provides the first evidence that supports the involvement of msx1 in splitting hh stripes in hexapods, and suggests that the anterior head region is formed by an evolutionarily conserved segmentation mechanism, that is splitting, throughout arthropods.

Interactions between air temperature and snow cover during overwintering produce extreme effects on the population dynamics of the alpine butterfly, Parnassius smintheus

Authors: Matter Stephen[2] and Roland Jens[1], [1]University of Alberta, Canada, [2]University of Cincinnati University of Alberta, United States

Abstract: We have been monitoring the dynamics of a network of 21 populations of this alpine butterfly since 1995. We show how the population dynamics are dominated by weather conditions early in the overwintering period (Nov.). Snow cover and temperature both act quadratically so that population growth is highest at mean values and lowest at extremes. There is also a strong interaction of these factors. Lab and field experiments show that warn, dry conditions result in premature emergence and cold, dry conditions freezing. Analysis of overwintering survival and temperature on the ground where eggs indicate that interaction between snow cover and temperature is only partly due to its effects on temperature at ground level and overwintering survival. Temperatures and snow cover negatively affecting population growth occur commonly, however the combination of these factors at very high or low levels represents an extreme event with large negative effects on population growth.

High evolutionary potential in the chemical defenses of an aposematic Heliconius butterfly

Authors: Mattila Anniina L. K.[5], Bacquet Caroline[3], D. Jiggins Chris[1], de Castro Erika[1], Montejo-Kovacevich Gabriela[1], Saastamoinen Marjo[2] and H. Opedal Øystein[4], [1]Department of Zoology, University of Cambridge, United Kingdom, [2]Helsinki Life Science Institute, University of Helsinki, Finland, [3]Ikiam, Universidad Regional Amazónica, Ecuador, [4]Lund University University of Helsinki, Sweden, [5]Organismal and Evolutionary Biology Research Programme, University of Helsinki, Finland

Abstract: Chemical defences against predators underlie the evolution of aposematic coloration and mimicry, which represent classic examples of adaptive evolution. Yet, unlike color patterns, little is known about the evolutionary potential of chemical defences. Neotropical Heliconius butterflies exhibit incredibly diverse warning color patterns and widespread mimicry. Their larvae feed exclusively on cyanogenic Passiflora vines, can metabolize and sequester host plant toxins, as well as biosynthesize defensive cyanogenic toxins themselves. Here, we investigate variation of biosynthesized toxicity both in wild populations along environmental gradients and in common-garden broods and feeding treatments in Heliconius erato, together demonstrating considerable intraspecific variation and evolutionary potential in this important chemical defense trait. Among wild populations, toxicity varied markedly between populations from Central and South America. Within wild populations, the distribution of toxicity was consistently skewed, indicative of automimic “cheaters” that may exploit, and consequently deplete, the protection of the warning coloration. In a common-garden rearing design comprising more than 300 butterflies across 20 broods, variation in host-plant nutritional quality or cyanogen levels did not translate into differences in toxicity of butterflies feeding on these plants. Instead, toxicity had a significant heritable genetic component, in part explained by maternal inheritance. The evolvability of toxicity was high, suggesting that toxicity can evolve rapidly. Through its link with the evolution of warning color pattern mimicry, the high evolutionary potential of cyanogenic toxicity may have facilitated diversification and ecological speciation in Heliconius, highlighting the importance of understanding the evolution of chemical defense in aposematic and mimetic species.

Thermogenesis in a feeding matrix formed on carrion by Necrodes littoralis L. (Coleoptera: Silphidae)

Authors: Matuszewski Szymon[1] and Madra-Bielewicz Anna[1], [1]1/ Laboratory of Criminalistics, Adam Mickiewicz University, Poznan, Poland. 2/ Wielkopolska Centre for Advanced Technologies, Adam Mickiewicz University, Pozna, Poland

Abstract: Carrion beetles form a feeding matrix by spreading anal and oral exudates over cadaver surface. The matrix is a complex microenvironment emerging from the interactions between beetles, microbes that inhabit the matrix and the putrefying resource. Beetles contribute to its formation and maintenance mostly through exodigestion of carrion and manipulation of its microbial content. The matrix probably has several functions. We tested the hypothesis that the matrix, which is formed on carrion by Necrodes littoralis L. (Silphidae) produces heat. Using thermal imaging we demonstrated that heat produced in the matrix formed on meat by adult or larval beetles was larger than in meat decomposing without the insects. Larval beetles regularly warmed up in the matrix. These findings indicated that the spreading of exudates over carrion by adult or larval Necrodes beetles has thermal benefits for the insects and therefore may be considered as a new form of thermoregulation on carrion.

Moreover, by comparing thermogenesis and beetle fitness in larval colonies with and without the presence of adult beetles in the pre-larval phase, we found that formation of the matrix by adult beetles had deferred thermal benefits for the larvae. After adult beetles had prepared the meat in the pre-larval phase, thermogenesis of the matrix in the larval feeding phase increased, whereas development times and mortality of the larvae decreased. This behavior of the adult beetles brought distinct thermal benefits for their offspring and therefore may be classified as a new form of indirect parental care with an important thermal component.

At present we are experimenting to get a deeper insight into spatio-temporal patterns, mechanisms, determinants and fitness effects of thermogenesis in N. littoralis.

The significance of fungus-carrying organs, mycangia, in understanding the biology and evolution of ambrosia beetle-fungus symbioses

Authors: Mayers Chase, Cornell University, School of Integrated Plant Science, Plant Pathology and Plant-Microbe Biology Section, Ithaca, NY, United States

Abstract: Ambrosia beetles farm fungi in tunnels deep within wood and rely on special fungal crops (ambrosia fungi) to survive and to nourish their young, but each generation must maintain the same domesticated cultivars despite generally flying to new trees to sow fungal gardens and establish their progeny. For more than fifty years, a diversity of pocket-like spore carrying organs (mycangia) have been known to facilitate this cultivar persistence in ambrosia beetles. However, the significance of mycangia in ambrosia beetle biology and evolution extends beyond transmission, and each ambrosia beetle lineage has unique mycangia that both enabled the inception of and currently define their symbioses. Understanding these fascinating organs is paramount to understanding the varied ambrosia beetle-fungus symbioses. Some ambrosia beetle lineages maintain strict associations with specific ambrosia fungi, and mycangia have enabled some ambrosia beetle lineages to still farm the fungi they first domesticated millions of years ago. Conversely, mycangia can also confer flexibility; some beetle lineages used their mycangia to capture already-domesticated fungi from other beetle lineages or replace ancestral cultivars with new ones, and some lineages continue to actively trade fungi. Patterns between mycangia and the fungi they carry make them valuable indicators for which fungi an invasive beetle can be expected to vector. Mycangia also likely exert significant evolutionary influence on the symbiosis. Most mycangia are lined with gland cells that secrete nutrients, which promotes the active and potentially selective growth of ambrosia fungi inside them. Mycangia shelter delicate ambrosia fungi from the environment and may have allowed the fungi to develop traits for nutrition and rapid colonization rather than dispersal and survival. Mycangia likely enforce genetic bottlenecks on the fungi that prevent selfish evolution and escape from symbiosis despite apparent sexual reproduction. These have proven to be perplexing pockets, however, and many mycangium mechanisms remain elusive. A short history of mycangium research is presented to contextualize our current knowledge and gaps in understanding, and the argument is made that mycangia should be appreciated as important components of the ambrosia symbiosis and an avenue for future research.

Dynamic analyses for the optimization of a pest control system based on vibrations

Authors: Mazzoni Valerio[2], Berardo Alice[1], [1]C3A - Center Agriculture Food Environment, University of Trento, via Edmund Mach, 1, San Michele all'Adige (TN), Italy Fondazione Edmund Mach, via Edmund Mach, [2]Fondazione Edmund Mach Center for Research & Innovation, Italy,

Abstract: In many Hemipteran insects, vibrational communication is fundamental for reproduction in that it can provide cues that enable partner identification, location and courtship. If this communication fails, none of the previous actions will be possible and the species reproduction is compromised. From this concept, a new method of pest control, an alternative to pesticides, is currently under development: the vibrational mating disruption, which is based on the use of disturbance noise (DN, i.e., disruptive synthetic vibrations specifically designed to interfere with the mating communication).

In this study, we describe from an engineering point of view this method, applied in the field for the control of the grapevine leafhoppers Scaphoideus titanus and the Empoasca vitis. In order to prevent mating, the DN is continuously transmitted by a system of mini-shakers through the vineyard, from the trellis (i.e., poles and wires) to the grapevine leaves. The DN can disrupt the target species because of its specific frequency pattern and provide the respect of certain threshold of intensity. For these reasons, (i) we must reduce all the possible causes of dissipation and/or (ii) optimize the signal transmission at the source i.e. the mini-shakers. Since this method is applied in the field, many uncontrollable factors can contribute to dissipating the signal (materials, junctions, external perturbations just to name a few). Therefore, in the first instance, we decided to focus on the mini-shaker position to enhance its performance. In this study, we report our dynamic analysis of the shakers to suggest some changes, by varying the shaker assembly, stiffness, mass and position, and so generate improvements on the quality and the intensity of the signal to be transmitted. Both numerical (finite element) simulations and field measurements are shown to validate the proposed solutions.

Vibrational communication of the greenhouse whitefly Trialeurodes vaporariorum (Westwood) (Homoptera: Aleyrodidae)

Authors: Mazzoni Valerio[2], FATTORUSO VALERIA[1], Anfora Gianfranco[1] and Pavlovcic Petra[3], [2]Fondazione Edmund Mach Center for Research & Innovation, Italy, [1]Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy, [3]Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach 1, 38010 San Michele all'Adige, TN, Italy

Abstract: Biotremology is a new discipline that studies the vibrational communication of animals. The applied biotremology investigates the control of insect pests of crops using vibrational signals (VS) to manipulate their behaviour (i.e., attraction, mating disruption, repellence).
The greenhouse whitefly (GW), Trialeurodes vaporariorum (Westwood) (Homoptera: Aleyrodidae) is considered one of the most harmful insect pests in greenhouses. The GW mating behaviour has been partially investigated and its vibrational communication is mostly unknown. A deeper knowledge of its intraspecific communication is necessary to evaluate the applicability of control methods.
In this study, we used the laser doppler vibrometer to record the VS, coupled with video recordings to link the signals production to the insect behaviour. VS were characterized in terms of spectral and temporal parameters and an ethogram was designed.
We identified three types of male vibrational emissions ("chirp", "pulses" and a Rivalry Signal), differently arranged according to the stage of the mating process, and one female responding signal here recorded and described for the first time. The GW showed to have a complex mating behaviour, consisting of four different stages: "call", "alternated duet", "courtship" and "overlapped duet". The analysis performed with the Markovian behavioural transition matrix showed that the "overlapped duet" stage seems to cover a crucial role to achieve a successful mating, in that strictly associated to the female acceptance.
This study demonstrates that vibrational communication plays an important role in GW mating process, therefore future studies should assess whether VS playbacks could be exploited to manipulate its behaviour. This would be the first case of pest control with vibrations in greenhouses.

Accessing biological control genetic resources: the South American experience

Authors: Mc Kay Fernando, Foundation for the study of invasive species, Argentina

Abstract: The Nagoya Protocol (NP) is a supplementary agreement to the Convention on Biological Diversity (CBD). It provides a framework for the effective implementation of the fair and equitable sharing of benefits arising out of the utilization of genetic resources. Biological control is one of many research activities that requires access to genetic resources. Historically, the principle of free multilateral use and exchange of natural enemies between countries has allowed prompt implementation of biological control programs against invasive alien species. However, this global benefit-sharing changed when countries adopted national ABS regulatory measures without undertaking a strategic planning process. At present, 8 South American countries are parties to the NP and 5 are not. Several points in the national ABS regulations are a cause for concern for research entomologists and biological control practitioners in South American countries. Complicated procedures to access genetic resources for non-commercial research such as classical biocontrol programs, uncoordinated redundant and bureaucratic procedures to control biodiversity research or utilization, and the lack of institutional capacities to facilitate ABS matters and a rapid turnover of officials, are some of the common difficulties shared by research entomologists and biological control practitioners in South America. Projects have even been abandoned due to difficulties and long delays in satisfying a country's provincial or national requirements and the various interpretations of how to protect their biodiversity. This presentation agrees with the objectives of the CBD and the NP in favor of a fairer and more equitable sharing of benefits arising from the use of genetic resources and the legitimate sovereign rights of countries and provinces over their genetic resources. However, it analyzes the unintentional negative consequences ABS provincial or national regimes can have on biological control research and practice. The present work aims to describe the present challenges for the access and use of biological control genetic resources in South America, particularly in Argentina.

Why Flies? Making the Undesirable, desirable

Authors: McAlister Erica, Natural History Museum, London, United Kingdom

Abstract: Flies have had a lot of bad PR. Their roles as Vectors dominate the news. But what about their roles in pollination, food webs, decomposition, biological control and just their natural splendour - how much is known about them and their ecological roles to other entomologists, researchers, the public and the Funders? And whose fault is it? Maybe we need to talk about our subject better?

SciComm has only recently been valued within many Academic departments as a useful and meaningful way of communicating research but there are still very few active scientists who regularly engage and communicate with a wider audience on their research topics. In this day and age, with less funding and a lack of understanding of key scientific topics can we afford to not get involved with more SciComm?

I will introduce how I balance the need to communicate my science and the subjects I study with my need to do my science, how I can show off the collections and value of them without it having a negative impact on other work areas, and how I can get folks to listen to me rant about the value of all flies, including the mosquitoes.

Systematics of the important but problematic wasp genus Psyllaephagus (Hymenoptera: Encyrtidae): parasitoids of lerp insects (Hemiptera: Psylloidea)

Authors: McClelland Alana[5], Cooper Steve[4], Rodriguez Juanita[3], Austin Andy[2] and Fagan-Jeffries Erinn[1], [1]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, SA 5005, Australia, [2]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, SA 5005, Australia, [3]Australian National Insect Collection-CSIRO, Canberra, ACT, Australia, [4]The South Australian Museum, [5]The University of Adelaide, Australia

Abstract: Species of the host specific, obligate parasitoid wasp genus Psyllaephagus (Hymenoptera: Encyrtidae) are the principal natural enemies of psyllids (Hemiptera: Psylloidea). The genus contains approximately 240 described species worldwide, of which 110 are known from Australia, where they comprise a poorly known fauna that parasitise lerp forming psyllids. As such, they are important for regulating natural psyllid populations as well as biocontrol of pest lerp insects. However, the taxonomy of the Australian fauna is in a state of confusion, with species being poorly described and mostly unidentifiable, due, in part to their tiny size and morphological complexity, but more so to the poor condition of type material and the absence of host records. Most Australian Psyllaephagus species are virtually unidentifiable due to their largely intractable taxonomy and historically poor descriptions based largely on trivial characters (colour, pattern) from often single specimens from undetermined hosts and patchy location records. This results in a misrepresentation of the true diversity of the Australian fauna and an almost complete lack of knowledge regarding host psyllid and plant associations. This lack of knowledge limits understanding of the evolution, ecology and true diversity of the group. It is likely that the taxonomy of Psyllaephagus can only be robustly resolved by employing a combined approach that integrates morphology, multi-gene sequencing and verified host data. Therefore, the three primary components of this PhD study are: 1) undertaking extensive field collecting and rearing of parasitoids from authoritatively identified host psyllids from across the continent; 2) generating a multi-gene sequence dataset for all specimens, and 3) examining the morphology of freshly collected, and pinned museum material, and comparing these to holotype material, particularly those that have associated host data. These components will provide an important framework to answer key questions regarding the biology, diversity, identification and host relationships of Australian Psyllaephagus.

The biological control triangle as a guide for selecting natural enemies for biological weed control

Authors: McEvoy Peter, Oregon State University Corvallis, OR, United States

Abstract: What evidence do we require to assure biocontrol is necessary, safe, and effective? To help answer this question, practitioners of biological control would like some simple heuristic that may not be optimal or perfect but is sufficient for their immediate goals. Here I propose the biological control triangle, which is an adaptation of the disease triangle used by plant pathologists to help envision and evaluate interactions among a host, a pathogen, and an environment. My modification of this framework incorporates (1) attributes of the enemy that confer virulence (including host specificity, colonizing ability, foraging ability, and feeding ability), (2) attributes of the host that confer susceptibility (including resistance and tolerance), and (3) abiotic and biotic drivers that create a permissive environment. Abiotic drivers include disturbance, temperature, moisture, wind, as well environmental cues such as photoperiod; biotic drivers include effects of neighboring plants, herbivores, carnivores, and mutualists. I also include practical considerations such as how easy a candidate control organism is to rear and redistribute. Progress requires more attention to the measurement and meaning of each attribute, transforming incomplete verbal definitions into variables and parameters that derive their meaning from a precise theoretical context. The biological control triangle offers a basis for understanding and predicting outcomes of invasion and biological control, identifying knowledge gaps, facilitating communication, and directing management of invasive plant species.

Transcriptional control of developmental timing

Authors: McKay Daniel, UNC Chapel Hill

Abstract: Systemic pulses of ecdysone trigger global changes in gene expression during developmental transitions and coordinates their timing between physically distant tissues. Gene expression changes induced by ecdysone are both tissue- and temporal-specific. The molecular basis for this specificity remains unclear. We investigate these questions through genetics and genome-wide profiling of ecdysone-regulated transcription factors during metamorphosis in Drosophila. Ecdysone regulates transcription through a genetic hierarchy. At the top of this hierarchy is the ecdysone receptor, a heterodimer of EcR and Usp. We have discovered that EcR binds extensively across the genome in a temporal and tissue-specific manner. In addition to its direct role in regulating gene expression genome wide, EcR induces expression of a set of primary response transcription factors. Genome-wide profiling of primary response factors indicates they also exhibit widespread binding. More importantly, we find that they play key roles in controlling accessibility of temporal-specific enhancers. By contrast, EcR does not control accessibility of enhancers. Instead, it differentially regulates their activity. The model that emerges is one wherein ecdysone triggers activation of primary response transcription factors through EcR; these factors then remodel the chromatin landscape in combination with tissue-specific transcription factors to drive temporal changes in lineage-specific gene expression programs.

Taking natural surveys to the lab: Describing infection patterns of a recently-discovered insect densovirus in a western North American Lycaenid

Authors: McKeegan Kelli[1], Smilanich Angela[1], Forister Matthew[1] and Teglas Michael[1], [1]University of Nevada, Reno, United States

Abstract: Understanding host-pathogen relationships in natural systems requires knowledge of the patterns of infection at the individual level. Studying the effects of life stage, host diet, and maternal infection status on disease progression helps inform us of pathogen transmission strategies along with the ability of the host to eliminate or tolerate infection. The Junonia coenia densovirus (JcDV) was first discovered in the buckeye (Junonia coenia) but has since been discovered to infect multiple species of Lepidoptera. JcDV is contracted orally by larvae and causes hypoxia and interruption of molting, often leading to death before adult emergence. The Melissa blue (Lycaeides melissa) is a multivoltine, sexually dimorphic butterfly that exists in genetically isolated populations across western North America. It specializes on native species of legumes (Lupinus, Glycyrrhiza, Astragalus, and Lotus genera), but has recently been found to incorporate feral alfalfa (Medicago sativa) as a novel host. In our preliminary indication that JcDV infects wild Lycaenids, we found compelling variation of viral frequency and load across populations of L. melissa adults. In this study, we reared larvae from wild-caught L. melissa females from a subset of populations, on different host plants. Larvae were infected with JcDV at the third instar and monitored for condition (i.e. mass) and survival. Additionally, frass was collected for a measure of virus eliminated into the environment, and a subset of larvae were sacrificed at 2-day increments post-inoculation to be screened for viral load. The results of this study help us describe the course of infection in this particular host-pathogen system, and uncover possible transmission strategies of the virus and disease resistance abilities of the host. By investigating the patterns of infection through manipulation in individuals, we can begin to understand the disease dynamics and ecological interactions of entomopathogens in the wild.

Using RNAi to Manage Invasive Wasps in New Zealand

Authors: McLaughlin Gemma[1] and Gilligan Josh[1], [1]University of Otago, New Zealand

Abstract: Invasive wasps Vespula vulgaris are extremely successful in New Zealand, where they reside at their highest densities on a global scale. The use of fipronil as an insecticide has worked with great success, but is limiting in terms of distribution, especially in their most populous regions, Nothofagus beech tree forests. Here, we attempt using RNAi with a variety of genes via both feeding and microinjection. Results varied with each gene; where krupple feeding subjects had no obvious uptake while individuals treated with cinnabar via microinjection displayed striking phenotypes. These findings provide insight into the viability of RNAi as a form of wasp control in countries where they reside as pests.

Native bee phenology: Quantifying phenological niches of bees in the Chihuahuan Desert, New Mexico, USA

Authors: McLaughlin Jade[1], Hallmark Alesia[1] and Rudgers Jennifer[1], [1]University of New Mexico, United States

Abstract: Understanding pollinator responses to climate change is increasingly important as we recognize how vital pollinators are to the global community. A more thorough understanding of the life history traits of these animals can help in predicting these responses and defining both current and future interactions between pollinators and their environments. Our study quantifies the phenological niches of bees in order to evaluate the risks of climate change to the disruption of plant-pollinator networks, particularly for specialist bees and the plants they pollinate. We analyzed data collected at the Sevilleta Long Term Ecological Research Program(LTER), where they have the world's longest continuously monitored bee community (2002 to present). This study has specimens collected monthly from February to October and has thus far resulted in the identification of over 300 species in the central New Mexico region. A monthly plant phenology dataset with species level resolution has been monitored concurrently with the bee data at the same location. By comparing plant and pollinator phenology with local climate data we ask the following questions: Do phenological niches change over time? Which biotic or abiotic factors influence phenological niches? How do phenological niches affect competition and coexistence?and Can we use phenological niches to predict future species interactions under climate change? The methodologies for quantifying and detecting phenological mismatch and its relationship to climate change are still in their early stages. Renner and Zohner (2018) suggest long-term data will be hugely influential in refining this area of research. We predict that precipitation will play a major role in bee seasonality due in part to the arid-land environments. Determining the phenological drivers of mutualist interactions could indicate if trophic asynchrony is occuring in the Chihuahuan Desert and its likelihood to occur in similar environmental regions around the world. Our results could influence understanding of pollinator seasonality and life histories, plant-pollinator mutualisms, the management of potentially threatened species, and agricultural impacts of native pollinators.

Natal origin, host plant use and mating: Reflections of “you are what you eat” in migrant Lepidoptera.

Authors: McNeil Jeremy[1] and Hobson Keith[1], [1]Department of Biology The University of Western Ontario London, ON, Canada

Abstract: Many traditional techniques, such as mark-recapture or telemetry, are not particularly effective tools for studying the migration of insects. In this presentation we will discuss our ongoing research involving the use of naturally occurring stable isotope ratios (d13C, d15N and d2H) in various insect tissues to study different aspects of migration of two two noctuid pest species, the western bean cutworm, Striacosta albicosta, and the true armyworm, Mythimna (Pseudaletia) unipuncta, and the monarch butterfly, Danaus plexippus. We will describe how we are using novel isotopic approaches to address questions relating to natal origin, origin of mates based on spermatophores, larval host plants and habitat type, as well as the relative contribution of larval and adult food sources on lipid resources.

The scale of neighborhood effects on Solanum carolinense herbivore damage and reproduction

Authors: McNutt David[2], Inouye Brian[1] and Underwood Nora[1], [1]Florida State University, United States, [2]Tallahassee Community College, United States

Abstract: Associational effects (AE) occur when the frequency or density of plant neighbors affects the damage a focal plant receives from insect herbivores. While many studies have documented AE on individual plants, understanding the fitness consequences of AE requires isolating the potentially interactive effects of competitors on plant size and damage. Additionally, spatial scale is known to affect insect foraging decisions, so the strength of AE may vary with spatial scale of the defined neighborhood. However, it is not understood whether spatial scale affects the magnitude of AE or the degree to which the fitness effects of intra- or interspecific competitors are mediated by damage versus plant size. To answer these questions, we varied the frequency, intraspecific density, and interspecific density of the clonal perennials Solidago altissima and Solanum carolinense in a field experiment. Three times during the growing season, we measured the size and damage level of each of the 438 Solanum plants in the experiment. At the end of the growing season, we measured the plant biomass and total diameter of the fruits of each Solanum plant as correlates of asexual and sexual reproduction, respectively. We then used SEM to quantify the effect of a Solanum plant’s neighborhood (competitor density and frequency), damage, and size at each survey date on its neighborhood, size, and damage at the next survey date. We also quantified the effects of a plant’s neighborhood, size, and damage level at the final survey date on its final biomass and fruit production. We performed this analysis at nine different spatial scales by defining neighborhoods at nine different radii around each focal plant, ranging from 25cm to 300cm. We found both damage- and size-mediated neighborhood effects of Solanum density, Solidago density, and Solidago frequency on Solanum fitness; the presence of these effects depended on spatial scale. There were negative effects of Solanum density on Solanum damage (i.e., resource dilution), which resulted in positive effects on Solanum biomass and fruit production. The effects of intraspecific density on fruit production existed only at scales up to 100cm around the host plant and opposed the negative, size-mediated effects of intraspecific density on fitness existing at all spatial scales. We also found positive effects of Solidago density and frequency on Solanum damage (i.e., associational susceptibility), which resulted in negative effects on Solanum biomass and fruit production. Interspecific density effects on fruit production existed at scales up to 100cm around the host plant, and interspecific frequency effects on biomass and fruit production existed at scales up to 200cm. These negative effects reinforced the negative, size-mediated effects of interspecific density and frequency on Solanum fitness.

Developing synthetic sex distorters for the genetic control of an agricultural pest insect

Authors: Meccariello Angela[2], Windbichler Nikolai[2] and Aris Papathanos Philippos[1], [1]Department of Entomology, The Robert H. Smith Faculty of Agriculture, Food and Environment, Hebrew University of Jerusalem, Israel, [2]Department of Life Sciences, Imperial College London, United Kingdom

Abstract: The Mediterranean fruit fly (medfly), Ceratitis capitata, is one of the world’s most economically important agricultural insect pests. Currently, medfly control is mainly based on the use of insecticides and on the Sterile Insect Technique (SIT). SIT involves mass-rearing?, sorting and release of sterilized male flies that through mating with wild females locally suppress the wild population. X-shredding is a novel genetic control strategy based on CRISPR-induced shredding of the X chromosome during spermatogenesis and has been successfully applied to Anopheles gambiae the malaria mosquito. Here, we describe the development of an in-vivo CRISPR system in the medfly using Cas9 nuclease targeting the white eye gene during spermatogenesis and demonstrate highly efficient mutagenesis in progeny. We also describe the identification of abundant and X-chromosome specific CRISPR target sites and develop X-shredders targeting these sequences. Our best-performing X-shredder strains display 75% sex ratio distortion towards males. These results open new possibilities for developing sex ratio distorters in this important agricultural pest. The successful transfer of this system to the medfly represents an important step towards the development of novel genetic control approaches in this pest and the potential for its universal application in other pests with a XY male karyotype.

Plant genotypic variation and herbivore specialization influences plant-insect interactions across a geographic gradient

Authors: Medina Lilhac[1] and Craig Timothy[2], [1]United States, [2]University of Minnesota, Duluth, United States

Abstract: Anthropogenic changes, such as invasive species and climate change, strongly influence plant-herbivore evolution and these changes can result in the outbreak of weeds and pests, and a decline in native species. However, specialists and generalists herbivores have different constraints on their behavior, and we predicted that this would lead to different preference-performance relationships. We hypothesized that genotypic and geographic variation in plant traits would differentially influence plant resistance across a gradation of insect specialization.

We compared the responses of a polyphagous, an oligophagous, and a monophagous herbivore to genotypic variation in tall goldenrod, Solidago altissima. We compared how the highly specialized endophagous gall fly, Eurosta solidaginis, the moderately specialized ectophagous red aphid, Uroleucon nigrotuberculatum, and the ectophagous generalist chrysanthemum lace bug, Corythucha marmorata responded to differences in genotypic variation of tall goldenrod resistance.

We predicted that the greater the insect specialization, the stronger the relationship between oviposition preference and offspring performance would be. We used replicated plant genotypes from six populations in the USA and Japan to compare preference and performance of the three herbivores. We tested the prediction that the preference-performance relationship would be influenced by herbivore specialization and local adaptation. We also tested the prediction that the suitability of plant genotypes would differ for each of the herbivores, and that it would be influenced by variation in plant traits.

Overall, we found that insect specialization influenced insect preference for local and nonlocal plant genotypes. We also found that goldenrod genotypes varied in their morphological traits, and that this influenced insect preference and performance. Gall flies preferred the local plant population, however, it also preferred two nonlocal plant populations. Red aphids showed a preference to both plant population and plant genotype within population. Lace bug preference was positively influenced by the presence of galls, and therefore they preferred the same populations as the gall flies. We conclude that differences in the responses of specialist and generalist herbivores to variation in plant genotypes in plant traits influences their distribution and abundance.

How automation, machine learning, and DNA barcoding can accelerate species discovery in “dark taxa”: Overview

Authors: Meier Rudolf[4], Wuehrl Lorenz[2], Hartop Emily[3], Srivathsan Amrita[3] and Rettenberger Luca[1], [1]Karlsruhe Institute of Technologie, [2]Karlsruhe Institute of Technology, [3]Leibniz Institute for Evolution and Biodiversity Science Berlin, [4]Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Insect biodiversity remains poorly understood although it comprises much of the terrestrial animal biomass, most species, and supplies many ecosystem services. One major obstacle is specimen-rich samples obtained with quantitative sampling techniques (e.g., Malaise trapping). Traditional sorting requires too much time. At the Center of Integrative Biodiversity discovery at the Museum für Naturkunde in Berlin, we work on specimen-based approaches that pick individual specimen from bulk samples for barcoding. We developed a robot (“DiversityScanner”) that detects, images, and measures individual specimens and moves them into the wells of a 96-well microplate. The images are used to train convolutional neural networks (CNNs) that are capable of assigning the specimens to common 14 insect “families”. To obtain biomass information, the images are also used to measure specimen length and estimate body volume. In order to obtain DNA barcodes, we have developed cost-effective barcoding techniques with MinION sequencers and bioinformatics tools for approximate species-level sorting. I here outline how the DiversityScanner can be a key component for automated species discovery in “dark taxa.” via a combination of automation, machine learning, and DNA barcoding. Two additional talks present more information on how to integrate morphology into the workflow and how the DiversityScanner works.

Detection of viral RNAs by Dicer-2 in Drosophila

Authors: Meignin Carine[1], Rousseau Claire[1], Talide Loïc[1] and Bellet Matthieu[1], [1]CNRS-UPR9022, Institut de Biologie Moléculaire et Cellulaire, Université de Strasbourg, France

Abstract: Viruses are the most abundant intracellular parasites on earth, which can infect all cell types. Their impact is constant on our life from the diseases they cause as well as agricultural losses. Therefore, studying the mechanisms with which different organisms control viral infections is very important. The host's first line of defense - innate immunity - is initiated by the recognition of viruses as non-self. The key to this system is largely based on the detection of viral nucleic acids. In mammals, recognition of viruses can occur in two ways: inside the endosomal compartment by Toll-like receptors (TLR) or in the cytoplasm by RIG-I like receptors (RLR) as well as others cytoplasmic receptors. We aim to understand the dynamics of RNAi proteins during viral infection as well as the role of modifications of viral RNAs which could be recognized as non-self in the host cell.

In order to understand how viral nucleic acids are detected by the immune system, it is important to consider on the one hand (i) how the RNAi proteins (eg Dicer-2, R2D2 and AGO2) recognize viruses and then inhibit them and secondly (ii) the different types of nucleic acids generated during a viral infection. In Drosophila, the only known receptor for viral RNA to date is the protein Dicer-2, a key component of the RNAi pathway. Dicer-2 is an RNaseIII-like enzyme that cleaves duplex double-stranded RNA (dsRNA) by 21 bp called siRNAs. One of the strands of siRNA is then loaded onto the enzyme AGO2 in the RISC complex (RNAi Induced Silencing Complex). This strand will then guide the RISC complex towards the viral RNAs whose sequence is complementary, which will then be cleaved by AGO2 (an enzyme from the RNase H family). All viruses tested to date are subject to RNAi-dependent testing. Even if the RNAi pathway essential for antiviral immunity in Drosophila, the question of recognition of viral RNAs remains open.

Chemical diversity in plant – egg parasitoid interactions: a useful tool for biological Control?

Authors: Meiners Torsten, Julius Kuehn Institute (JKI), Federal Research Centre for Cultivated Plants, Germany

Abstract: Worldwide, in many crop systems a large number of parasitoids of arthropod pests have the potential for biocontrol of the pest organisms. However, their efficacy is often not high enough to warrant a substantial reduction of their hosts - and of yield losses. How can we enhance this efficacy? First, we need to understand the evolution and complexity of parasitoid – environment interactions. Plant - arthropod interactions have evolved in complex environments, formed primarily by the diversity of host and non-host plants. The functions of diverse areas next to crops are numerous because they allow the existence of alternative hosts, provide sites for aestivation or overwintering, and give nourishment to adults. However, a big part of this complexity is of chemical nature and plant chemical diversity might be used as a tool to enhance the efficacy of (egg) parasitoids. Parasitoids of crop pests have evolved physiological and behavioral mechanisms to cope with or even to utilize the chemical diversity of the crop environment for successful host finding.

Also in agroecosystems plant constituents fulfill a multitude of biological functions and determine the relationships between crops, pests and beneficial arthropods from the level of molecules to their function in the ecosystem and the agricultural landscape. In conservation biological control, strategies for conservation and enhancement of parasitoid efficacy need to be developed or improved that involve a positive effect of chemical diversity on beneficial arthropods. What is needed to make this happen? One option to achieve this is to adjust the composition of field margins or other non-crop areas in a way that they are supporting functionally populations of parasitoids of nearby crop pests. While commercial seed mixtures for birds, bees and butterflies exist, there are hardly any mixtures available supporting biocontrol. Seed mixtures for field margins or flowering areas including non-host plants are needed that support host search, maintenance and survival of beneficial arthropods and deliver ecosystem functioning and ecosystem services by providing the required chemical diversity. To achieve this a) the diversity of plant compounds from selected field margin or flowering area plants need to be investigated and b) the scent diversity of the entire flowering area needs to be determined and compared with overall arthropod biodiversity and specific multitrophic interactions. At the same time, it should be investigated how the composition of primary and secondary plant compounds varies depending on the abiotic environment and affects the arthropod communities in terms of plant quality, resistance and stress tolerance on the arable land and in the neighboring non-crop areas. This knowledge will allow deciding if chemical diversity in plant/ egg parasitoid interactions can be applied as biocontrol tool.

Comparative biology and behaviour of Trissolcus japonicus and Trissolcus mitsukurii at different temperatures

Authors: Mele Alberto[1], Avanigadda Dinvesh Sai[1], Martina Elisa[1], Simoni Filippo[1], Duso Carlo[1], Scaccini Davide[1] and Pozzebon Alberto[1], [1]University of Padua

Abstract: Trissolcus japonicus and Trissolcus mitsukurii are two Asian scelionid egg parasitoid that has been observed parasitizing Halyomorpha halys in Italy. These two parasitoid are active natural enemies of H. halys in Asia. In the North of Italy these two parasitoid species shows an overlapping distribution and are potentially engaged in an interspecific competition for the same resource represented by H. halys eggs. Differential response to climatic factors can influence the outcome of the competition. In laboratory experiments, we compared the life table parameters of these two egg parasitoid species under 3 constant temperatures (21, 26 and 31°C). We also compared behavioural response along increasing temperature from 5 to 25°C. The net reproductive rate of T. japonicus was greater than T. mitsukurii at 26°C and 31°C. The intrinsic rate of increase at 26°C and 31°C is similar between the two species, whereas the intrinsic rate of increase and the finite rate of increase was greater for T. mitsukurii at 21°C. Results suggest a better performances of T. mitsukurii at low temperature as compare to T. japonicus, while higher performances of the latter were observed temperature above 26°C. Behavioural response to increasing temperature suggest that T. mitsukurii activity start at lower temperature as compare to T. japonicus. Overall, of the result suggest that T. mitsukurii is more adapt to low temperature regimes as compare to T. japonicus that are expected to be advantaged under high temperatures conditions.

From a rare inhabitant into a potential pest – Status and outlook of the nun moth (Lymantria monacha) population in Finland based on pheromone trapping

Authors: Melin Markus[1], Viiri Heli[5], Tikkanen Olli-Pekka[2], Elfving Riku[3] and Neuvonen Seppo[4], [1]Natural Resources Institute of Finland, Finland, [5]UPM Kymmene, Finland, [2]University of Eastern Finland, School of Forest Sciences, Finland, [3]University of Oulu, Department of Biology, Finland, [4]University of Turku, Biodiversity unit, Finland

Abstract: Forests are being hit by climate change in various ways. This includes abiotic factors such as droughts, but also an increased risk of damage caused by biotic agents such as insects. There are numerous examples from cases where a pest insect has benefitted from endured growing season or from warmer summers. Similarly, new pest insects have been able to expand their range due to climatic conditions that have changed from hostile to tolerable.

Such seems to be the case with the nun moth (Lymantria monacha), Europe's most significant defoliator of coniferous trees. For centuries, the species has had massive outbreaks across Central-Europe while it has been only a rare inhabitant in Northern Europe. Recently, the nun moth population in Finland has not only expanded in range, but also grown more abundant.

Extensive field survey in 2019 showed that, so far, the northernmost individuals occupy forests near the 64 N degrees. The species was present in every trapping site below the latitude of 62 N degrees. More importantly, at some sites the abundance of the nun moth suggested that local forest damage may not be a distant scenario. Given the current climatic scenarios for Fennoscandia, it is likely that the nun moth populations will continue to grow, which is why systematic surveys on their abundance and range expansions are vital.

In the proposed presentation, I wish to illustrate the results from the first-ever conducted extensive pheromone survey of the nun moth in its northernmost range: abundance across the study area and range boundaries. In addition, I will discuss the efficacy of the trapping method as well as the future of the species and its forest damage potential, especially given the current climatic scenarios of Finland.

Irrigation decreases abundances of insects and spiders in Mediterranean vineyards

Authors: Melloul Emile[1], Rocher Leo[2], Gros Raphaël[2], Bischoff Armin[2] and Blight Olivier[2], [1]Avignon University, France, [2]Institut of Mediterranean Biodiversity and Ecology

Abstract: In a changing world, the identification of vulnerability and resilience factors of agroecosystems to climate change has become a major challenge. Globally, mean annual temperatures and drought periods are increasing which poses a threat to agriculture and related biodiversity. As a key sector of French agriculture, viticulture must be adapted to increase resilience to climate change. In southern France, the proportion of irrigated vineyards has increased in recent years to cope for higher evapotranspiration and lower rainfall. While irrigation is clearly beneficial to viticulture under water stress, the consequences on biodiversity of such artificial microclimatic conditions have not been studied. The objective here was to evaluate the effects of irrigation on inter-row vegetation and arthropod communities in Mediterranean vineyard systems. We selected nine pairs of vineyards in the Luberon region (Southern France), one irrigated and one unirrigated. In each vineyard, we sampled vegetation and arthropods (spiders, wasps, ladybird larvae and adults, wild bees, hoverflies) in two quadrats. We found a significant reduction in flower cover and abundance of different arthropod groups such as spiders, ladybirds, and wasps in irrigated vineyards. These results have important implications for the conservation of arthropod biodiversity and its associated ecosystem services in Mediterranean vineyards.

Determining contact chemical compounds responsible for host plant recognition in a belowground specialized phytophagous insect

Authors: Menacer Kathleen[1], Le Moal Clémence, Cabon Lilian, Hervé Maxime[1], Cortesero Anne Marie[1], [1]University of Rennes 1

Abstract: In phytophagous insects, key behaviors driving fitness are influenced by plant-related cues. Specialized species have therefore developed the ability to detect and recognize chemical cues produced and emitted by plants of their host range. Despite the considerable importance of belowground insects in ecosystems, determinants of their host plant selection remain poorly understood. We investigated host acceptance by larvae of the cabbage root fly (Delia radicum), a specialist of brassicaceous plants. We used Brassica rapa and Sinapis alba and two cultivars of each species to assess root damage caused by larvae. We also conducted feeding experiments on artificial substrates supplemented with root extracts and used bioguided fractionation to isolate the smallest active chemical fraction.

A contrast in root development was observed between infested and non-infested plants of all cultivars except for one mustard cultivar. All root extracts stimulated larval feeding on the artificial substrates. A feeding contrast was only observed between the two mustard cultivars and one subfraction (the most polar) appeared to contain the molecules responsible for this contrast.

This work supports the involvement of contact compounds in host acceptance by belowground insects and highlights similarities between above- and belowground insects in the mechanisms underpinning host plant selection.

Coding of behaviorally ‘‘meaningful’’ odors by which Conopomorpha sinensis Bradley (Lepidoptera: Gracillariidae) pinpoints its host

Authors: Meng Xiang[2], Ouyang Gecheng[1], Dai Jianqing[1] and Hu Junjie[2], [1]Guangdong Institute of Applied Biological Resources, China, [2]Guangzhou University, China

Abstract: Insect olfactory systems can detect important host signals efficiently from a complex odor background. Conopomorpha sinensis Bradley (Lepidoptera: Gracillariidae) as a host-specific pest of Litchi chinensis and Euphoria longan is periodically outbreaking in southern China. Little is known about the functions of individual volatiles and their combinations in the attraction of C. sinensis to these host taxa. In our study, we analyzed the behavioral and electroantennogram (EAG) responses of C. sinensis to eight major host volatile compounds and their mixtures. Both female and male C. sinensis exhibited an EAG response for all of the volatiles tested, and the volatile components were more stimulatory to female than to male C. sinensis. EAG responses of female antennal stimulation with component ß-guaiene were significantly different to components caryophyllene and ß-elemene, while odorant mixtures including compounds ß-farnesene and a-pinene significantly altered the behavioral and EAG responses of females. Further testing of the female and male behavioral responses to host volatile compounds were obtained in flight orientation studies using a wind tunnel. These findings demonstrate that C. sinensis behavior can be affected by single compounds or compound mixtures. The coding of behaviorally ‘‘meaningful’’ odors provides a new method for the biocontrol of C. sinensis.

IPM is Key to Effective Pest Management: New Biological Tools and Solutions For IPM in Cotton crops

Authors: Mensah Robert, Senior Principal Research Scientist (PSM) Ex Director, Australian Cotton Research Institute Formerly: NSW Department of Primary Industries Locked Bag 1000, Narr

Abstract: Since the 1960s, the control of cotton pests (particularly, Helicoverpa spp., sucking pests, mites etc) in Australia and most cotton growing countries has relied exclusively on the use of synthetic insecticides. The adoption of GM cotton with multiple toxins targeting Helicoverpa spp. has present to be a strong platform for IPM due to the selective toxicity of the Bt proteins. However, even these systems are challenged by potential for target pest resistance to the Bt proteins, which is still essentially a toxin based approach; and, ironically, altered pest complex due to reduced insecticide use. In GM cotton systems in Australia and other parts of the world, sucking bugs have emerged as important pests requiring targeted control or risking the problem of resistance. Sustainable IPM systems in both conventional and GM cotton systems requires a broader array of tools to manage pests and reduce primary reliance on synthetic insecticides This presentation focuses on new approaches to achieve this including innovative bio-control technologies, bio rational pesticides, new and safer pest control alternatives, use of refuge crops as a source of natural enemies, the use of selective insecticides, sampling regimes, decision support tools such as use of beneficial insects to pest ratio treatment thresholds which incorporate the action of existing natural enemies. This will enable growers to build long term self-sustaining IPM systems.

New Innovative Integrated Pest Management Tools and strategies For Cotton crops in Australia

Authors: Mensah Robert, Senior Principal Research Scientist (PSM) Ex Director, Australian Cotton Research Institute Formerly: NSW Department of Primary Industries Locked Bag 1000, Narr

Abstract: Sustainable integrated pest management (IPM) systems in both conventional and transgenic (Bt) cotton systems requires a broader array of tools to manage pests and reduce primary reliance on synthetic insecticides. This presentation focuses on new approaches to achieve this innovative bio-control technologies, bio-rational pesticides, new and safer pest control alternatives, use of refuge crops as a source of natural enemies, the use of selective insecticides, sampling regimes, decision support tools such as use of beneficial insects to pest ratio treatment thresholds which incorporate the action of existing natural enemies. This will enable cotton growers to build long term self-sustaining IPM system. The presentation will challenge the industry to think outside the square, look at the big picture and to think about the long term sustainability of cotton industries worldwide.

Since the 1960s, the control of cotton pests (particularly, Helicoverpa spp., sucking pests, mites etc) in Australia and most cotton growing countries has relied exclusively on the use of synthetic insecticides. The adoption of GM cotton with multiple toxins targeting Helicoverpa spp. has present to be a strong platform for IPM due to the selective toxicity of the Bt proteins. However, even these systems are challenged by potential for target pest resistance to the Bt proteins, which is still essentially a toxin based approach; and, ironically, altered pest complex due to reduced insecticide use. In GM cotton systems in Australia and other parts of the world, sucking bugs have emerged as important pests requiring targeted control or risking the problem of resistance. Sustainable IPM systems in both conventional and GM cotton systems requires a broader array of tools to manage pests and reduce primary reliance on synthetic insecticides This presentation focuses on new approaches to achieve this including innovative bio-control technologies, bio rational pesticides, new and safer pest control alternatives, use of refuge crops as a source of natural enemies, the use of selective insecticides, sampling regimes, decision support tools such as use of beneficial insects to pest ratio treatment thresholds which incorporate the action of existing natural enemies. This will enable growers to build long term self-sustaining IPM systems.

Conserved molecules involved in insect olfaction

Authors: Menuz Karen, University of Connecticut, United States

Abstract: The past few decades have witnessed an explosion of research into insect olfactory systems. The odorant response profile and behavioral significance of multiple receptors from two odorant receptor families have been characterized. However, most receptors are poorly conserved amongst insects, and few other molecules that contribute to odorant responses in olfactory neurons have been identified. Using RNASeq screens in Drosophila, we have identified a number of previously unstudied candidate genes with potential roles in olfaction. We found that one of these genes, a conserved ammonium transporter, acts as a non-canonical odor receptor for ammonia, an attractive odor for a wide variety of insects. Expression of ammonium transporters in the antennae of nearly all insect species examined suggests they could play a similar role in other species. Our recent work centers on a conserved calcium-activated chloride channel expressed in all Drosophila olfactory neurons, but not detected in the brain or other tissues. This ion channel allows for olfactory neuron odorant responses to closely track the level of fluctuating odorants, by enhancing signal termination. Together our approach is yielding an improved understanding of the molecular basis of olfactory signaling in the antenna, and could suggest novel targets for the development of future insect deterrents.

Ecostacking: the way forward for IPM

Authors: Menzler-Hokkanen Ingeborg[1], Hokkanen Heikki[2], [1]Department of Environmental and Biological Sciences, University of Eastern Finland, Kuopio, Finland, [2]Organizer, Finland

Abstract: Despite great advances in IPM, global pesticide use has largely continued unaffected, with negative implications for farmer livelihoods, biodiversity conservation, and the human food systems. Recently, the whole concept of IPM has been challenged due to its ambiguity, inconsistencies in implementation, insufficient engagement of farmers, and lack of basic understanding of its ecological concepts. Ecostacking as a concept makes full use of the benefits accruable from ecosystem services via stacking and conservation of functional biodiversity in cropping systems. Stacking implies combining in a synergistic manner the beneficial services of functional biodiversity from all levels and types. This is a comprehensive approach, where the various ecosystem service providers are fully integrated with the rest of the cropping system including agronomic practices. Ecostacking as an approach aims to stimulate the scientific community to develop, design, and implement integrated systems for optimised provision of ecosystem services and the use of plant protection tools, with focus on ecological, economic, and social sustainability of the integrated system.

Caste- and sex-based differences in brain anatomy in the Eastern subterranean termite, Reticulitermes flavipes

Authors: Merchant Austin, University of Kentucky

Abstract: Termites demonstrate a complex division of labor in which individuals develop into one of multiple castes that each possesses a unique role within the colony. Castes show significant differences in the number and type of tasks that they are able to perform, ranging from versatile workers to soldiers that are specialized for colony defense and little else. Given the role of the brain in controlling behavior and sensory processing, are these extreme behavioral differences reflected in differences in brain anatomy between termite castes? Using a deformation-based morphometric analysis, I compared brain anatomy across major castes found in the Eastern subterranean termite, Reticulitermes flavipes. In addition, I investigated the possibility of sexually dimorphic brain anatomy within castes. Significant differences in brain anatomy were found among castes, localized in distinct regions of the brain. Altogether, these results represent the first steps towards understanding the neural basis of caste in this complex group.

Duox determines insect gut symbiosis by stabilizing respiratory network

Authors: Mergaert Peter[1], Shigenobu Shuji[4], Ohbayashi Tsubasa[2] and Kikuchi Yoshitomo[3], [1]Centre national de la recherche scientifique (CNRS), France, [2]Centre national de la recherche scientifique, France, [3]National Institute of Advanced Industrial Science and Technology (AIST), Hokkaido center, Japan, [4]The National Institute for Basic Biology (NIBB), Japan

Abstract: Many insects harbor in specific organs large numbers of symbiotic bacteria, which produce essential nutrients for their host. How the respiratory activity of this large population of aerobic symbionts is maintained and oxygen is efficiently transported to the symbiotic organ is unclear. In insects, oxygen is delivered to organs by the tracheal system consisting of a tubular epithelial network containing a luminal chitin and protein matrix. Here we show that the proliferation of symbiotic Burkholderia insecticola in the midgut crypts of the stinkbug Riptortus pedestris triggers the formation of an extensive network of tracheae enveloping the symbiotic organ. We found that the expression of the gene encoding the ROS-producing dual oxidase (Duox) is tracheae-specific and its down-regulation by RNAi results in the loss of dityrosine crosslinks in the tracheal matrix, a collapse of the tracheal system and a disruption of symbiosis. Down-regulation of the hypoxia-responsive transcription factor Sima or the regulators of tracheae formation Trachealess and Branchless produces similar phenotypes. On the contrary, Duox-dependent ROS did not directly contribute to epithelial immunity in the midgut in response to symbiont or pathogen. Thus, symbiotic bacteria form a strong oxygen-sink in the insect body and the establishment of a tracheal network assures oxygen homeostasis in symbiosis. In addition to known roles in immunity and in the formation of diverse extracellular matrices, Duox is also a crucial enzyme for tracheae stability by establishing a dityrosine network of luminal matrix proteins. We expect that these are conserved functions in insects.

Movement of insects among patches modifies the relationships between insect density and plant patch size.

Authors: Merwin Andrew[1], Inouye Brian[2] and Underwood Nora[2], [1]Baldwin Wallace University, United States, [2]Florida State University, United States

Abstract: Predicting the relationship between insect density (individuals per unit area) and plant patch size is a longstanding goal of insect ecology with potential implications for conservation and pest management. An early conceptual model—the resource concentration hypothesis—suggested that larger patches of plants should have higher densities of insects. However, experimental and observational studies have found all possible relationships—negative, positive, and no relationship—underscoring the need to identify insect, plant, and landscape characteristics that can reconcile these disparate observations. One commonly overlooked factor with the potential to influence the relationship between insect density and patch size is inter-patch movement. For example, in landscapes where insects can readily move among patches, insect abundance in larger patches could reduce the number of potential immigrants to neighboring patches of other sizes and, thus, potentially influence the insect density-patch size relationship. Using a correlated random walk model with simplifying assumptions, we show that in landscapes with multiple patches of different sizes, where insects move among patches through matrix habitat, equilibrium density is higher in large patches compared to small patches (i.e. resource concentration). By contrast, in landscapes with only one patch, where insects cannot move among patches of different sizes, our model shows that larger patches have lower equilibrium insect densities than smaller patches (i.e. resource dilution) when comparing across landscapes. Further, we show that these patterns depend critically on the perimeter-to-area ratio of plant patches rather than area per se. Thus, our model highlights the need to not only consider the geometry of a given plant patch, but to also consider the landscape of patches and the potential movement of insects among them when attempting to predict relationships between the insect density and patch size.

Management of brown marmorated stink bug in Georgia

Authors: Meskhi Nikoloz, National Food Agency, Ministry of Environmental protection and Agriculture of Georgia, Georgia

Abstract: In Georgia Brown Marmorated Stink Bug (Halyomorpha halys) populations were observed during the 2015 season with the first significant damage to hazelnut reported a year later. In addition to hazelnuts, BMSB also has the potential to inflict severe damage to other crops, such as maize, apple, peach, etc.

Since 2017, within the frame of the official program, National food Agency has administered large scale control measures against BMSB in western Georgia. For the monitoring, pheromone traps have been used and in 2017, more than 20000 traps have been installed throughout the whole country. Based on data obtained from monitoring, chemical treatment has been carried out with the help of special NFA equipment. From chemical insecticides synthetic pyrethroids were used.

At locations where the state has enacted measures, the harvest was preserved and pest population decreased

Aphid biocontrol in greenhouses using cocktails of natural enemies

Authors: Messelink Gerben[1] and Bloemhard Chantal[1], [1]Wageningen University & Research BU Greenhouse Horticulture, Netherlands

Abstract: Aphids are among the most challenging pests to control with biological control agents in greenhouse crops. Their fast reproduction soon results in high densities that are difficult to control. Even the presence of one single aphid species often requires releases of several species of natural enemies (parasitoids and predators) to achieve effective control. An additional complexity is the fact that crops are usually attacked by several species of aphids that differ in vulnerability for natural enemies. A common practice in that case is to release cocktails of parasitoid species that each target different aphid hosts. However, it is hardly understood how this diversity of aphid hosts affects the performance of specialist aphid parasitoids. In greenhouse trials with sweet pepper, we studied how mixed populations of green peach aphids, Myzus persicae, and foxglove aphids, Aulacorthum solani, influence the control by specialist and generalist parasitoids. The presence of unsuitable aphid hosts distracted specialist parasitoids from their suitable aphid host and reduced control efficacy. In contrast, unsuitable aphid hosts could still be controlled by parasitoids through non-consumptive effects of parasitoids that developed within suitable aphid hosts. Thus, diversity of aphid species can have both positive and negative consequences for biological control with parasitoids. The control efficacy of parasitoids was further evaluated by releasing cocktails of parasitoids (Aphidius ervi, Aphidius colemani, Aphidius matricaeriae, Aphidius gifuensis and Praon volucre) for the control of either the green peach aphid or the foxglove aphid in a sweet pepper crop. The performance of the different aphids parasitoids appeared to vary strongly throughout the season. Overall we conclude that releasing cocktails of aphid parasitoids might be a good strategy to ensure complementary effects, but mixtures may need to be adapted for the species of aphids present in crops and time of the year.

Natural variation in an odorant receptor alters neural activity and underlies preference for human odor in Aedes aegypti

Authors: Metz Hillery[1], Breda Jess[1] and McBride Lindy[1], [1]Princeton University, United States

Abstract: Mosquitoes use olfaction to target hosts for bloodmeals, and some show innate preference for the odor of specific hosts. Here, we leverage the recent evolution of a human-preferring subspecies of the yellow fever mosquito (Aedes aegypti aegypti) from a generalist ancestor (Ae. aegypti formosus), and use the tools of functional genetics and functional imaging to gain insight into odor coding. In a unique approach, we use genetic complementation (i.e. hemizygosity) tests to measure the effects of four alleles sampled from wild populations on both odor-guided host preference behavior and the activity of primary sensory neurons in the antennal lobe. We functionally confirm a role for AaegOr4 in preference for humans, where AaegOr4 alleles sensitive to the human odorant sulcatone increase preference for human odor compared to an insensitive allele. Additionally, our data suggest that the effects of AaegOr4 are strongest for a human subject showing naturally high sulcatone levels. Functional imaging confirmed that variation in the ligand-sensitivity of alleles measured in vitro correlates with neural activity in vivo.

Because host odors are complex blends comprised of tens to hundreds of individual compounds—each of which may be emitted from many sources in the environment—host discrimination must rely on the integration and coding of unique blend information. Nevertheless, our results demonstrate that the peripheral perception of a single odorant can significantly alter host preference behavior in Aedes aegypti, and represent a functional test of evolved behavioral differences between natural populations.

Uncovering the role of circadian transcription factors in regulating the overwintering dormancy of the Northern house mosquito, Culex pipiens

Authors: Meuti Megan E., The Ohio State University Department of Entomology Columbus, OH, United States

Abstract: Females of the Northern house mosquito, Culex pipiens, are the major vectors of West Nile virus, but during the winter they do not bite or transmit disease. Instead, they divert energetic resources from reproduction towards survival and enter a reproductive diapause. Although we know that the short daylengths of late summer and early fall are the environmental cue that cause females to initiate diapause, we do not understand precisely how mosquitoes and other animals measure daylength. Currently my lab is determining whether circadian transcription factors, vital components of the daily timekeeping machinery in all animals, are involved in measuring daylength and initiating seasonal responses in this disease vector. Our findings show that some circadian transcription factors and their predicted targets show altered daily expression profiles in female mosquitoes exposed to long day, diapause-averting conditions and short day, diapause-inducing conditions. Furthermore, suppressing expression of circadian transcription factors with RNAi prevents short-day reared mosquitoes from entering diapause while knocking down other genes associated with the clock prevents mosquitoes from becoming reproductively active. Ongoing work focuses on connecting the circadian clock to the hormonal pathways, such as Juvenile Hormone and insulin signaling, that are known to regulate diapause. In this way, we hope to identify novel targets that will allow us to manipulate the seasonal biology of Cx. pipiens by either tricking them into going into diapause during the summer, or preventing them from entering diapause in the fall.

Insects and other Invertebrates as Pharma

Authors: Meyer-Rochow Victor Benno, 1. Department of Genetics and Physiology, Oulu University, Oulu SF-90140, Finland; and 2. Department of Plant Medicals, Andong National University, Andong GB 36, South Korea

Abstract: Insects and other invertebrates have been used since time immemorial as a healthy food item. They were credited with potential to ease the problem of global food shortages (Meyer-Rochow 1975), but historically their role in traditional healing methods has been an even greater one. Bioactive honey, anti-rheumatic and anti-inflammatory bee venom, meloid beetles' cantharidin and Chinese cockroaches come to mind. Based on studies on erectile dysfunction and testosterone in rats silkworm pupal extract has been likened to Viagra-like effects (Oh et al. 2012). Umemura (1943) lists 28 species of Lepidoptera used therapeutically in Japan and In Germany just over 100 ys ago beetles of 13 families played some therapeutic roles. Bengaline, an isolate of scorpions in India, has been shown to exhibit antiproliferative and apoptogenic activity against human leukaemic cell lines (DasGupta et al. 2010). Insects and other arthropodes produce the broadest repertoire of antimicrobial peptides (AMPs), which must be considered alternatives to conventional antibiotics (Meyer-Rochow 2017).

Honeybees and hornets are on the menu: nutritional value

Authors: Meyer-Rochow Victor Benno[1], Ghosh Sampat[3], Jung Chuleui[2], [1]1. Department of Genetics and Physiology, Oulu University, Finland; and 2. Department of Plant Medicals, Andong National University, Andong GB 36, South Korea, [2]1Agricultural science & technology research institute, Andong National University, Andong, GB, Korea 2 Department of Plant Medicals, Andong National University,, [3]Department of Plant Medicals, Andong National University, South Korea

Abstract: Different species of honeybees and hornets have received acceptance as edible insects among several populations of Asia and Africa. In order to explore the proximal background of human entomophagy, understanding these insects' nutritional benefits is of considerable importance. We examined the nutritional contents, including amino acids, fatty acids and minerals from different developmental stages of honeybees and hornets. Bees and hornets were found to contain protein which is comparable if not superior to the conventional foods of animal origin. Seventeen proteinergic amino acids were detected and quantified with similar patterns of distribution in these species. A different pattern was found for fatty acids. The higher proportion of mono and polyunsaturated fatty acids in the lipid fraction of the hornets could not only have nutritional but also medicinal benefits like reducing cardiovascular disorders, and inflammations. The presence of a high level of iron, calcium, and zinc and moreover the high K/Na ratio could supplement the requirements of these minerals and help mitigating mineral deficiencies especially among those of the population with inadequate nutrition. Further discussion involved issues like the extent of production of brood without stressing adult bees or hornets, utilization of drones and development of industrial production system. The results could help understanding the prospects of these edible species in the mainstream food system.

Miniaturization to the Extreme: The Compound Eye of a 0.65 mm Long “3-Eyed” Gall Midge (Diptera; Cecidomyiidae)

Authors: Meyer-Rochow Victor Benno[1], Yamahama Yumi[2], [1]1. Department of Genetics and Physiology, Oulu University, Finland; and 2. Department of Plant Medicals, Andong National University, Andong GB 36, South Korea, [2]Hamamatsu University School of Medicine

Abstract: Cecidomyiid midges of the genera Trisopsis and Lestodiplosis possess three compound eyes. The single dorsal compound eye of our only 0.65 mm long cecidomyiid specimen contained 90 ommatidia and represented the fusion product of left and right dorsal moieties jointly covering an area at the top of the head of 7000 µm2. Each of the two latero-ventral compound eyes on either side of the head consisted of approximately 35 ommatidia that did not differ anatomically from those of the dorsal eye (with the exception of the interommatidial angles, which measured 10-12° and thus much narrower than those of the dorsal eye). With regard to photoreception Diptera are interesting subjects. Not only has the compound eye of Drosophila been one of the genetically most-researched photoreceptors of animals generally, but because moreover the dipteran compound eye possesses an ‘open rhabdom’, which for biophysical reasons faces limitations when it comes to miniaturization. In a 0.7 mm size cecidomyiid midge with one dorsal and two lateral compound eyes, the retinal layers of both the dorsal and the lateral eyes were extraordinarily thin, only measuring approximately 12 µm, but all ommatidia were capped by 8 µm thick and 8-10 µm wide corneal lenses with a dense and regular coverage of 160 nm high corneal nipples. Despite being a species of the order Diptera, for which open rhabdoms are characteristic, our tiny cecidomyiid possessed the fused type of rhabdom with microvilli measuring 65 nm in diameter. It is postulated that dspite the reduction in body and eye size, rhabdomeres could not be scaled down as they had already reached their functional cross sectional limit of 1.5-2.0 µm in Diptera the size of Drosophila. A further reduction would have rendered the rhabdom ineffective as a waveguide. As the tiny insect was a swift flyer and on the basis of the eye‘s anatomy it is discussed what the insect could possibly see with its tiny eyes.

Kampinos WetLIFE: Protection and restoration of wetlands in Puszcza Kampinoska Natura 2000 site in Poland, creating habitat for butterflies and dragonflies (LIFE19 NAT/PL/000746)

Authors: Miazga Michał, Regional Environmental Center, REC Poland, Poland

Abstract: The Kampinos Forest Natura 2000 site has the largest complex of wetland habitats in central Poland. Well-preserved habitats now cover just 5% of the primaeval wetland area, after land reclamation over the past 150 years severely lowered groundwater levels. The site is especially vulnerable to extended dry periods and increasing fluctuations in water levels caused by climate change. Through this project, Kampinos National Park is restoring over 6000ha of habitat through the removal of non-invasive species, improvements to the hydrology, creation of ponds and naturalisation of man-made water courses to benefit species in need of strict protection including butterflies such as the scarce large blue (Maculinea teleius) and large copper (Lycaena dispar) and large white-faced darter (Leucorrhinia pectoralis).

Intracellular Burkholderia symbionts of eriococcids Acanthococcus aceris and Gossyparia spuria (Hemiptera: Coccomorpha)

Authors: Michalik Anna[5], Bauer Eugen[1], Michalik Katarzyna[3], Kalandyk-Kolodziejczyk Malgorzata[4], Kaltenpoth Martin[1] and Szklarzewicz Teresa[2], [1]Department for Evolutionary Ecology, Institute for Organismic and Molecular Evolution, Johannes Gutenberg University Mainz, [2]Department of Developmental Biology and Morphology of Invertebrates, Institute of Zoology and Biomedical Research, Jagiellonian University, [3]Department of Developmental Biology and Morphology of Invertebrates, Jagiellonian University, Kraków, Poland, [4]Department of Zoology, University of Silesia, Katowice, Poland, [5]Jagiellonian University, Poland

Abstract: Hemipterans are known as hosts to bacterial or fungal microorganisms that supplement their unbalanced diet with essentials nutrients. Among them, scale insects (Coccomorpha) are characterized by the large diversity of symbiotic systems. Numerous investigations have revealed that they may be associated both with bacteria (e.g. Tremblaya phenacola, Tremblaya princeps, Uzinura dispidicola, Wolbachia) as well as fungi (Ophiocordyceps). We analyzed using microscopic and molecular approaches, symbionts of two scale insects belonging to Eriococcidae family – Acanthococcus aceris nad Gossyparia spuria. Histological and ultrastructural studies have shown the presence of numerous, small, rod-shaped bacteria in the cytoplasm of fat body cells. Based on their 16S rDNA sequence, these bacteria were identified as bacteria Burkholderia (Betaproteobacteria). Metagenome sequencing has indicated that the symbionts of Acanthococcus aceris and Gossyparia spuria possess highly reduced genomes (<900KBp) with a low GC content (~38%), making them the smallest Burkholderia genomes yet sequenced. Overall, the genomic repertoire of the symbionts is congruent in terms of gene content and synteny, highlighting a convergent reductive genome evolution in these bacteria. Compared to free-living Burkholderia, the symbiotic strains have less genes involved in housekeeping functions, while retaining genes for essential amino acid biosynthesis, indicating potential roles for their hosts similar to other nutrient-supplementing insect symbionts. The transovarial transmission of bacteria Burkholderia between generations also confirms their crucial role in the biology of eriococcids analyzed.

Symbiont loss and replacement in Fulgoromorpha (Insecta, Hemiptera)

Authors: Michalik Anna[3], Lukasik Piotr[3], Stroinski Adam[4], Franco Diego[2] and Szklarzewicz Teresa[1], [1]Department of Developmental Biology and Morphology of Invertebrates, Institute of Zoology and Biomedical Research, Jagiellonian University, [2]Institute of Environmental Sciences, Faculty of Biology, Jagiellonian University, Gronostajowa 7, 30-387 Cracow, Poland, [3]Jagiellonian University, Poland, [4]Museum and Institute of Zoology, Polish Academy of Sciences, Warszawa, Poland

Abstract: Nutritional symbiosis with heritable bacterial or/and fungal microorganisms is widespread within sap-sucking hemipterans. These symbionts provide essential amino acids and vitamins that are lacking in the diet of their host insects, which makes them necessary for their growth and reproduction. Within Fulgoromorpha, Sulcia (Bacteroidetes) and Vidania (Betaproteobacteria) are regarded as their ancestral symbionts, maternally transmitted and co-diversifying with hosts for over 200 million years. However, the literature data indicate that additional, more recently acquired bacteria or fungi may co-reside with, or sometimes replace, these two ancient bacterial symbionts.

We combine microscopic (LM, TEM, FISH) and molecular (amplicon sequencing, molecular cloning, metagenome sequencing) approaches to characterize the symbiotic systems of several species belonging to the following families of planthoppers: Dictyopharidae, Derbidae, Achilidae, Cixiidae, Tettigometridae, Issidae, Delphacidae and Flatidae.
The ancestral nutritional symbionts Sulcia and Vidania are present in all tested representatives of families Dictyopharidae, Cixiidae and Tettigometridae as well as in some of Achilidae, Issidae and Delphacidae. In some families ancestral bacterial symbionts are associated with additional gammaproteobacteria such as: Sodalis (some Dictyopharidae, Issidae, Delphacidae, Tettigometridae), Arsenophonus (some Dictyopharidae) or Purcelliella (Cixiidae) or fungi (some Issidae). Members of Derbidae family and some representatives of Achilidae lost the Sulcia symbiont and retained only Vidania. In the issid Issus coleoptratus Sulcia was lost and replaced by fungal symbionts which co-reside with bacteria Vidania. In turn, representatives of Flatidae family are host to fungal symbionts only. The most diverse, in respect of symbiont composition, is the family Delphacidae. Our investigations revealed that members of this family: (1) may possess both Sulcia and Vidania, (2) besides ancestral symbionts, may host Sodalis, or (3) may harbor fungal symbionts exclusively.
Our investigations confirmed the hypothesis that during the evolution of Fulgoromorpha both loss and symbiont switching /replacement took place.

Symbiotic systems of treehoppers (Hemiptera: Cicadomorpha: Membracoidea: Membracidae). Ultrastructure, distribution and transovarial transmission

Authors: Michalik Anna[3], Ahlén Mulio Sandra[5], Stroinski Adam[4], Swierczewski Dariusz[2] and Szklarzewicz Teresa[1], [1]Department of Developmental Biology and Morphology of Invertebrates, Institute of Zoology and Biomedical Research, Jagiellonian University, [2]Faculty of Mathematics and Natural Sciences, Jan Dlugosz University, Poland, [3]Jagiellonian University, Poland, [4]Museum and Institute of Zoology, Polish Academy of Sciences, Warszawa, Poland, [5]Poland

Abstract: Treehoppers live in mutualistic associations with symbiotic microorganisms which supplement their diet with essential amino acids. Many microscopic and molecular studies have allowed to reveal that most auchenorrhynchans harbor two ancestral symbionts bacterium Sulcia and betaproteobacterium (e.g. Nasuia in leafhoppers and treehoppers). Some of auchenorrhynchan species harbor additional symbiotic microorganisms, e.g. gammaproteobacteria Arsenophonus and Sodalis, in others the betaproteobacterium or both ancestral symbionts have been lost and replaced by other bacteria or yeast-like microorganisms.
We examined symbionts of three species of treehoppers: Centrotus cornutus, Gargara genistae and Stictocephala bisonia. In all the examined species, large elongated organs termed bacteriomes are present in the close vicinity to the ovaries. The bacteriomes are composed of numerous large bacteriocytes that are densely packed with symbiotic bacteria. The external region of the bacteriome contains bacteriocytes filled with large pleomorphic bacteria Sulcia. The internal region is occupied by bacteriocytes with large lobated bacteria Nasuia. In C. cornutus, between the bacteriocytes with bacteria Sulcia and Nasuia, bacteriocytes with elongated bacteria Arsenophonus are localized. Bacteria Arsenophonus co-reside also in bacteriocytes with bacteria Nasuia. In G. genistae, instead of the bacteria Arsenophonus, the small almost spherical bacteria Serratia are present both in their own bacteriocytes and in bacteriocytes with bacteria Nasuia. The presence of autophagosomes and lamellar bodies in the bacteriocytes with bacteria Arsenophonus and Serratia in all the examined individuals indicates that these microorganisms undergo autophagic degradation. In all of the examined species of C. cornutus and G. genistae, in the cytoplasm and nuclei of all the cells of the bacteriome numerous small rod-shaped bacteria Rickettsia are present.
Our observations indicate that all symbionts are inherited in a way typical of auchenorrhynchans, through the infection of the posterior ends of ovarioles containing vitellogenic oocytes. The symbiotic microorganisms leave the bacteriocytes and begin to migrate towards the ovarioles. The bacteria gather around the posterior ends of the ovarioles and enter the cytoplasm of follicular cells which surround the oocytes. Subsequently microorganisms enter the space between the oocyte and follicular epithelium (perivitelline space). Symbionts closely adhere to each other and aggregate in an accumulation, termed a ‘symbiont ball’.

Landscape effect on bioaccumulation of pesticide residues in local food webs in agroecosystems

Authors: Michalko Radek[1], Purchart Lubos[1] and Košulic Ondrej[1], [1]Mendel University in Brno, Czech Republic

Abstract: One of the main reasons the existing strict European regulation of pesticides use fails in protecting ecosystem health is that natural dynamics and ecosystem functioning are often overlooked. For example, no empirical study to date has investigated how landscape composition affect bioaccumulation in local food webs in agroecosystems through a multiple-residue mixture of pesticides. This knowledge is essential for designing highly functional landscapes that would minimize pesticides' incorporation into food webs and negative impacts of pesticides on the environment, biodiversity, and human health. We explored the presence of pesticides in the groups soils, plants, rodents, and spiders within fruit orchards and vineyards. We found the concentration of pesticides to be highest in spiders as predicted by the biomagnification hypothesis. The spectrum of pesticides found in the studied groups, however, contained pesticides not locally applied. Widespread occurrence of multiple pesticide residues could be due to transport from the surrounding conventional fields or as "ghosts" from past treatments. Moreover, application of illegal pesticides and product counterfeits can be also a possible reason. However, each group contained some pesticides that were detected exclusively in that given group and that were not applied in a focal agroecosystem. In spiders and rodents, this 'group-specific pesticide composition' suggests that also spillover of spiders and rodents or spillover of their prey from surrounding agroecosystems and non-crop habitats to the focal agroecosystems might be an important source of pesticide transfer to local food webs.

The protease network that regulates innate immunity in mosquitoes

Authors: Michel Kristin[4], Osta Mike A.[2], Scoglio Caterina[3], Kuang Junyao[3] and R. Kanost Michael[1], [1]Department of Biochemistry and Molecular Biophysics, Kansas State University, United States, [2]Department of Biology, Faculty of Arts and Sciences, American University of Beirut, Lebanon, [3]Department of Mechanical and Electrical Engineering, Kansas State University, United States, [4]Division of Biology, Kansas State University, United States

Abstract: The mosquito immune system kills harmful pathogens and maintains a healthy microbiota. If overzealous, it however negatively affects the mosquito's blood feeding frequency, fecundity, and survival. Striking the balance is therefore key to mosquito fitness and thus vectorial capacity. Mosquito humoral immune reactions, including opsonization and melanization are regulated by proteolytic cleavage of thioester-containing proteins (TEPs) and pro-phenooxidase (proPO), respectively. Proteolysis in this system is performed by Clip-domain containing proteinases (cSPs), and regulated by non-functional proteinase-homologs (cSPHs), and serine proteinase inhibitors of the serpin family. However, the interplay of these factors is potentially complex, as each of these factors belong to large protein families, with nearly 20,000 individual molecular interactions possible with the mosquito hemolymph. To identify the critical interactions between the cSP, cSPH, serpins, TEP and proPO proteins that regulate mosquito immunity, we performed a meta-analysis of 256 transcriptomic datasets of Anopheles gambiae, the African malaria mosquito.
We assembled a co-transcription network, consisting of 178 nodes of six types based on protein families, and 1229 individual links between all nodes. To test whether this network can predict immune system function of individual putative immune factors, we experimentally tested the function of CLIPB4, the cSP node with the highest weighted degree centrality in the network. Detailed biochemical and genetic analyses confirmed that CLIPB4 is required for melanization in the mosquito hemolymph, directly cleaving proPO as well as upstream cSPs. As a visualization tool, the aggregated network highlights the complexity of the system, consisting of several highly branched protease cascades with positive and negative feedback loops. As an analysis tool, this network can be utilized to infer the potential biochemical interactions required for humoral immune system function in mosquitoes.

Reconstructing evolution of ancestral anatomies in Hymenoptera using PARAMO pipeline

Authors: Miko Istvan[2], Uyeda Josef[3] and Yoder Matthew[1], [1]University of Illinois, Champaign, United States, [2]University of New Hampshire, United States, [3]Virginia Tech, Blacksburg, United States

Abstract: Ancestral character state reconstruction has been long used to gain insight into the evolution of individual traits in organisms. However, organismal anatomies (= entire phenotypes) are not merely ensembles of individual traits, rather they are complex systems where traits interact with each other due to anatomical dependencies (when one trait depends on the presence of another trait) and developmental constraints. Comparative phylogenetics has been largely lacking a method for reconstructing the evolution of entire organismal anatomies or organismal body regions. Herein, we present a new approach named PARAMO (Phylogenetic Ancestral Reconstruction of Anatomy by Mapping Ontologies, Tarasov and Uyeda 2019) that takes into account anatomical dependencies and uses stochastic maps (i.e., phylogenetic trees with an instance of mapped evolutionary history of characters, Huelsenbeck et al. 2003) along with anatomy ontologies to reconstruct organismal anatomies.
Our approach treats the entire phenotype or its component body regions as single complex characters and allows exploring and comparing phenotypic evolution at different levels of anatomical hierarchy. These complex characters are constructed by ontology-informed amalgamation of elementary characters (i.e., those coded in character matrix) using stochastic maps. In our approach, characters are linked with the terms from an anatomy ontology, which allows viewing them not just as an ensemble of character state tokens but as entities that have their own biological meaning provided by the ontology. This ontology-informed framework provides new opportunities for tracking phenotypic radiations and anatomical evolution of organisms, which we explore using a large dataset for the insect order Hymenoptera (sawflies, wasps, ants and bees).

Action of species-selective JH-receptor agonists on insect development

Authors: Miláček Matěj, Department of Molecular Biology and Genetics, USB, Czech Republic

Abstract: Juvenile hormone (JH) maintains larval character of insect juveniles by activating the Kr-h1 gene through a JH receptor complex (JHR) comprising Met and Tai proteins. Metamorphosis to adults requires absence of JH and Kr-h1 expression during the final juvenile stage in both hemimetabolous and holometabolous insects. Administering JHR agonists at this time prevents adult development. Synthetic JH mimics that presently serve to control pest and disease vectors display poor selectivity toward target species. To develop selective means for insect control, we screened a chemical library of 90K compounds for activators of JHRs from diverse target species. We have found compounds that bound Met, stimulated assembly of the JHR complex, and blocked adult development in a species-selective manner. When treated with the specific JHR agonists, last-instar hemimetabolous larvae molted to a doomed extra larval instar, whereas treated pupae of holometabolans either formed second lethal pupae (beetles) or arrested without producing viable adults (mosquitoes). In contrast, development of honey bee pupae was unaffected by the compounds targeting other species. Our data demonstrate that novel, species-selective compounds for insect research and control can be developed.

Exploring and predicting multitrophic interactions between plant, whiteflies, parasitoids, and endosymbionts under changing climate

Authors: Milenovic Milan[3], Rapisarda Carmelo[4], Junk Jürgen[2], Eickermann Michael[1], [1]Luxembourg Institute of Science and Technology, Luxembourg, [2]Luxembourg Institute of Science and Technology, Luxembourg, [3]Luxembourg Institute of Science and Technology, Luxembourg; University of Catania, Italy, [4]University of Catania, Italy

Abstract: The impact of elevated CO2 levels, air temperature and relative humidity on the multitrophic interactions between plant, sap-sucking insects, and their antagonists and symbionts has not been studied in detail. Whitefly Bemisia tabaci is an important sap-sucking insect pest on a wide range of host plants globally including tomato where it causes direct damage by feeding and indirect damage through virus transmission. Biological control of whiteflies using parasitoids in European greenhouses is a standard practice. In addition, bacterial endosymbionts (ES) of B. tabaci also play an important role in the interaction between plant, whitefly, parasitoids, and the environment. At the moment studies investigating endosymbionts' role in whitefly biology under future climate scenarios currently do not exist.

In our study, we investigate the effects of physical consistent elevated CO2 levels, relative humidity and temperatures on multi-trophic interactions, including effects on the tomato plant, B. tabaci pest, its natural enemy (Eretmocerus), and endosymbionts. We peer into the underlying mechanisms using RNA sequencing techniques and identify differentially expressed genes in both tomato and whitefly to gain a better understanding of how the plant-whitefly system responds to climate change, parasitoid presence, and ES composition. Further, we combine the information on metabolic changes obtained through analysis of gene expression profiles with traditional life parameters of plant, whitefly, and parasitoids to get a comprehensive picture of multitrophic interactions under climate change effects.

The direct outcome of this study is a detailed prediction of climate change effects on the very important global pest and their associated multi-trophic interactions. These predictions together with a detailed molecular understanding of plant's and insect's biochemical responses to whitefly colonization under current and future environmental conditions will help create novel whitefly control methods. Additionally, these predictions are crucial in developing effective and sustainable climate change adaptation strategies for policy support as well as ensuring food security like vegetable production.

Minimum dispersal distance and ecological apparency mediate colonization of Arctostaphylos host plants by Tamalia gall aphids

Authors: Miller Donald, California State University, Chico, United States

Abstract: Fire is an important ecological process in chaparral plant communities in California. Arctostaphylos shrubs (Ericaceae) typically germinate following wildfire, providing new opportunities for specialist Tamalia gall aphids (Aphididae) to establish populations on fresh growth. Following wildfire at a study site in the Cascade foothills of northern California, I tested the hypotheses of minimum dispersal distance and ecological apparency to predict relative rates of colonization by a gall-inducing aphid (Tamalia coweni) and its inquiline aphid (Tamalia inquilina). Methods included mapping the spatial distribution of 500 host plants in a 1-hectare study population using a high-precision Trimble Global Positioning System (GPS) instrument, as well as Geographic Information System (GIS) software. These data yielded estimates of the frequency and timing of plants first colonized by gall-inducers, as well as the frequency of inquilines subsequently invading galls.

Results show that, beginning in 2008, less than 4% of the 135 juvenile plants were colonized by Tamalia aphids. The proportion of plants with aphid galls has increased continuously: 75% had been colonized by 2018. Assuming Tamalia aphids establish galls on young plants (sinks) from existing populations on mature plants (sources), my results are generally consistent with a minimum dispersal distance hypothesis. Colonization rates of host plants are a function of their height, which is consistent with the ecological apparency hypothesis. Inquilines can disperse and colonize new habitats efficiently, in synchronization with their gall-inducing host aphids. These findings have implications for patterns of evolutionary diversification in both gall-inducer and inquiline lineages.

Developing a molecular diagnostic test to detect parasitism in a highly-invasive lepidopteran

Authors: Miller Kyle, Newcastle University, United Kingdom

Abstract: The Oak Processionary moth (OPM) is a species native to central and southern Europe but is an invasive species, and serious forestry pest, in several northern European countries (Germany, the Netherlands, and the UK). OPM is a defoliator of Quercus (Oak) species and potential human health threat due to small urticating hairs which produce a pseudo-allergic response in humans. In London, OPM have been present since 2006, with a breeding population establishing and expanding. Concerns about the financial and environmental cost of nest removal and pesticide application have led to calls for alternative control measures, including biocontrol with parasitoids such as Carcelia iliaca.

Here, extracts of OPM larval samples with known parasitism status were used to test four LAMP primer sets. The results show the successful development of a LAMP based diagnostic assay that successfully amplifies C. iliaca from ground OPM lysate, excluding the need for complicated DNA extraction. Being able to gather C. iliaca distribution data from ground OPM samples allows for the development of predictive models to understand the ecological variables that allow for the presence of C. iliaca. This information would inform integrated pest management decision making frameworks for land managers.

Spatial responses of parasitoids to host patches, resource concentration or dilution?

Authors: Mills Nicholas, University of Minnesota, United States

Abstract: Importation biological control, the introduction of a specialist natural enemy from the region of origin of an invasive pest or weed, has been practiced for more than 100 years and has provided some iconic success stories, but also a number of failures. To improve both the success and safety of biological control in the future it is important to consider all opportunities that can help to transform biological control into a more predictive science. Once established, whether or not an imported natural enemy can reduce the abundance and distribution of an invasive host, likely depends on a suite of life history and behavioral traits that include phenological synchronization and foraging efficiency among many others. One key aspect of foraging efficiency is how individuals respond to the patchy distribution of hosts in a spatially fragmented environment when facing potential competition and predation risk. Another is what distributions of natural enemy foraging effort lead to the greatest temporal reduction in mean host density among patches. Here we explore the current theoretical framework for natural enemy foraging behavior and find some evidence that a weak resource dilution distribution of natural enemies among patches might be an important trait for improving the success of importation biological control.

Off- and early season, biological control of Mediterranean fruit fly Ceratitis capitata with entomomathogenic nematoded

Authors: Milonas Panagiotis[2], Chronopoulou Anna[1], Kapranas Apostolos[1], Papachristos Dimitrios[1] and Lytra Ioanna[1], [2]Benaki Phytopathological Institute, Greece, [1]Benaki Phytopathological Institute, Greece

Abstract: The purpose of the study is to investigate the efficacy of commercially available entomopathogenic nematodes (EPNs) Heterorhabditis bacteriophora Poinar, Steinernema Carpocapsae Weiser, and Steinernema feltiae Filipjev for the off-season control of the Medfly Ceratitis capitata (Diptera: Tephritidae). In laboratory experiments we investigated the efficacy and residual activity of EPN on soil substrate with organic content and moisture level similar to that of an orchard at a temperature of 19 ± 1 ° C. Steinernema feltiae and to a lesser extent S. carpocapsae, had a significant residual activity of up to two weeks. Whether the observed residual activity is due to the recycling of nematodes in recurrent additions of medfly larvae to the substrate (100 larvae every 14 days, three times) or to the residual duration of the nematodes themselves on the substrate requires further investigation. The ability of the three species of nematodes to move into artificially infected fruits, oranges and apples, laying on the soil substrate, was also assessed. The number of medfly pupating on the substrate in all three nematode treatments was significantly lower than in the control treatment. In conclusion, preliminary laboratory experiments showed that a single off-season application of S. feltiae or S. carpocapsae at relatively low doses (1.5mi /m2) can significantly reduce the overwintering larvae of madfly both in the soil and in the fallen fruits. In other experiments we explored whether application of a new formulation containing S carpocapsae on the canopy of orchards, early in the season (spring) can provide additional control via infestation of the adult flies as they emerge from the soil.

Presence, seasonal abundance and molecular studies on genetic and bacterial diversity of insect vectors of Xylella fastidiosa in olive orchards from Greece

Authors: Milonas Panagiotis[1], Kapantaidaki Deborah[1], Papachristos Dimitrios[1], Antonatos Spyridon[1] and Evangelou Vassiliki[1], [1]Benaki Phytopathological Institute, Greece

Abstract: During 2017 and 2018, samplings were carried out in several locations of Greece, distributed in 15 regional units, to study the presence of insect vectors of Xylella fastidiosa in olive orchards. In every location, samples were taken from the canopy of olive trees and from the ground vegetation cover, with a sweep net. In total, more than 40 Cicadellidae species were identified. However, none of them belonged to the subfamily of Cicadellinae. Five Aphrophoridae (Philaenus spumarius, P. signatus, Neophilaenus campestris, Aphrophora alni and Lepyronia coleoptrata) and one Cercopidae species (Cercopis sanguinolenta) were identified from the ground vegetation and the same Aphrophoridae species (except L. coleoptrata) were also found on the trees' canopy. Philaenus spumarius was found in nine out of the 15 regional units surveyed and was the widest distributed species.

In 2018 and 2019, detailed sampling throughout the year were performed in four areas of Greece in order to study the seasonal abundance of nymphs and adults of P. spumarius and N. campestris. Both species were present in olive orchards during spring and autumn while during summer months were absent. Their population densities greatly varied among the orchards sampled. A representative portion of the captured spittlebugs were analyzed with molecular methods and the analysis confirmed the absence of X. fastidiosa in the tested individuals.

Genetic divergence and/or relatedness within or between the different P. spumarius, P. signatus and N. campestris populations, was examined using molecular methods in 92, 24 and 62 adults from different populations of three species respectively, collected from different areas of Greece. Fragments of the mitochondrial genes Cytochrome Oxidase I (COI), cytochrome b (cytb) and of the nuclear gene Internal Transcribed Spacer (ITS) were amplified and sequenced. In addition, molecular experiments were carried out for examining the bacterial composition and diversity. One hundred fiftyfive, 28 and 81 collected adults from different populations of P. spumarius, P. signatus and N. campestris respectively, were screened for the presence of the secondary endosymbionts Cardinium, Rickettsia, Arsenophonus, Hamiltonella and Wolbachia. Among the different insect species and populations within the insect-species studied, the infection status and frequency of the endosymbionts varies significantly. The highest endosymbiont diversity is found in P. spumarius. There is no evidence for the presence of Cardinium in any of the three examined insect species. P. spumarius harbors Rickettsia, Arsenophonus, Hamiltonella and Wolbachia, P. signatus harbors only Rickettsia and N. campestris harbors Rickettsia, Hamiltonella and Wolbachia. Moreover, a multilocus sequence typing (MLST) approach has been used for the individuals harboring Wolbachia.

Nest boxes for birds increase insectivory in apple orchards

Authors: Miñarro Marcos[1] and García Daniel[2], [1]Servicio Regional de Investigación y. Desarrollo Agroalimentario (SERIDA), Spain, [2]Universidad de Oviedo. Dpto. Biología de Organismos y Sistemas and Unidad Mixta de Investigación en Biodiversidad (CSIC-Uo-PA), Oviedo

Abstract: The use of nest boxes for attracting insectivorous birds can be a strategy of conservation biological control. We evaluate this issue in cider-apple orchards from Asturias (NW Spain) by comparing bird insectivory and arthropod abundance on apple trees between orchards with and without nest boxes occupied by birds. We also monitored adult birds to identify the preys they feed to nestlings. Nest boxes were mainly occupied by great and blue tits. Insectivory, estimated from bird attack on plasticine caterpillar models, was higher (36-47%), and arthropod biomass was lower (49%), in orchards with occupied nest boxes. According to the preys, blue tit was the species with higher predation rate on apple pests. We showed that nest boxes can help to increase the biological control of apple pests.

Antiviral RNAi Response against the Insect-Specific Agua Salud Alphavirus

Authors: Mine Altinli, Leggewie Mayke[1], Gyanwali Rashwita, Scherer Christina, Srennu Vattipally B., Fegebank Marvin, Zibrat Bernhard, Fuss Janina, Schnettler Esther[2], Schulze Jonny[5], Badusche Marlis[3] and Junglen Sandra[4], [1]arch, partner side Hamburg-Lübeck-Borstel-Riems, Germany, [2]Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany German Centre for Infection research, partner side Hamburg-Lübeck-Borstel-Riems, Germany, Germ, [3]Bernhard Nocht Institute for Tropical Medicine; German Centre for Infection research, partner side Hamburg-Lübeck-Borstel-Riems, Germany, [4]Charité Universitätsmedizin Berlin, Germany, [5]Molecular Entomology, Molecular Biology and Immunology Department, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany

Abstract: RNA interference (RNAi) is the cornerstone of antiviral defense against arboviruses in mosquitoes. More specifically, it is understood that mainly the small interfering (si) and PIWI-interacting (pi) RNA pathways are involved in the control of these viruses. In contrast to arboviruses, little is known about the interaction of insect-specific viruses (ISVs) and the RNAi pathways. Due to their persistent nature and prolonged co-evolution in the insect host, it is safe to hypothesize that ISV-RNAi interactions differ compared to arboviruses. While investigations into this area further contribute to the characterization of ISVs, it also highlights potential intersections that might in the long run affect vector competence of mosquitoes for arboviruses of public health concern. Additionally, it could shed light on essential changes needed for an ISV to make the switch to becoming an arbovirus.

In this study we investigate the interactions of a recently isolated insect-specifc alphavirus, Agua Salud alphavirus (ASALV) with its mosquito host. Through the knockdown of transcripts of the different key RNAi pathway proteins, we show the antiviral role of Ago2, Ago1 and Piwi4 proteins against ASALV in Aedes aegypti-derived cells. Data from knockout cells further confirmed the main antiviral role of the siRNA pathway.

Taken together, ASALV interactions with the mosquito RNAi response differ from those of arthopod-borne alphaviruses in some aspects, although they also share some commonalities. Further research is needed to understand whether the identified differences can be generalised to other insect-specific alphaviruses.

LIFE ROsalia: Conservation of saproxylic beetles in the Carpathians in Romania (LIFE19 NAT/RO/000023)

Authors: Mirea Marian[2] and Chiriac Silviu[1], [1]Environmental Protection Agency Vrancea, [2]University of Bucharest, Center of Environmental Research

Abstract: The Romanian Carpathians are considered a biodiversity hotspot in Europe, with large, forested areas, including old-growth forests. Past forestry practices, such as selective logging resulting in forest high grading and removal of ancient or decaying trees has reduced the heterogeneity of forest structure and composition. These practices led to forest habitats with few veteran trees and a small amount of deadwood, which the protected group of saproxylic beetles rely on for completing their complex life cycles. The LIFE ROsalia project is improving habitat conditions for five saproxylic beetle species (Rosalia alpina, Osmoderma eremita, Cerambyx cerdo, Morimus funereus, and Lucanus cervus) in the forests of the Putna-Vrancea Natura 2000 site by demonstrating conservation actions for increasing the connectivity of favourable habitats for the beetle species. Actions include providing artificial and natural deadwood habitats, clearing overgrowth, and establishing a participatory monitoring system with foresters using a citizen science approach.

Surveying the acoustic biology of longhorned beetles (Coleoptera: Cerambycidae)

Authors: Mitchell Robert[2], Reading Emma[1], Sedlock Jodi[1], S. Poeschl Lyndsay[2] and Peters Nicole[2], [1]Department of Biology, Lawrence University, Appleton, United States, [2]Department of Biology, University of Wisconsin Oshkosh, United States

Abstract: Many species of longhorned beetles (Cerambycidae) stridulate audibly by rasping the posterior margin of the pronotum over a stridulatory plate, or pars stridens, on the mesonotum. The function of stridulation is largely unknown, but individuals may stridulate when encountering conspecifics, and are especially likely to stridulate when disturbed. These “chirps” frequently range into ultrasonic frequencies, and we hypothesized that they may be a disruptive response to bat predation. We have recorded chirps of diverse species of longhorned beetles to determine how the acoustic properties of the chirp correlate with evening activity periods (and thus bat activity), species (suggesting intraspecific communication), or individual morphology. Additionally, we have coupled our approach with scanning electron microscopy (SEM) to observe the structure of the pars stridens in each species. Our preliminary results suggest that the properties of the pars stridens are similar within species, but they may vary considerably even among closely related species.

Molecular mechanisms of juvenile hormone biosynthesis and metamorphosis in Gryllus bimaculatus

Authors: Mito Taro[1], Watanabe Takahito[1], Noji Sumihare[1] and Ishimaru Yoshiyasu[1], [1]Tokushima University

Abstract: Juvenile hormone (JH) acid methyltransferase (JHAMT) plays a crucial role in JH biosynthesis. We previously reported that Myoglianin (Myo) suppresses JHAMT expression to down-regulate JH production in the cricket, Gryllus bimaculatus.

To improve our understanding of the role of Myo, we generated myo gene knockout (KO) crickets and characterized the phenotype of myo KO nymphs. We found that supernumerary nymphal molts were observed in the myo KO nymphs. The myo KO nymphs subsequently failed to cause the juvenile-to-adult transition. We further found that a significantly increased expression of JHAMT was detected in the myo KO fourth instar nymphs. In addition, JH titers were elevated in myo KO nymphs.

Next, we examined the function of JH and ecdysteroid target genes, Krüppel homolog 1 (Kr-h1), Broad complex (Br-C) and E93, in the metamorphosis of hemimetabolous G. bimaculatus. Depletion of Kr-h1 or Br-C at the sixth instar nymphs induced precocious adult moults. In contrast, E93 knockdown prevents final (eighth) nymphs transitioning to adults, instead producing supernumerary nymphs.

Our results suggest that the regulatory mechanisms underlying pupal transition in holometabolous insects are evolutionarily conserved in hemimetabolous G. bimaculatus, with the penultimate and final nymphal periods being equivalent to the pupal stage.

A New Genus of Cerocephalinae (Hymenoptera: Pteromalidae) from Madagascar

Authors: Mitroiu Mircea-Dan, Universitatea “Alexandru Ioan Cuza” din Iasi

Abstract: A new genus of Cerocephalinae with brachypterous females is described from Madagascar based on material from Muséum national d’Histoire naturelle Paris. Although its morphology is not in complete agreement with the current subfamily diagnosis, the new genus is classified in Cerocephalinae based on the following shared features: head globose, with interantennal concavity bearing sharp carina and parascobal area strongly raised; antennal shape and structure, with no anellus, six funiculars and completely fused clava; and the shape and structure of pronotum and gaster. The new genus is compared with all previously described genera of the subfamily and the limits of Cerocephalinae are discussed.

Circannual rhythms in two Anthrenus carpet beetles: comparison between spring- and autumn-pupation types

Authors: Miyazaki Yosuke[1] and Watari Yasuhiko[1], [1]Ashiya University, Japan

Abstract: The circannual rhythm is a biological rhythm with a period of about one year. Circannual rhythms in insects have mainly been reported in pupation of the varied carpet beetle, Anthrenus verbasci. This species has a long larval duration and pupates every spring. The circannual pupation rhythm of A. verbasci shows self-sustainability, temperature compensation of the period, and entrainability to a zeitgeber (photoperiodic change), which indicates that a circannual clock of A. verbasci is an endogenous oscillator. Although this rhythm has been reported since the early time of the circannual rhythm research, circannual rhythms have been rarely reported in other insects and no interspecific comparisons have been made. We focused on A. nipponensis of the same genus. This species has been reported to pupate in autumn. If there is also a circannual rhythm in the pupation of A. nipponensis, it is considered that the properties of rhythm can be compared between two species of the same genus with half a year difference of pupation phase. Therefore, we investigated whether circannual rhythm is exhibited in pupation when larvae of A. nipponensis are kept under various constant conditions. Moreover, we compared circannual rhythms of pupation between A. verbasci and A. nipponensis.

Behavioral mechanisms for the evolution of termite nest construction

Authors: Mizumoto Nobuaki[1], Bardunias Paul[2], Pratt Stephen[1] and Bourguignon Thomas[3], [1]Arizona State University, United States, [2]Florida Atlantic University, United States, [3]Okinawa Institute of Science & Technology Graduate University, Japan

Abstract: The nest structures built by social insects are complex group-level patterns that emerge from interactions among individuals following simple behavioral rules. The theory of complex systems predicts that there is no simple one-to-one relationship between variations in collective patterns and variation in individual behaviors; therefore, it is essential to know how actual behavior evolves to change pattern formation. In this presentation, we discuss the role of behavioral rules in the evolution of collective building in termites.

First, we show that the evolutionary divergence of termite tunneling patterns is achieved by quantitative tuning of shared behavioral rules, rather than the acquisition of novel behaviors. We compared tunnel formation between two closely related species, Reticulitermes tibialis and Heterotermes aureus, and found that H. aureus builds more highly branched tunnels than R. tibialis. Our behavioral analysis and data-based modeling revealed that these species share the same behavioral repertoire, but a quantitative difference in the probability of sidewall excavation leads to diverse tunneling patterns. In contrast, we also found that Paraneotermes simplicicornis, which evolved tunneling independently, possesses a distinct behavioral repertoire, but shows convergence of branching patterns with R. tibialis.

Second, we inferred the evolutionary process of termite shelter-tube construction through phylogenetic analysis. Although the use of shelter-tubes in natural conditions is variable, most modern species have the potential to build shelter-tubes. With this information, our ancestral reconstruction suggests that the behavioral rules for shelter-tube construction evolved once in the common ancestor of modern termites, and are shared among species.

Together, these results elucidate the complex relationship between individual behavior and group-level patterns; in some cases, distinct behavioral rules can produce similar group-level patterns, but in others, a common rule set can yield the evolution of distinct patterns via parameter tuning. Our result emphasizes the importance of direct comparative studies of both individual behaviors and group-level patterns.

Wildflower strips and their management affect resource availability and utilisation by parasitoids

Authors: Mockford Alice[4], Urbaneja Alberto[1], Westbury Duncan B[4], Tena Alejandro[2] and Ashbrook Kate[3], [1]Institut Valencià d'Investigacions Agràries (IVIA), [2]Instituto Valenciano de Investigaciones Agrarias, Spain, [3]School of Science and the Environment, University of Worcester, United Kingdom, [4]University of Worcester, United Kingdom

Abstract: The use of wildflower strips to provide carbohydrate resource for parasitoids and enhance pest regulation has become a cornerstone of habitat management for pest regulation. However, how wildflower strips and subsequent management might influence resource availability and utilisation by parasitoids has never been studied.

In a randomised block experiment, three treatments were applied in the alleyways between the rows of trees in three Spanish orange orchards: i) a control treatment where naturally occurring vegetation was managed under standard farm practice; ii) a standard management treatment, where sown wildflower strips were cut once a year; and iii) an active management treatment, where sown wildflower strips were cut three times a year.

Wildflower strips under standard management prevented the seasonal decline of available nectar observed in the control and active management treatments and instead, supported fructose feeding in parasitoids across all three seasons. The abundance of floral nectar and hemipteran honeydew in the alleyways and orange trees was consistently greater with the wildflower strips under standard management than with the control treatment or active management wildflower strips. In turn, the standard management wildflower treatment was associated with twice the abundance of primary parasitoids than with the control and active management treatments in both summer and autumn. In addition, in autumn, parasitoids were most likely to have recently fed on carbohydrate in the standard management treatment. Finally, increased carbohydrate feeding in parasitoids was associated with greater structural heterogeneity of the alleyway vegetation.

This study demonstrates that the nutritional status of parasitoids in a perennial crop, such as orange, can be improved by wildflower strips which could then enhance pest regulation services. Furthermore, the study emphasises the importance of investigating the management of wildflower strips when targeting specific resource requirements.

Creating a sustainable, 21st century IPM toolkit to combat a historic pest issue; Tipula larvae in agricultural settings.

Authors: Moffat Aisling, Teagasc, SRUC and the University of Edinburgh, Ireland

Abstract: Tipula larvae are important agricultural pests as their feeding cause's significant damage in cereals and grassland. A previously effective chemical has been withdrawn from use within the EU due to the associated risks, to both human health and the environment. Current control options are extremely limited. Our research aims to create a modern IPM toolkit for dealing sustainably with Tipula larvae infestations in grassland specifically. This involved a national survey across Ireland, which was conducted to determine (i) the Tipula species of agronomic importance, and (ii) the soil factors that limit larval survival/occurrence. Larval feeding experiments were established, with six plant monocultures and a mixed-species sward, to identify optimum grassland sward compositions for highly infested fields. Soil microbiome analysis from fields across Scotland and Ireland was also carried out to investigate the microbial communities present in fields with high and low pest pressure. This analysis will give insight into potential biocontrol agents for future control options, and will complete our IPM toolkit. Through better understanding the pest of interest, the role of soil properties and cultivar choice, we aim to provide farmers with an IPM toolkit for a pest with limited control options. (Refer to attachment for full draft).

Exogenously acquired sticky compounds influence herbivore selection in plants

Authors: Mofikoya Adedayo, University of Reading, United Kingdom

Abstract: Plant surfaces represent the first point of physical contact in plant-insect interactions and as such, various plant surfaces have evolved differing physicochemical properties to attract, repel and deter insects. Physical properties such as waxiness and leaf trichomes act as physical barriers against herbivory, some trichomes secrete secondary metabolites consisting of plant volatile organic compounds (VOCs) that are cues for plant selection for herbivores, gravid female insects, pollinators as well as natural enemies (parasitoids). Field scale studies in the Finnish subarctic provided evidence that semivolatiles compounds released by understorey shrubs Rhododendron tomentosum adhere to the surface of surrounding mountain birch (Betula pubescens) trees. Furthermore, laboratory tests show that these compounds may also adhere to the surface white cabbage Brassica oleracea and confer some resistance to oviposition by the diamondback moth, Plutella xylostella even under pollution conditions. These findings provide evidence that companion aromatic plants may confer associational resistance to main plants in agriculture and forestry systems.

Exogenously acquired chemicals on plant surfaces confers herbivore resistance in forest and agriculture systems

Authors: Mofikoya Adedayo[4], Kivimäenpää Minna[2], Holopainen Jarmo[1] and Blande James[3], [1]Department of Environmental and Biological Sciences, UEF, Finland, [2]Natural Resources Institute Finland, [3]University of Eastern Finland, Finland, [4]University of Reading, United Kingdom

Abstract: Plant surfaces represent the first point of physical contact in plant-insect interactions and as such, various plant surfaces have evolved differing physicochemical properties to attract, repel and deter insects. Physical properties such as waxiness and leaf trichomes act as physical barriers against herbivory, some trichomes secrete secondary metabolites consisting of plant volatile organic compounds (VOCs) that are cues for plant selection for herbivores, gravid female insects, pollinators as well as natural enemies (parasitoids). Field scale studies in the Finnish subarctic provided evidence that semivolatiles compounds released by understorey shrubs Rhododendron tomentosum adhere to the surface of surrounding mountain birch (Betula pubescens) trees. Furthermore, laboratory tests show that these compounds may also adhere to the surface white cabbage Brassica oleracea and confer some resistance to oviposition by the diamondback moth, Plutella xylostella even under pollution conditions. These findings provide evidence that companion aromatic plants may confer associational resistance to main plants in agriculture and forestry systems.

Some host trees properties contribute to variation in the Emerald Ash borer gut microbiome: Important ecological knowledge for applied biological control

Authors: Mogouong Judith[1], Guertin Claude[2] and Constant Philippe[2], [1]Cornell University, United States, [2]Institut national de la recherche scientifique Armand-Frappier Santé Biotechnologie Research Centre, Canada

Abstract: The Emerald Ash Borer (EAB), Agrilus planipennis Fairmaire, is an exotic insect pest native to Asia that causes environmental and economic damage to ash trees (Fraxinus spp.) in North America. This Buprestidae first detected in 2002 at Canada-U.S. border, is now known as the most serious pest in recent decades, particularly because of the environmental, ecological and economic impacts. The microbiome of wood boring beetles has been largely studied, and it now established that it may play crucial role for their host survival. Besides that, there is still lack of information on the mechanisms by which that microbiome maintains its role. More importantly, some concerns related to the drivers of that microbiome need to be addressed. Some environmental factors such as temperature and nutrition could act as determinants, and influence the composition of these insects' microbiome. One goal of our study was to address the following question: does host tree properties contribute to variation in the Emerald Ash borer gut microbiome structure? An approach based on the amplicon sequencing high throughput technique targeting the bacterial 16S rRNA and the ITS2 fungal internal transcribed spacer couple with different multivariate analyzes revealed the taxonomic structure of the insect's gut microbiome characterized by some ecological markers, and its plasticity when facing some variations in its environment. More specifically the bacterial and fungal communities associated with the host leaves (phyllosphere) appeared to play a determinant role in the variation observed in the insects' gut microbiome. Interestingly, our results suggest that most of the insect's gut fungal microbiome may be transitory probably acquired from the insect environment, whereas some specific bacterial taxa could be considered as habitual residents in the insect's gut microbiome. Moreover, the fungal microbiome was found more sensitive to those host tree properties. Our findings bring out some research questions such as what are the roles of the microorganisms found in the insects' gut? Or how important is the fungal community found in the gut microbiome? By improving the knowledge to the understanding of the microbial ecology, the future for potential biological pest management may be more efficient.

Effect of honey bee management strategies on Varroa destructor and small hive beetle (Aethina tumida) in Hawaii

Authors: Mogren Christina[1], Hausler Daniel[2], [1]University of Hawaii at Manoa, Plant and Environmental Protection Sciences Department, United States, [2]University of Hawai'i at Manoa, United States

Abstract: Beekeepers around the globe have to make informed management decisions when treating for hive pests. Varroa destructor, an ectoparasitic mite that feeds on the honey bee fat body, is considered the most devastating pest of the European honey bee (Apis mellifera). Varroa mites were introduced to the U.S. state of Hawaii in 2007 and are exclusively present on Oahu and Hawaii islands. To prevent further spread, state law prohibits the movement of used beekeeping equipment and live bees between islands. There are two main paradigms among beekeepers regarding varroa management; IPM (chemical control) using organic and conventional pesticides, and holistic (chemical-free options), which include the mechanical removal of drone brood. Integrated approaches may take advantage of Varroa sensitive hygienic traits as well. Small hive beetles (SHB, Aethina tumida) are colony parasites native to sub-Saharan Africa whose larvae tunnel through the combs and excrete a yeast in their frass that ferments hive products, making them unmarketable. Discovered in Hawaii in 2010, SHB is now ubiquitous across the archipelago, where current research is primarily focused on developing biocontrol agents. Hawaiian beekeepers can choose among various management strategies to combat varroa and SHB. For varroa, products registered for use in Hawaii include six organic and three conventional pesticides. No products are available that are registered for use against SHB in Hawaii, so standard mechanical methods for trapping and removal are the only option available to beekeepers. The goal of this project is to evaluate the effectiveness of IPM and holistic management practices against these economically important pests of honey bees in Hawaii.

Varroa mite and SHB levels were measured monthly under both management strategies on two islands: IPM and holistic for varroa on Oahu (varroa-positive) and holistic on Maui (varroa-negative). Varroa levels were assessed using an alcohol wash method, and SHBs trapped in Beetle Blaster (oil) traps were used to compare populations between colonies. Statistical comparisons were made between hive pest levels as well as IPM vs. holistic management paradigms.

There is relatively little research present on holistic management of honey bees, and results from this study will provide data directly to those that have a preference or restriction to this paradigm. Since IPM is not the only management option, the importance of knowing the capability of holistic pest control is significant to many beekeepers. This study is a foundation for future research on honey bee pest management options and how additional factors, such as nutrition, can integrate with management strategies to make them more or less effective.

Temporal shifts in nutrient quality of pollen collected by honey bees (Apis mellifera) in Kauai, Hawaii

Authors: Mogren Christina, University of Hawaii at Manoa, Plant and Environmental Protection Sciences Department, United States

Abstract: Honey bees were introduced to the Hawaiian Islands for pollination services and honey production in the 1850s, and since then have become ubiquitous across the archipelago. The honey bee queen rearing industry in the state is the largest in the world, with the subtropical climate allowing for year-round production. Many large mainland U.S. and Canadian beekeepers depend upon the availability of quality queens reared in Hawaii, particularly in the spring. However, the major native pollinating insects of endemic plants in Hawaii are beetles, which have different nutrient requirements for development and growth than honey bees. Since colonization by the Polynesians and later by Europeans, weed plants from regions to which honey bees are native have been continuously introduced, and honey bees are strongly suspected of serving as pollinators to these invasive plants. Pollination services are important for boosting yields of specialty crops such as Macadamia nuts and coffee, but it is not known to what extent honey bees forage upon native plants and whether this could be driven by nutrient quality of native vs. introduced plant pollen, in an ecosystem that evolved primarily with beetle pollinators. To determine the extent to which honey bees rely upon native vs. introduced plants, bee-collected pollen was analyzed from an apiary in Lihue, Kauai. Pollen samples were collected monthly, and sorted to color as a proxy for plant species. Each color group was identified to species using next-generation sequencing analysis of the ITS2 nuclear ribosomal gene and the macronutrients (lipids, protein, glycogen) and amino acids quantified. Statistical comparisons were made between native and introduced plant species pollen, and through time to see how nutrient values and plant species composition shifted throughout the year. Data will be presented in the context of future management considerations for honey bees in Hawaii, and how this may be used to inform beekeeping practices in subtropical island areas where European honey bees have been introduced.

A new bioassay to measure mosquito mortality and outdoor bite prevention strategies under semi field conditions

Authors: Mohamed Mgeni[1], Saddler Adam[1], Stica Caleb[1], Odufuwa Olukayode[1] and Moore Sarah[1], [1]Ifakara Health institute, Tanzania

Abstract: Introduction: The important component of mosquito-borne disease control programs worldwide is through the implementation of appropriate vector control tools. There is a gap in tools that provide protection against vectors that bite outdoors. Spatial repellents (SR) create a bite-free space through the evaporation of low doses of insecticides that repel and kill mosquitoes while requiring minimal compliance from users. These tools have demonstrated an ability to control both indoor and outdoor biting mosquitoes. Such tools must be evaluated in the semi-field system (SFS) prior to testing at the community level. We developed a bioassay to capture similar data as collected for insecticide-treated nets (ITNs) to inform mathematical models and predict the impact of transfluthrin SR on vectorial capacity.

Method: We treated hessian (jute) sacking with five doses of transfluthrin, 1g, 5g, 7.5g, 10g, 12g, and 15 g, or water for the control. The Ifakara Large Ambient chambers test (I-LACT). The I-LACT is a newly developed assay that simulates outdoor conditions and allows the recapture of all released mosquitoes. Each dose was evaluated in a block of four replicates, where volunteers were rotated while the treatment was fixed. Two blocks were conducted for each dose. Fifty pyrethroids susceptible Anopheles gambiae mosquitoes were released in each chamber where a volunteer sat in a plastic chair and allowed mosquitoes to feed. After an hour, mosquitoes were collected using aspirator held with access to sugar for 24 hours and scored as 1) fed alive, 2) fed dead, 3) unfed alive, 4) unfed dead. Feeding success and percentage mortality of free-flying mosquitoes was estimated and data were analyzed by generalized linear mixed-effects regressions with the binary distribution.

Result: There was a dose-response observed in both feeding inhibition and mortality induced by transfluthrin. For each 1g increase in transfluthrin, the probability of feeding decreased by 19% (OR 0.81(95% CI 0.80-0.83), $p<0.0001$) and the probability of dying increased by 38% (OR 1.38 (95% CI 1.31-1.45), $p<0.0001$). However, mosquito mortality stepped up from 10% to 58% when the dose was increased from 12.5 g to 15g while feeding success decreased from 30% to 15% between 10g and 12.5 g transfluthrin.

Conclusions: Transfluthrin treated material applied to houses with 15g per structure effectively reduces outdoor feeding and induces substantial mortality in pyrethroid susceptible mosquitoes. Therefore, products that release a similar concentration of transfluthrin may have an application for public health as they functioned as an “outdoor bednet” giving both personal protection (bite reduction) and community protection (mosquito mortality) sufficient to substantially reduce vectorial capacity of malaria vectors when applied at scale.

Integrated Pest Management of the Tomato Leaf Miner, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) in Tomato under green houses in Algeria

Authors: Mohammed Beddane, The directorate of agricultural services Phytosanitary inspection service, Algeria

Abstract: The tomato leaf minor (TLM), Tuta (Scrobipalpuloides) absoluta (Meyrick) (Lepidoptera: Gelechiidae) is one of the major devastating insect pests attacking tomato in many of the tomato-producing regions worldwide.
At present, depending on the cropping system and infestation intensity, the main control tools used against TLM rely too heavily on conventional insecticides that have led to the development of insecticide resistance .
In addition, the problems of using chemical control are further exacerbated by awareness of environmental pollution, toxicity to natural enemies and increasing risks to human and mammals (Tillman et al., 2000). Therefore, the use of insecticides has become subordinated to other control methods, such as biological control singly and/or in integrated with other methods as use of aggregation pheromones and biopesticides that have gained more credibility in the last decades (Senior et al., 2001; Agamy, 2003 and Mandour et al., 2012). Biological control using natural enemies would be the concerted use as a major component of any integrated pest management (IPM) program for controlling TLM. Egg parasitoid species of family Trichogrammatidae are considered efficient biological control agents and are widely used commercially for the suppression and control of lepidopterous pests on many crops (Agamy, 2003).

Being the progeny of a mother who lived in conventional orchards makes you more asymmetric than having a mother who lived in organic orchards in the European earwig Forficula auricularia.

Authors: Moiroux Joffrey[1], Le Navenant Adrien[2], Rault Magali[2] and Suchail Séverine[2], [1]Avignon University, France, [2]UMR IMBE, Avignon University, Aix Marseille University, CNRS, IRD - Avignon, France

Abstract: Organisms have to deal with many detrimental environmental factors throughout their development, such as stressful temperatures, competition or pollutants, which may result in developmental instability. For a long time, fluctuating asymmetry - i.e. small, random deviations away from perfect bilateral symmetry - has been used as a bioindicator to evaluate this developmental instability. When investigating the influence of any factor on fluctuating asymmetry, individuals are usually directly exposed during their development. In this study, we measured fluctuating asymmetry of several morphological traits in the progeny of European earwig females sampled before mating in conventional, integrated and organical orchards. Individuals which were used for measurements were thus never exposed directly to insecticides.
We observed a higher unsigned fluctuating asymmetry for six morphological traits in the progeny of females which were sampled in organic orchards, where chemical pesticides are not used, compared to the progeny of females which were sampled in integrated and conventional orchards, where chemical insecticides are allowed. Chemical compounds used for plant protection may thus have long-term effects on developmental stability of non-target insect species through maternal effects.

Understanding the Influence of Global Warming on Pest Management: Impact of Cross Effects between Temperature and Three Insecticides on Codling Moth Susceptibility

Authors: Moiroux Joffrey[1], Perrin Marie[2] and Delattre Thomas[3], [1]Avignon University, France, [2]Avignon University, France, [3]INRA, PSH Unit, Team Biological Control by Conservation, Avignon, France

Abstract: The frequency of insecticides' application is expected to increase with climate change since most of the insect pests are bound to appear earlier in the season, produce more generations because of a shorter development time at a higher temperature, and expand their distribution in the future. Temperature is known to influence the absorption, penetration, translocation and detoxification of pesticides by organisms. It is therefore necessary to investigate interactions between insecticides and temperature to predict possible outbreaks of pests in a climate change context and adapt pest management to future climatic conditions.
We conducted such an experiment on the codling moth, Cydia pomonella, one of the main pests in orchards worldwide that is commonly targeted with insecticides. Codling moth larvae were exposed to different concentrations of two chemical and one biological insecticides at five temperatures, and their mortality was recorded daily to assess the impact of cross effects between temperature and insecticides on this pest susceptibility.
We observed that larval mortality decreased as temperature increased for one of the two chemical insecticides, the emamectin. The lethal dose, 50% was indeed lower at 30 and 35°C than at 20 and 25°C. Preliminary results on the spinosad, a biological insecticide, are consistent with this result. Temperature did no influence larval mortality associated with the second chemical insecticide. Underlying physiological mechanisms are still investigated and will be discussed.
Our results highlight the disruption that may occur in pest management strategies because of the influence of high temperatures on the efficiency of pesticides. Such research is required to adapt application of pesticides to future climatic conditions.

Bioactive constituents, in vitro radical scavenging and antibacterial activities of selected Apis mellifera honey from Kenya

Authors: Mokaya Hosea[1] and Lattorff Michael[2], [1]International Center of Insect Physiology and Ecology. Jomo Kenyatta University of Agriculture and Technology, Kenya, [2]University of Nairobi; Martin-Luther-University Halle-Wittenberg

Abstract: There is limited information about the relative composition and health benefits of various honey consumed across Africa. This study aimed at estimating the bioactive constituents, in vitro radical scavenging and antibacterial activities of 16 kinds of honey obtained from different geographical locations in Kenya. Manuka 5 + honey was included for comparison. Some of the tested honey had biochemicals and bioactivities similar to or higher than Manuka 5 + honey. The honey exhibited DPPH radical scavenging ability, with several types of honey showing superior scavenging potential than Manuka 5 + honey, owing to their high phenol content. All types of honey inhibited the growth of E. coli and further showed a substantial amount of nonperoxide antimicrobial activity. The geographical origin of honey had an influence on its bioactive contents. Overall, these findings suggest that Kenyan honey has great therapeutic potential, and thus, its clinical application should not be overlooked.

What drives caterpillar abundance on individual trees: enemy pressure, leaf or tree growth, genetic traits, or phylogenetic neighbourhood?

Authors: Molleman Freerk[1], Walczak Urszula[1] and Melosik Iwona[1], [1]Adam Mickiewicz University in Poznań, Poland

Abstract: The abundance of insect herbivores on individual host trees can be driven by processes ranging from ongoing leaf development via recent microevolution to ancient phylogeny represented in the neighbourhood. To elucidate the relative importance of these processes, we sampled spring caterpillars (leaf-mining casebearers, semi-concealed, and free-living) from oaks (Quercus petraea) that varied in budburst phenology, trunk diameter, genotype, genome size, and phylogenetic neighbourhood. We found that free-living caterpillar abundance decreased with leaf age. Larger trees tended to show higher parasitism rates of herbivores. Casebearers were less abundant on more heterozygous oaks, but we detected no other effects of genotype or genome size on caterpillar abundance. In contrast to most previous studies, oaks growing among phylogenetic distant tree species had higher abundances of all three caterpillar guilds. This was not driven by the co-dominant species. Furthermore, in homogeneously phylogenetically distant neighbourhoods, parasitism tended to be lower. Lower parasitism, in turn, was associated with higher abundances of co-dominant caterpillar species. The overall dominating effect of phylogenetically distant neighbourhoods increasing caterpillar abundance further suggests that the consequences of growing amongst distantly related tree species may depend on factors such as geographic region and tree age.

Collections-based genomics deciphers phylogeographic patterns in the Holarctic sawfly Pristiphora cincta Newman (Tenthredinidae)

Authors: Monckton Spencer K., Department of Biology, York University, Canada

Abstract: Sawflies in the subfamily Nematinae (Hymenoptera: Tenthredinidae) are cold-adapted insects that reach their greatest species richness in temperate, boreal, and arctic/subarctic regions of the Northern Hemisphere – a pattern that runs counter to that of most other organisms. In North America, most of their present range was covered by ice during the Pleistocene glaciations, meaning that they must have persisted in unglaciated refugia to the south, in Beringia, and possibly in other cryptic northern refugia. Along what corridors they repopulated the northern half of the continent, and from where, remain questions of great interest for understanding patterns of diversity for sawflies in particular and for North American insects in general. The holarctic species Pristiphora cincta Newman inhabits the temperate and boreal zones of North America and Eurasia, having seemingly crossed the Bering Land Bridge at least twice. As an herbivore on birch (Betula) and Vaccinium, it is hypothesized to have survived in small, geographically-restricted refugia on the peripheries of the Laurentide ice sheet, in Beringia, and in unglaciated parts of Eurasia. To evaluate the relative importance of these putative refugia, and to investigate present-day patterns of genetic diversity among populations of P. cincta, I use an approach called hyRAD to generate genome-wide RADseq data for pinned specimens sourced from natural history collections. With genomic data from representatives from across this species' range, I apply approximate Bayesian computation (ABC) to test ecologically-informed hypotheses about the phylogeographic history of P. cincta. I present the results of model-based phylogeographic analyses and interpret those results with respect to patterns of genetic diversity among populations, use of glacial refugia, and patterns of post-glacial recolonization. Broader implications for the diversity of Pristiphora Latreille, comprising more than 60 species in North America, are discussed, along with the potential to extend this study to include two other co-distributed species.

A Computational Approach for the Prediction of Relevant Olfactory Receptors in Insects

Authors: Montes Zaide[2], Reyes Alejandro[3], Molina Jorge[1], [1]1. Research Center in Microbiology and Tropical Parasitology (CIMPAT), Department of Biological Sciences, Universidad de los Andes, Bogota, Colombia, [2]1. Research Group on Computational Biology and Microbial Ecology. 2. Research Center in Microbiology and Tropical Parasitology (CIMPAT), Department of Biologi, [3]1. Research Group on Computational Biology and Microbial Ecology. 3. Max Planck Tandem Group in Computational Biology, Universidad de los Andes, Bogota, Colombia

Abstract: Insects are extremely successful organisms. A sophisticated olfactory system is in part responsible for their survival and reproduction. The detection of volatile organic compounds can positively or negatively affect many behaviors in insects. Compounds such as carbon dioxide, ammonium, indol, and lactic acid are essential for many species of mosquitoes in order to locate vertebrate hosts. For instance, in Anopheles gambiae the olfactory receptor AgOR2 is strongly activated by indol, which accounts for almost 30% of human sweat. Likewise, in some insects of agricultural importance, the identification of pheromone receptors such as in lepidoptera species has become a promising field for integrated pest management. For example, the disruption of the pheromone receptor, BmOR1, mediated by transcription activator-like effector nucleases (TALENs), remove completely the sensitivity to bombykol, affecting the pheromone-source searching behavior in male moths. In consequence, the identification of olfactory receptors in the genomes of insects is fundamental to improve our understanding of the ecological interactions, and to provide alternatives in the integrated pests and vectors management. Hence, the objective of this study is to propose a bioinformatic workflow to enhance the detection and identification of potential olfactory receptors in insects. Applying Hidden Markov Models (HMMs) and other computational tools, potential candidates for pheromone receptors in Lepidoptera were identified, as well as potential carbon dioxide receptors in Rhodnius prolixus, the main vector of Chagas disease. This study showed the capacity of a bioinformatic workflow with a potential to improve the identification of certain olfactory receptors in different Orders of insects.

Time of development of the forensically important carrion beetle Thanatophilus sinuatus (Silphidae: Silphinae) at constant temperatures

Authors: Montoya-Molina Santiago[1], Ruzicka Jan[1] and Jakubec Pavel[1], [1]Faculty of Environmental Sciences, Czech University of Life Sciences Prague, Czech Republic

Abstract: The species of the genus Thanatophilus (Silphidae: Silphinae) are recognized to be useful evidence for medico legal investigations primarily for the estimation of Post Mortem Interval (PMI). Thanatophilus sinuatus is a common carrion beetle found at early stages of decomposition on vertebrate carrion and human corpses across Europe. Regardless of the benefits for forensic sciences, thermal summation models are still unavailable for the species, therefore it cannot be used for PMI calculations. Thermal summation models or accumulated degree-days (ADD) methods are used as solid evidence to PMI estimation. The present study will provide information regarding developmental times of Th. sinuatus at five constant temperatures (16 °C, 18°C, 20°C, 21°C, 24°C). Immatures stages for the study were obtained from laboratory rearing under controlled conditions (16:8 h of light/dark period). Based on the data of temperature and development length a linear regression model was used to calculate the Lower Developmental-Threshold (LDT) and the Accumulated Degrees-Days (ADD). As expected, egg-adult development times decreased at higher temperatures. Results for each of the five developmental stages of Th. sinuatus from ovipositions to adult were: LDT(Egg) = 17.0 °C, ADD(Egg) = 12.0 ADD; LDT(Larvae1) = 17.4 °C, ADD(Larvae1) = 6.0 ADD; LDT(Larvae2) = 18.0 °C, ADD(Larvae2) = 5.9 ADD; LDT(Larvae3) = 16.9 °C, ADD(Larvae3) = 43.3 ADD; LDT(Pupae) = 16.0 °C, ADD(Pupae) = 46.4 ADD. As mentioned before, results are preliminary, but eventually they will provide critical data for the use of Th. sinuatus during criminal investigations.

High temperature survival and oviposition maxima of two forensically important flies

Authors: Monzon Michael[2], Hamilton George[2], Weidner Lauren[1] and Rusch Travis[1], [2]Rutgers, The State University of New Jersey, [1]Arizona State University

Abstract: The growth and development of blow flies (Diptera, Calliphoridae) is heavily influenced by the ambient temperature of their surroundings. Recent case and fieldwork from Canada and Australia indicate adult blow flies may access concealed carrion in automobile trunks. However, adult flies are incapable of egress even as the internal trunk temperatures far exceed the outside ambient temperature. This incubator experiment sought to determine the likely maximum temperatures for survival and successful oviposition in two forensically important blow flies of North America. The species investigated in this study were Phormia regina (Meigen) and Lucilia sericata (Meigen). Temperature treatments lasted for 24 hours for both studies. Both species were reduced to ~50% survival by 41°C. Similarly both species likely reach their survival threshold by 44°C. Preliminary body size analysis of L. sericata suggests females over 7mm in length may be more likely to survive extreme temperatures for sustained periods. Further, L. sericata consistently produced viable eggs until 43°C while instances of P. regina oviposition severely diminished passed 40°C. Our findings suggest heat was a more significant factor than species in both survival and oviposition trials.

Nano technology for prolonged flystrike control

Authors: Moradi Vajargah Mona[1], Song Hao[1], Zhang Jun[1], James Peter[1], Mitter Neena[1] and Yu Chengzhong (Michael)[1], [1]The University of Queensland, Australia

Abstract: Flystrike, caused by the Australian sheep blowfly Lucilia cuprina (Wiedemann) is amongst the most costly diseases affecting the sheep industry and a significant animal welfare concerns. Effective flystrike control relies heavily on two major methods; mulesing and insecticides. Mulesing is untenable because of sensitivity to animal welfare concerns, while for chemical development of resistance to blowfly control products.

We have developed a patented technology to fabricate novel hollow silica (SiO2) nano-capsules that can be loaded with active molecules to enable superior protection against insect pests. We investigated the relative toxicity of different prototype nanoparticle formulations loaded with ivermectin and cyromazine in comparison to the current commercial formulations. Bioassays were conducted using wool-serum system before and after artificial weathering to determine formulation parameters that provide the best efficacy. We showed improved effect following UV exposure for ivermectin and after wetting for cyromazine in comparison with standard formulations. Our particular FSN60 formulations enable 23% higher chemical loading than the other designs. So depending on the release dynamics, it is expected this can be used to achieve further improved longevity of effect with. This study will assist the development of novel, labour efficient, options for managing flystrike and countering resistance in sheep blowflies.

A tiger-moth tale and the Wallacean shortfall

Authors: Moraes Simeão, State University of Campinas (UNICAMP), Brazil

Abstract: Dysschema is the largest genus in the Pericopina, with 69 species. Taxonomic typological treatment and lack of understanding of geographical distributions contributed to a proliferation of publications and disputed validity of names in this group of tiger moths. Highly polymorphic Dysschema species with the tiger wing pattern were recently united in the “Dysschema eurocilia clade”. Only typological taxonomic treatment is available and ecological traits have not been used to delimit species displaying this tiger phenotype. Ecological niche modelling (ENM) and comparative morphological studies can clarify taxonomic scenarios, delimit species, and infer speciation mechanisms. We analyzed the genital morphology and wing patterns for the putative species in the ‘D. eurocilia clade’ and estimated the ecological niche using ENM. The morphological data and ENMs suggested an alternative hypothesis to previous taxonomic works on species within the ‘D. eurocilia clade’. The ENM models also revealed distribution patterns supporting the northern Andes as a geographical barrier between Central and South America, while the interconnected Andean valleys might represent areas of sympatry. Additionally, the predicted distribution showed that the South American species in “D. eurocilia clade” have distribution through the diagonal of open formations, which might represent a relict distribution known as the Pleistocene Arc.

Towards large-scale phylogenomic and morphological analysis of museum specimens

Authors: Moraes Simeão[5], Mayer Christoph[1], Ahrens Dirk[2], Buschbacher Keanu[4], Dietz Lars[3], Martin Sebastian[3] and Steinhage Volker[4], [1]Alexander Koenig Zoological Research Museum, [2]Arthropoda department, Zoological Research Museum Alexander Koenig, Bonn, Germany, [3]Centre for Molecular Biodiversity Research, Zoological Research Museum Alexander Koenig, Bonn, Germany, [4]Department of Computer Science, University of Bonn, Germany, [5]State University of Campinas (UNICAMP), Brazil

Abstract: Museum collections are repositories for biodiversity through space and time. To use museum specimens efficiently for scientific studies it is important to generate access to as much high quality morphological and molecular data per specimen as possible. Most of the hitherto applied approaches to generate large scale molecular data require good DNA quality and quantity, and cannot handle museum specimens due to the DNA damage occurring over time. We here present a target enrichment approach to sequence around 1700 loci across Lepidoptera for both new and old material. Using this approach we sequenced >500 loci for almost 130 year old material and more than 1000 loci for specimens collected 80 years ago and later. Additionally, an automated approach based on convolutional neural networks to efficiently identify species, or populations, and to generate data on morphological features for individual specimens based on whole drawer scans or specimen photos is in development. Using this approach we can automatically generate large amounts of morphological data, without the need of for example, placing landmarks, which is often a major bottleneck in such studies.

No geographic variation in chill coma recovery time of Ceratitis capitata adults after repeated frost events, in spite of population-specific survival costs

Authors: Moraiti Kleopatra[1], Papadopoulos Nikos T.[1], [1]University of Thessaly, Greece

Abstract: The Mediterranean fruit fly, Ceratitis capitata (Diptera: Tephritidae), is a chill-susceptible invasive, insect pest. Adults are capable of fully recovering after a short cold exposure at temperatures that induce a chill coma. However, the effects of repeated cold exposures on chill coma recovery time and post-recovery survival of flies remained unexplored. Here, we addressed the impact of three frost events in chill coma recovery time and post-recovery survival after a period of four days. We used adults from three temperate populations from different climatic zones from Greece (Thessaloniki and Chios Greece) and Israel (Yotvata). Flies (from F4-F5 generations were reared at 25oC up to adult day 10 and then exposed to three cycles of 4h exposures to 0oC (using slurry ice), each separated by 20h at 25oC with full access to adult diet and water. The recovery time was marked as the time needed for each individual to reach the upright position or fly. Our results reveal that multiple frost events evoke population-specific fitness costs in terms of survival of adults during the chill coma and repairing periods. Nonetheless, there is no geographic variation in both chill coma recovery time and short-term post-recovery survival after the three frost events.

Pollinating insects of oil palm in Colombia; habits, population dynamics and their relationship with the fruit set

Authors: Morales Rodriguez Anuar[1], Barrios Trilleras Carlos Enrique[1], Tejeda Rico German Esteban[1] and Diaz Castro Roberto Jose[1], [1]Cenipalma

Abstract: Insects mainly mediate pollination in oil palm. To identify the most frequent pollinating insects, their habits, and population dynamics, two plantations planted with oil palm Elaeis guineensis were selected in the municipalities of El Copey and Agustín Codazzi, Colombia. In these plantations, two plots were selected, and 10 male and 10 female inflorescences were reviewed; in these sampling, the species Elaeidobius kamerunicus, E. subvittatus, and Mistrops costaricensis were identified as the main oil palm pollinating insects. Subsequently, the behavior and habits of visiting the inflorescences by these insects in 20 male and 20 female inflorescences were recorded. It was determined that the activity of the pollinators begins around 7 am, reaching its highest activity at noon, and later the activity decreases, ceasing entirely around 5 pm. Finally, the population dynamics of pollinating insects in male and female inflorescences were monitored from December 2020 to March 2022. With the Spearman correlation, it was observed that the highest population densities in the female inflorescences were recorded in April and December with a positive correlation between the number of E. kamerunicus and the fruit set in the plots planted in Codazzi (r: 0.428; P-value: 0.047) and in El Copey (r: 0.415; P-value: 0.049).

Population dynamics of Leptopharsa gibbicarina and its relationship with biotic and abiotic factors in oil palm in Colombia

Authors: Morales Rodriguez Anuar[1], Barrios Trilleras Carlos Enrique[1], Díaz Castro Roberto Jose[1], Tejeda Rico Germán Esteban[1], [1]Cenipalma

Abstract: Leptopharsa gibbicarina is one of the most critical oil palm pests in Colombia. To determine the influence of environmental factors on the populations of L. gibbicarina, the population dynamics of L. gibbicarina were monitored in two oil palm plots in Agustín Codazzi and Copey north of Colombia, from December 2020 to February 2022. Data on the population dynamics of L. gibbicarina were correlated with precipitation, relative humidity, temperature, and biological control through Spearman correlations. No relationship was recorded between precipitation, relative humidity or temperature and the population fluctuation of L. gibbicarina (P - 0.05). On the other hand, a significant correlation was found between biological control and the population fluctuation of L. gibbicarina, being in El Copey -0.432 (p=0.045), while in Agustín Codazzi it was -0.223 (p=0.034). The main biological control agent was Beauveria bassiana among the other entomopatogenic fungi; several outbreaks were observed during the evaluation time. Beauveria bassiana has been isolated in all the samplings carried out and has generated mortalities close to 25%.

Keeping the baby with the bathwater: Mining and mapping raw reads using HMM improves accuracy and data recovery

Authors: Moran Kevin[2], Pooley Ashton, Valentine Michael and Skevington Jeffrey[1], [1]Canadian National Collection of Insects, Arachnids and Nematodes, Canada, [2]Carleton University, Canada

Abstract: Investigation into existing phylogenetic DNA dataset preparation pipelines revealed failure to recover data, improper contig assembly, and transcript re-use. PhyMMR, Phylogenetics through Markov Mapped Reads, was developed to resolve these issues. Coded in Rust, this dataset preparation pipeline brings significant improvements in data recovery, accuracy, ease of use, and lowers time required to produce an analysis ready dataset from months to days.

PhyMMR allows for the combination of transcriptome, genome, AHE and UCE data. Hidden Markov Modeling using HMMER, in combination with BLAST, is used to map raw reads to reference sequences. Mapped reads undergo a cleaning process involving end-trimming, cross-contamination check, and an outlier check prior to assembly. Using published UCE and AHE datasets, we demonstrate PhyMMR increases target data recovery by 1.5x to >20x compared to existing pipelines.

Use of PhyMMR resolves poorly supported nodes previously thought intractable. To illustrate this strength, we present a phylogeny of Diptera using publicly available data to assemble a dataset of 130 families and more than 250 subfamilies.

Cutting the knot: Untangling a paraphyletic Eristalinae (Diptera: Syrphidae) using phylogenomics

Authors: Moran Kevin[3], Ashton Pooley, Skevington Jeffrey[2], Young Andrew[4], Mengual Ximo[5] and Kelso Scott[1], [1]Canadian National Collection of Insects, Arachnids and Nematodes, [2]Canadian National Collection of Insects, Arachnids and Nematodes, Canada, [3]Carleton University, Canada, [4]University of Guelph, [5]Zoologisches Forschungsmuseum Alexander Koenig

Abstract: Next generation sequencing, in combination with the dataset preparation pipeline PhyMMR, cuts through the stubborn knot represented by the paraphyletic subfamily Eristalinae (Diptera: Syrphidae) to recover a new hypothesis of Syrphidae relationships. Eristalinae is revealed as a paraphyletic assemblage of five monophyletic clades: Eristalinae, Merodontinae, Cerioidinae, Volucellinae and Alipumilinae.

The study utilizes probes developed specifically for use with Syrphidae and samples 1302 orthologous genes. 136 of 145 described genera within Eristalinae are sampled, with the use of pinned museum specimens allowing for inclusion of rarer genera, for a total sampling of more than 300 taxa.

Multiple independent Australian-Chilean relationships are revealed, raising the question whether Syrphidae underwent Trans-Antarctic dispersal or Gondwanan vicariance.

Death does not escape the definition of time and space, at least in forensic entomology

Authors: Moreau Gaetan[1], Boudreau Denis[1] and Michaud Jean-Philippe[2], [1]Biology Department, Pavillon Remi-Rossignol, Universite de Moncton, Canada, [2]Royal Canadian Mounted Police (RCMP), Serious Crimes Branch, Airdrie, Alberta, Canada

Abstract: Time and space are indisputably two of the most important variables in forensic science, allowing to establish the chronology and circumstances of events, to understand the evidence obtained and, ultimately, to exonerate or incriminate individuals. These two variables also have singular characteristics and properties, their treatment being subject to different algebraic/statistical approaches than other variables of forensic importance such as temperature, cadaver exposure, precipitations, etc. In this presentation, theoretical and practical issues related to the handling of time and space will be discussed from the perspective of forensic research and applications. To this end, data on the ecological succession of Diptera and Coleoptera species on large vertebrate carcasses in Canada will be examined. Specifically, the analysis will focus on illustrating the temporal, spatial, and spatiotemporal dynamics of these datasets and highlight how forensics gains accuracy and mechanistic understanding when time and space are properly accounted for.

Trait-based approaches in urban ecology

Authors: Moretti Marco, Swiss Federal Research Institute WSL, Switzerland

Abstract: Cities worldwide are characterized by unique human stressors potentially leading to biodiversity changes through strong abiotic and biotic filtering. In this regard, functional traits (i.e. fitness-related individual characteristics) are considered good candidates to predict both biodiversity (B) response to stressors across taxa and regions, and to shade light on the mechanisms behind [direct and indirect] consequences on ecosystem functions (EF) and services (ES). However, most of our knowledge about BEF-relationships are still scares and mainly based on taxonomic components of biodiversity and (semi)natural ecosystems.
To advance in trait-based BEF/BES ecology in cities, we first need to identify the main filters and traits under selection, and then test their effects on measurable EF/BS.
In my talk, I will summarize key concepts based on theories and empirical studies that have investigated functional aspects of biodiversity in cities. I will illustrate 1) which traits are filtered from the regional to the urban species pool, 2) how this latter is further shaped by the distinct urban green space types, and 3) how the resulting species assemblages affect EF/ES. Finally, 4) I will present future perspectives, such as the importance of intraspecific trait variation to investigate species adaptation to urban characteristics and the potential role of trait-based approaches to bridge ecological and social science and improve conservation in the face of an urbanizing world.

BANKER-SHEET™: Development and improvement of a new release device of predatory mites

Authors: Mori Kotaro, Ishihara Sangyo Kaisha, ltd, Japan

Abstract: Although predatory mites are widely used for controlling small pest in crops, environmental stresses adversely affect their performance. The main barriers for the predatory mite population are as follows: 1) short of food (e.g. pollen, prey) over a long time after predatory mite release; 2) severe climatic environments and 3) side effects of pesticides. To solve these problems, we developed plant-attached shelters, Banker-Sheet™ that hold sachets of <i>Neoseiulus californicus</i> (McGregor) or <i>Amblyseius swirskii</i> (Athias-Henriot). The shelter is made of a water-resistant paper that protects against adverse effects of chemical application and rainfall, and acts as a buffer against temperature and humidity fluctuation. The basic features including shelter function has been studied (Shimoda et al. 2017; 2019). We conducted laboratory experiments to estimate the number of predatory mites released from Banker-sheet™ under different conditions. More mites (<i>N. californicus</i> and <i>A. swirskii</i>) were released from Banker-sheet™ than from unsheltered sachets (23 and 20 ?). <i>N. californicus</i> continued to release from Banker-sheet™ for more than one months at temperatures 17 and 15 ?. These results indicate Banker-sheet™ is potentially useful for protecting predatory mites against environmental stressors and enhances their release to crops. Banker-sheet™ with either <i>N. californicus</i> or <i>A. swirskii</i> (called Miyako-Banker™ and Suwaru-Banker™) became commercially available in Japan. We are going to apply this new device to various crops such as vegetables, fruit trees, and flowers. This research was supported by grants from the Project of the NARO Bio-oriented Technology Research Advancement Institution (Research program on development of innovative technology, 26070C and 28022C).

Molecular monitoring of Neoseiulus californicus released from sheltered slow-release sachets for spider mite control in a Japanese pear greenhouse

Authors: Mori Kotaro[2], Sonoda Shoji[6], Morishima Kaori[5], Osakabe Masahiro[3], Toyama Masatoshi[1], Aizawa Mineaki[5], Uesugi Ryuji[4] and Mikawa Yuya[5], [1]Institute of Fruit Tree and Tea Science, NARO, Japan, [2]Ishihara Sangyo Kaisha, ltd., Japan, [3]Kyoto University, Japan, [4]Tohoku Agricultural Research Center, NARO, Japan, [5]Utsunomiya University, Japan, [6]Utsunomiya University, Japan

Abstract: A novel system for spider mite control was developed with a slow-release sachet containing Neoseiulus californicus (McGregor) (Acari: Phytoseiidae) protected by a waterproof shelter. Monitoring the efficacy of the predator release system for spider mite control at a Japanese pear greenhouse requires discrimination of N. californicus from other indigenous phytoseiid mite species inhabiting the study site and subsequent identification of the released N. californicus. The report of our earlier study described a PCR-based method for discrimination of N. californicus species. For the present study, we first examined phytoseiid mite species composition in the greenhouse. Subsequently, we developed microsatellite markers to identify the released N. californicus. Finally, we installed the predator release system in the greenhouse and conducted a population survey of phytoseiid mites and spider mites. Results demonstrated that approximately one month is necessary for distribution of the released N. californicus on the leaves.

A Novel Repellent, Bemi-deotouchTM, to suppress infection of Tomato Yellow Leaf Curl Virus (TYLCV) transmitted by Bemisia tabaci (Hemiptera: Aleyrodidae)

Authors: Mori Kotaro[3], Kashima Takayuki[2], Morito Azusa[2], Ohnishi Jun[3], Sano Makiko[2], Kitamura Toshio[3] and Arimoto Yutaka[1], [1]Institute of Physical and Chemical Research, Japan, [2]Ishihara Sangyo Kaisha, ltd., Japan, [3]National Agriculture and Food Research Organization, Japan

Abstract: Bemi-detouchTM EC (acetylated glyceride; AG), food additive, was found to have 3 biological properties: repellency, mating disruption and anti-feeding activity against the adult sweet potato whitefly, Bemisia tabaci (Hemiptera: Alyeyrodidae). Tomato yellow leaf curl virus (TYLCV) is transmitted systematically by the only known natural vector B. tabaci, causing imajor economic loss of tomato production. But continuous field application of insecticides is not always feasible due to harmful effect on beneficial insects, deposition of pesticide residues on crops and the development of insecticide-resistant populations such as B. tabaci Q (MED Q1).

We found that the first function of AG was delayed initiation of plant sap ingestion caused by the adult repellency in the first 2 days in no-choice test. The second function was constant interference with adult feeding behavior, which resulted in a major reduction in honey dew excreta during the last 5 days of 7-days observation periods. In no choice test, the proportions of TYLCV-infected grape tomato seedlings treated with AG and water were 65 % and 94%, respectively after releasing viruliferous female for 7 days. In this test periods, almost no dead female was shown on the AG-treated leaf. Efficacy of AG to suppress TYLCV-infection were superior to most conventional insecticides. This compound shows no harmful effect on beneficial insects. AG is currently launched as a novel repellent pesticide in Japan.

This work was supported by Cabinet Office, Government of Japan, Cross-ministerial Strategic Innovation Promotion Program (SIP), "Technologies for creating next-generation agriculture, forestry and fisheries" (funding agency: Bio-oriented Technology Research Advancement Institution, NARO)

Addressing global challenges with unconventional insect ecosystem services: why should humanity care about insect larvae?

Authors: Morimoto Juliano, University of Aberdeen, United Kingdom

Abstract: Insects provide a wide range of services, the most widely known being pollination. However, our idea of insect services overlooks the full range of services that can be provided by insects, largely because services provided by life-stages other than the adult are often neglected. In this presentation, I will provide a collection of unconventional ecosystem services provided by insect larvae which highlights the importance of considering life stage-specific services in a holistic view of insect ecosystem services. More specifically, I discuss recent advances that revealed how insect larvae can degrade plastic, which is one of humanity's greatest environmental pollutants, and how larvae can be used to produce biofuel to help overcome the increasing contribution of the fossil fuel industry to climate change. I then discuss how toxic compounds produced by the larvae of some insects provide potential new medicines for clinical treatment and lastly, I discuss a unique example of how the larval stage of insects is entrenched into the cultural values of Aboriginal communities in Australia. By acknowledging life stage-specific ecosystem services provided by insects, my aim is to raise awareness of unconventional services that can underpin innovative solutions to contemporary global challenges, which can ultimately help create more sustainable and culturally diverse societies.

Chemical defenses of the yacon leaves

Authors: Morimoto Masanori, Kindai University, Faculty of Agriculture, Department of Applied Biological Chemistry, Nara, Japan

Abstract: Asteraceae plant species produce sesquiterpene lactones (SLs) probably as defense chemicals against herbivores. The Asteraceae crop, yacon (Smallanthus sonchifolius (Poepp. & Endl.) H. Rob) is a perennial plant species, and its enlarged roots are used as a foodstuff. Since this plant species exhibits high tolerance to herbivores, its SLs probably produced by their leaf trichomes were postulated to exhibit insect antifeedant activities. Thus, yacon leaves were rinsed with dichloromethane (DCM) to obtain the rinsate, and the residues were further extracted by DCM to obtain the DCM extract. Tests using dual choice leaf disks bioassay revealed that the rinsate contained several insect antifeedants against the tested insect pest, common cutworm (Spodoptera litura). The main constituents of the rinsate were isolated by silica gel flash chromatography using a hexane-ethyl acetate solvent system and active principles were identified as uvedalin (5-acetoxy-4-epoxyangeloyloxy-6-methylcarboxygermacrenolide) and its oxidative congener, enhydrin (5-acetoxy-10-epoxy-4-epoxyangeloyloxy-6-methylcarboxy germacrenolide), both of which are melampolides based on spectroscopic data. These SLs exhibited showed marked insect antifeedant activities, and thus, can function as defense weapons of yacon plant. The author further explored SLs and found parthenolide (10-epoxy-6-methyl germacrenolide) and erioflorin (6-epoxy-4-methacryloxy-6-methyl germacrenolide) from Tanacetum parthenum L. and Helianthus strumosus L., respectively, as insect antifeedants with moderate activity. Their SAR suggested that the substituents as well as the germacrenolide skeleton is critical for the activity. The volatiles from yacon leaves was measured by GCMS sampling the head-space method using PDMS-SPME fiber. Comparisons of volatiles within intact leaves, mechanical wounded leaves and common cutworms damaged leaves were evaluated. Also, the microorganisms on the leaf surface were separated using by the selected growth mediums for fungus or bacteria/yeast. The relationship with these separated microorganisms and productivity of defense chemical is discussed.

The Effect of Ant-Produced Compounds on Microorganisms

Authors: Morris Ashley[1], Pereira Roberto[1], [1]University of Florida, United States

Abstract: Sociality in insects is linked to efficient, multi-generational brood care, enhanced foraging, and protection against predators through a large number of constituents. Although beneficial, sociality involves crowded conditions that favor the quick introduction and transmission of pathogens. The ability for animals that live in group settings to detect and fight potential outbreaks is an essential adaptation for social insects, as evolution selects for the entire colony and not the individual members.

Many ants (Hymenoptera: Formicidae) have evolved chemical defenses to combat viral, bacterial, and fungal infections. Some of these compounds are extremely specialized against certain pathogens, while others are general and serve multiple purposes. Examples include the piperidine venom alkaloids and cuticular hydrocarbons produced by the Red Imported Fire Ant – RIFA (Solenopsis invicta Buren).

We isolated RIFA alkaloids and hydrocarbons through a hexane and water extraction. The solution containing alkaloids and hydrocarbons was pipetted at different quantities onto circular discs. Plates were sprayed with a bacterial suspension of Bacillus thuringiensis or Bradyrhizobium spp. or with a fungal suspension of Beauveria or Metarrhizium.

The combined effects of the venom alkaloids and cuticular hydrocarbons inhibited Bt, Bradyrhizobium, and Beauveria growth. Further experiments are planned with other microbes.

Attraction by stored product insects to microbial volatiles as an underexploited source for behaviorally-relevant compounds in food facilities.

Authors: Morrison William[3], Scully Erin[2], Maille Jacqueline[1], Yan Zhu Kun[1], Ponce Marco[1] and Kim Tania[1], [1]Department of Entomology, Kansas State University, United States, [2]USDA Agricultural Research Service, United States, [3]USDA-ARS Center for Grain and Animal Health Research, United States

Abstract: There has been a push to diversify postharvest IPM programs away from regular fumigant applications. One class of alternative IPM tactics is behaviorally-based management, where semiochemicals are deployed to manipulate pest behavior in ways that support food production, such as attract-and-kill or push-pull. However, apart from mating disruption, no behaviorally-based strategies exist commercially for stored products. A key challenge includes finding semiochemicals that can manipulate stored product insect behavior with the large amount of already-attractive food cues in the background at food facilities. One potential source for these are microbes. Because food facilities are generally well-sanitized, microbially-produced volatile organic compounds (MVOCs) represent a unique stimulus in an otherwise saturated background. Further, response to MVOCs may be conserved in postharvest insects because their historical food sources includes caches of food stored in damp locations for long periods by small mammals, birds, and other insects. Thus, we evaluated attraction by several species of stored product insects to MVOCs in the wind tunnel as well as release-recapture experiments. We also characterized the volatiles by dynamic headspace collection and GC-MS. After tempering grain to one of three moisture levels (12–19%) and incubating for one of three intervals (9–27 d), we evaluated the response of the insect community, and characterized microbial damage by using near infrared spectroscopy and DNA extractions. We found that Rhyzopertha dominica and Sitophilus zeamais responded positively to MVOCs in multiple assays. Our results show that MVOCs hold promise in manipulating the behavior of stored product insects. Future work should tie these behavioral responses to specific target genes.

Pheromone-based attract and kill strategies to restore IPM programs to apple orchards

Authors: Morrison William[3], C. Leskey Tracy[4], Short Brent[2], Lee Doo-Hyung[1], [1]Gachon University, South Korea, [2]Trece, United States, [3]USDA-ARS Center for Grain and Animal Health Research, United States, [4]USDA-ARS, Appalachian Fruit Research Station, Kearneysville, WV 25430, United States

Abstract: Brown marmorated stink bug (BMSB) is an invasive pest in the USA, Canada, Chile and a number of countries in Europe. Feeding by this species can lead to serious, if not catastrophic levels of injury if left unchecked. Indeed, in the USA, insecticide treatments in affected fruit orchards increased > 4x following its invasion. To reduce these inputs, we have developed spatially precise attract and kill strategies for BMSB that exploit its perimeter-driven behavior and attraction to and retention on host plants baited with pheromonal stimuli. In apple orchards, perimeter row apple trees spaced every 50 m and baited with the BMSB aggregation pheromone and pheromone synergist and provisioned with a killing agent (weekly insecticide treatments or long-lasting insecticide treated nets) resulted in acceptable levels of injury equivalent to that of conventional spray programs. These tools along with other IPM tactics offer the means to manage this invasive species more sustainably.

The role of endophytic entomopathogens in modulating plant-microbe-insect interactions

Authors: Mounger Jeannie[1], Birge Traci[2], [1]Biodiversity Unit University of Turku, Finland, [2]Finland

Abstract: During recent years, endophytic entomopathogens, such as Beauveria bassiana and Metarhizium anisopliae, have been acknowledged to show biocontrol potential against insect herbivores in different crops. Despite the reported negative effects of endophytic entomopathogens on insect herbivores, the exact mechanisms behind these outcomes are still largely unknown. Furthermore, while the harmful side effects of chemical pesticides on the natural enemies of the pests and pollinators are well explored, very little is known about the potential role of endophytic entomopathogens in steering higher trophic level ecosystem services, such as those conducted by the natural enemies of pests or pollinators. Given this, the aim of our ongoing project is to test how endophytic entomopathogens modulate plant-microbe-insect interactions. As a model plant-herbivore-microbe system, we use oilseed Brassica rapa, its most important pests (pollen beetle, Meligethes aeneus and flea beetles, Phyllotreta spp.), and entomopathogenic fungi (B. bassiana and M. anisopliae) which are known to be able to colonize tissues of oilseed rape plants as asymptomatic endophytes. We are currently running the first set of replicated greenhouse experiments to test the biocontrol potential of the fungi directly as entomopathogen and indirectly via phytohormone signaling pathways of its host plant. After this, we will determine if endophytic entomopathogens have bottom-up effects on natural enemies of pests as well as on pollinators.

Fungal grass endophytes reshape their hosts: Non-chemical plant traits as potential drivers of insect preference

Authors: Mounger Jeannie[1], Laihonen Miika[2], [1]Biodiversity Unit University of Turku, Finland, [2]Biodiversity Unit, University of Turku, Finland

Abstract: Systemic seed transmitted Epichloë endophytes are considered mutualistic defenders of their host grasses. Epichloë endophytes have shown to increase host resistance against various abiotic and biotic factors (e.g. herbivores) and can provide their hosts with competitive advantages compared to endophyte-free conspecifics. Much of the research on the defensive mutualism in grass-endophyte system has focused on the bioactive alkaloids produced by Epichloë endophytes. Here we examine non-chemical plant traits that are altered by the endophyte symbiosis and may affect exploitation behaviour of the insects visiting the plants. Epichloë species in natural population of tall fescue (Schedonorus phoenix, syn. Festuca arundinacea) can change e.g. coloration, phenology and architecture of its plant host. We concentrate on plant traits that involve changes in tactile or visual cues for the insects. We discuss how differences in non-chemical plant traits can affect exploitation behavior and plant choice of (herbivorous) insects resulting in uneven distribution of herbivores between endophyte-symbiotic and endophyte-free plants.

Bacterial diversity and community structure differences between ‘Candidatus Phytoplasma solani’ infected and non-infected insect vectors in North Italy vineyards

Authors: Moussa Abdelhameed[1], Mori Nicola[3], Quaglino Fabio[2] and Passera Alessandro[2], [1]Competence Centre for Plant Health, University of Bolzano, [3]University of Verona, [2]University of Milan

Abstract: In the present study, we described the bacterial diversity and community structure of the ‘Candidatus Phytoplasma solani’ infected and non-infected insect vectors (Cicadella viridis, Dictyophara europaea, Euscelis incisus, Euscelidius variegatus, Philaenus spumarius, and Psammotettix alienus), newly discovered in northern Italy alongside the main vector Hyalesthes obsoletus and a known host but non-vector, Cicadella viridis. A total of 300 individuals were captured with sweep entomological net and pooter in mid-June 2018 and transferred to the laboratory in 100% alcohol for molecular analyses. ‘Ca. P. solani’ was detected by nested PCR-based amplification of the stamp gene using as templates the total nucleic acids extracted from the insect specimens. Depending on the result of this PCR, specimens were separated into the “infected” and “non-infected” groups. A total of 14 individuals per species (7 specimens per group) were sent to Personal Genomics (Verona, Italy) for Illumina sequencing of the V3-V4 hypervariable region of the bacterial 16S rRNA gene

Biological control of Hyalesthes obsoletus Signoret, the main insect vector of 'Candidatus Phytoplasma solani', using entomopathogenic nematodes and fungi

Authors: Moussa Abdelhameed[1], Quaglino Fabio[3], Maixner Michael[2] and Mori Nicola[4], [1]Faculty of Science and Technology, UNIBZ, Italy, [2]Julius Kühn-Institute (JKI), Institute for Plant Protection in Fruit Crops and Viticulture, Siebeldingen, Germany, [3]University of Milan, [4]University of Verona

Abstract: Hyalesthes obsoletus Signoret is a univoltine, polyphagous species completing its complex life cycle, including the nymph subterranean cryptic stage, on herbaceous wild plants in European countries. In vineyards, it occasionally transmits 'Candidatus Phytoplasma solani', an obligate parasitic bacterium associated with Bois noir disease of grapevine, from its preferred host plants to grapevine. As no effective control measures targeting phytoplasmas are available, main strategies to manage the disease is based on the vector control. In the case of H. obsoletus, insecticide treatments on grapevine canopy are completely inefficient due to its life cycle. Consequently, the control of this planthopper focuses on its nymphs living on the host plant roots. In the present study, the control activity of entomopathogenic nematodes (EPNs; (Steinernema carpocapsae, S. feltiae, Heterorhabditis bacteriophora) and fungi (EPFs; Beauveria bassiana, Metarhizium anisopliae, Paecilomyces fumosoroseus, Lecanicillium muscarium) against H. obsoletus nymphs and adults were evaluated by laboratory bioassays and semi-field trials. Statistical analyses demonstrated that the majority of the examined EPNs and EPFs are able to control H. obsoletus nymphs and adults, exhibiting a range of effectiveness. In all the conducted trials, S. carpocapsae and P. fumosoroseus were found as the most effective biocontrol agents among EPNs and EPFs, respectively. Interestingly, considering their ability to colonize the soil after their inoculation, EPNs and EPFs can reduce the H. obsoletus population density for long time. Ecological competency and conditions that can impede or enhance the EPNs and EPFs performance should be investigated to optimize their performance in field conditions.

Role of the microbial community of Ips typographus in the outbreak dynamics in the Dolomites

Authors: Moussa Abdelhameed[1], Schuler Hannes[6], Schebeck Martin[4], Shahzad Guli Rayna[5], Battisti Andrea[3], Faccoli Massimo [2] and Stauffer Christian [7], [1]Competence Centre for Plant Health, University of Bolzano, [2]DAFNAE, University of Padua, [3]DAFNAE, University of Padua, Italy, [4]Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences Vienna, BOKU, Vienna Austria, Austria, Austria, [5]Faculty of Science and Technology, Free University of Bolzano, Italy, [6]Faculty of Science and Technology, University of Bolzano, [7]University of Natural Resources and Life Sciences, Vienna

Abstract: In the last years, a series of unfavorable weather conditions, including the storm Vaia, caused severe damages to conifer forests of the Dolomite region. Consequently, Norway spruce-dominated forests got more susceptible to infestations by the European spruce bark beetle Ips typographus. Microorganisms play an essential role in the beetle's biology, like development, fitness. Here, we aimed to improve our knowledge on the composition and the role of the microbial community associated with I. typographus, using a high-throughput sequencing approach. Particularly, we focused on the role of microorganisms in overcoming the conifer's host defense system. Beetles from three regions of the Dolomites – Eastern Tyrol, South Tyrol and Belluno were sampled and compared to populations from the Apennines, Russia, Romania, and Croatia, for potential Pleistocene refugia of I. typographus. Sequencing was performed using an Illumina MiSeq platform for the amplification of a partial fragment of the 16S rRNA gene. Pairwise comparison of the alpha-diversity showed a significant difference among locations. Similarly, the bacterial community composition varied among the sampled regions. The genus Erwinia showed a high abundance in all regions. This genus is known for its role in increasing the tolerance against the conifer monoterpene myrcene. Such dominance could explain the outbreaks of I. typographus in the Dolomites. Furthermore, the endosymbionts Wolbachia and Spiroplasma are known for their antagonistic relationships and involvement in reproductive performances of the host insect; their relative abundance in the I. typographus populations will be discussed. Our results increase our understanding of symbiotic interactions in I. typographus

Structure of population Chironomidae Larvae in coastal lakes

Authors: Mrozińska Natalia[1] and Obolewski Krystian[1], [1]Kazimierz Wielki University, Poland

Abstract: The study was realized in 10 coastal lakes, among which three types were selected: freshwater (Wicko Przymorskie, Jamno, Sarbsko, Liwia Łuża, Dołgie Wielkie), transitional (Kopań, Gardno) and brackish (Łebsko, Ptasi Raj, Resko Przymorskie). Samples were analyzed from two years. Chironomidae larvae in the studied coastal lakes were represented by 11 taxa. Lake Łebsko was the most abundant in species, while the lowest number of taxa was recorded in Lake Liwia Łuża. The results of the zoocenotic indices, i.e. alpha biodiversity and evenness for particular lakes, were comparable. The beta diversity (Wittaker index) for the area of the southern Baltic coast was low and amounted to 0,563. The results of the value of Chironomidae larvae dominance showed that in freshwater and brackish water lakes, Chironomus plumosus was the most abundant species, while in transitional lakes Procladius Skuse was the most abundant. Chironomus plumosus was dominant in biomass of all types. Brackish lakes had the highest density of Chironomidae larvae, medium values in freshwater lakes and the lowest in transitional reservoirs. Biomass was highest for freshwater lakes, medium for brackish water lakes and lowest in transitional lakes.

Host plant and developmental stage impact prevalence and load of a viral pathogen, Junonia coenia densovirus, in wild butterflies

Authors: Muchoney Nadya[2], Carper Adrian L.[1], Lowder Denali G.[2], Teglas Mike B.[2], Smilanich Angela M.[2] and Bowers M. Deane[1], [1]University of Colorado, Boulder, United States, [2]University of Nevada, Reno

Abstract: Incorporation of novel host plants can result in profound changes for insect herbivores. Characterizing variation in pathogen pressure across herbivore populations using native or novel host plant species may provide insight into the tritrophic outcomes of host range evolution. The Baltimore checkerspot butterfly, Euphydryas phaeton (Nymphalidae), recently incorporated an exotic plant, Plantago lanceolata (Plantaginaceae), into its host range. We investigated the consequences of this dietary expansion for interactions between E. phaeton and a naturally occurring entomopathogen, Junonia coenia densovirus (JcDV), across the course of herbivore development, which includes an obligate overwintering diapause during the larval stage. We quantified viral prevalence and loads in populations using either P. lanceolata or a native plant, Chelone glabra (Plantaginaceae) during three stages of the life cycle: post-diapause, pre-diapause, and diapause. We found that viral prevalence was higher in post-diapause caterpillars, pupae, and adults, compared to early-instar caterpillars in the pre-diapause and diapause stages. However, early-instar larvae that were infected with JcDV harbored higher viral loads, relative to their body size, compared to late-instar larvae, pupae, and butterflies. In addition, viral loads were substantially higher in post-diapause herbivores utilizing the exotic plant, P. lanceolata, compared to the native C. glabra, while host plant effects were minimal during earlier developmental stages. These results demonstrate that viral prevalence and burdens can vary considerably across the life cycle of an insect host and suggest that host plant mediated effects on herbivore susceptibility to infection may be most evident or consequential during later stages of development in this system.

Self-medication and host range expansions

Authors: Muchoney Nadya[3], Smilanich Angela[3], Carper Adrian[1], Teglas Mike[3], Ogliastro Mylene[2] and Bowers Deane[1], [1]University of Colorado, Boulder, [2]University of Montpelier, [3]University of Nevada, Reno, United States

Abstract: Self-medication is an important defense that some animals display when attacked. Since plant chemistry provides the basis for protection, sequestering insects may be best poised to exhibit this behavior. We investigated immunity and sequestration of two butterflies, the Baltimore checkerspot and the white peacock, in response to infection by an entomopathogen. Populations of both butterflies have recently incorporated a new host plant, Plantago lanceolata, into their diet and are capable of sequestering iridoid glycosides (IGs) from their host plants, including P. lanceolata. We reared infected and uninfected caterpillars on the new host plant and on their native host plants to understand the interaction between immunity, sequestration, and viral outcomes. In the Baltimore checkerspots, we found that high sequestration of IGs was correlated with lower viral loads. Interestingly, high sequestration also reduced immunity. Similar results were discovered with the white peacocks, and while we did not directly measure sequestration, viral loads were lower on P. lanceolata compared to the native host plant, which does not contain IGs. Although we did not measure self-medication behavior, our results suggest that these caterpillars may engage in self-medication, and future work will elicit whether they do, and whether this behavior may influence host range expansion.

Can Nematodes be used as a biocontrol option of the Potato leafminer (Liriomyza huidobrensis) pupae?

Authors: Mugala Thabu[1], P Malan Antoinette[3] and Addison pia[2], [1]Stellenbosch University, South Africa, [3]Stellenosch University, South Africa, [2]Stellenbosch, South Africa

Abstract: Although agriculture is crucial to economic growth in South Africa, it faces several challenges, most include pests and diseases that lead to crop losses. Such losses significantly hinder securing of food and hunger reduction. Therefore, a major concern is finding effective, environment-friendly control measures for insect pests. Potatoes are among the four most widely consumed vegetable crops worldwide, with more than 315 million ha being grown yearly. The South African potato production industry contributes 60% of the total percentage of vegetables grown in the country, and 4% of total agricultural produce. However, potatoes are infested by various pests and diseases, like the devastating leaf miner, Liriomyza huidobrensis Blanchard (Diptera: Agromyzidae). The aforesaid leaf miner, since the early 2000s, has become the most important pest of vegetable crops nationwide. The highly invasive species damages solanaceous crops, causing up to 70% loss. The damage caused by the leaf miner is direct, resulting from the female flies feeding on the leaf mesophyll during oviposition, with the larvae mining the leaves, and indirect, induced through pathogens entering through perforations that act as vectors of plant diseases. L.huidobrensis has developed resistance against a wide range of synthetic insecticides, hence the need to find an integrated pest mangement programme.The use of Entomopathogenic nematodes (EPNs) for the control of L. huidobrensis larvae has proven to be advantageous. In this study, two South African local EPN species, namely, Heterorhabditis baujardi and Heterorhabditis bacteriophora, were tested for their ability to infect and kill L.huidobrensis pupae at 25 °C. The initial results showed that Heterorhabditis baujardi was effective against L. huidobrensis pupae, resulting in 72% mortality while Heterorhabditis bacteriophora was ales effective with 50% mortality. Heterorhabditis baujardi was able to reproduce within the pupae and the second-generation nematodes were observed. This study demonstrated the high potential for the use of locally isolated EPNs for the control of Potato Leafminer pupae in South Africa, but further research is needed.

Involvement of juvenile hormone in the maternal induction of diapause in the parasitic jewel wasp, Nasonia vitriepnnis .

Authors: Mukai Ayumu, Faculty of Science and Engineering, Department of Life Science, Setunan University, Japan

Abstract: Diapause is a neurohormonal-controlled cessation of development or reproduction, and which usually involves the acquirement of hardiness against several environmental stresses. In most inset species, diapause is induced under shortening day-length and averted by lengthening day-length. Such an ability which respond to day-length (photoperiod) is termed by photoperiodism. In several insects, diapause induction occurs in respond to photoperiodic conditions which individuals have experienced by themselves. However, in some cases, diapause induction occurs in respond to photoperiodic conditions in the previous generation, i.e., maternal induction of diapause. Although it is considered that the involvement of hormonal change in the determination of diapause fate, little is known about the hormone which regulates maternal physiology to produce diapause-destined progeny. Several studies showed that the essential role of the juvenile hormone (JH) in diapause induction. JH is an acyclic sesquiterpenoid that is synthesized at and released from an endocrine organ, the corpora allata (CA). Although it is considered that diapause induction is regulated by the production or secretion of JH in the CA under photoperiodic regulation, the role of JH in physiological states of adult insect which determine progeny's diapause fate is unknown. The parasitic jewel wasp, Nasonia vitripennis (Hymenoptera: Pteromalidae) is a cosmopolitan parasitoid wasp and shows a clear photoperiodic response in maternal induction of diapause. When adult females are exposed to long-day conditions, they lay eggs that develop to adulthood without developmental interruption. In contrast, when adult females are exposed to short-day conditions, they lay eggs that are destined to enter diapause at the final (4th) instar larval stage.

In current study, involvement of JH in the maternal induction of diapause was investigated in N. vitripennis. First, we measured the mRNA abundance of 6 genes involved in JH biosynthesis under long- and short-day conditions. The level of juvenile hormone acid methyl transferase (JHAMT) mRNA was lowered by a short-day exposure, whereas mRNA levels of other genes were nearly identical between photoperiods. The effect of JHAMT RNAi on induction of diapause producers was also assessed. JHAMT RNAi increased the proportion of diapause producers, irrespective of photoperiodic conditions. Topical application of JH III, the Hymenopteran JH, lowered the proportion of diapause-destined progeny both in females reared under short-day conditions and females exposed low temperature. The role of JH in maternal induction of diapause will be discussed.

The role of the juvenile hormone in the photoperiodic response in a jewel wasp, Nasonia vitripennis

Authors: Mukai Ayumu[3], Shinada Tetsuro[2], Goto Shin. G[2], Mano Genyu[2], Lauren des Marteaux[1], [1]Harrow Research and Development Centre, [2]Osaka Metropolitan University, [3]Setsunan University, Japan

Abstract: Most temperate multivoltine insects enter diapause, a hormonally controlled developmental suspension, in response to the approaching harsh season. The circadian clock is involved in the perception of daylength as a seasonal cue and the endocrine effector regulates diapause induction. In some insect species, diapause induction is determined by environmental states that the mother received. Although maternally regulated diapause is common among insects, the maternal endocrinological mechanisms are largely veiled. To approach this issue, we used the parasitic jewel wasp Nasonia vitripennis, which produces non-diapause-destined offspring under long days and diapause-destined offspring under short days. We focused on the maternal physiological machinery to determine offspring diapause fate. Comparative transcriptomics and RT-qPCR revealed possible involvement of the juvenile hormone (JH) biosynthetic cascade in maternal diapause regulation. JH acid methyltransferase (jhamt) was typically downregulated under short days. The haemolymph JH concentration was reduced under short days. RNAi targeted at jhamt reduced haemolymph JH concentration and induced wasps to produce diapause-destined offspring even under long days. In addition, RNAi targeted at circadian clock gene period up-regulated jhamt expression. These results indicate that diapause in N. vitripennis is determined by maternal jhamt expression and haemolymph JH concentration in response to day length.

Fungivore-induced fungi volatiles attract parasitoid wasps Orthocentrinae (Hymenoptera: Ichneumonidae) as fungivore enemies: behavioral and electrophysiological responses of wasps to host cue

Authors: Mukai Hiromi[1], Kitajima Hiroshi[1] and Tokoro Masahiko[1], [1]Forestry and Forest Products Research Institute, Japan

Abstract: Tritrophic interactions between plants, herbivores, and carnivorous parasites are good models for understanding interspecific interactions of organisms in the food chain. Many studies have determined the function of plant infochemicals in plant-herbivore-parasitoid interactions; however, information about fungi infochemicals in fungi-fungivore-parasitoid interaction is less. This is because of the difficulty of reliable and long-term investigations as it concerns interspecific interactions surrounding these fungal species and the natural ecosystems surrounding these fungal species are fluctuating and complicated.

We previously reported that female parasitoid wasps, Orthocentrinae (Hymenoptera: Ichneumonidae) exhibited parasitic behavior on the larvae of the fungivorous flies Neoempheria spp. (Diptera: Mycetophilidae) (Mukai and Kitajima, 2019). Neoempheria spp. is one of the most ruthless insect pest of mushroom in Japan, and the breeding system of this fly has been developed using the commercial mycelial block of shiitake, Lentinula edodes (Agaricales: Omphalotaceae). We reared these insects in the laboratory, and investigated the host-locating behavior of parasitoids and the fungi infochemicals cues in fungi-fungivore-parasitoid interaction. Preliminary observations suggested that parasitoids get attracted to the odor of fungi and fungivorous flies. Odor preference experiments using Y-tube olfactometer showed that the parasitoid females exhibit a response to the odor of a piece of mycelial block of shiitake. The parasitoid females exhibited even stronger preference to a piece of mycelial block which have been consumed by larvae of the flies. GC-MS analyses revealed that the fluid extract of the fungivorous larva-infested mycelial block was different from that of the noninfested mycelial block. We also performed GC-EAD analysis, which revealed that the parasitoid females exhibited electrophysiological antennal response to some special odor components released from larva-infested mycelial block. It is speculated that the chemical information derived from the fungi or ingestion by larvae of fungivorous flies comprises reliable and detectable host-locating cues used by parasitoids to search for hosts. We provided the first observational and experimental evidence that fungivore-induced fungi volatiles mediated the fungi-fungivore-parasitoid tritrophic interaction.

“Vampires” or “Cows” - A new look at mosquito behavior

Authors: Muller Gunter, Malaria Research and Training Centre, Faculty of Medicine, Pharmacy and Odonto-Stomatology, University of Sciences, Techniques and Technology of Bamako, Mali

Abstract: Mosquitoes are known for their blood feeding behavior and resulting disease transmission and most past and current research focused on this aspect. However, only females feed every few days on blood, and blood is mainly or solely used for egg production. In contrast both, females and males, need daily sugar meals. Sugar is their main energy source, influences longevity and fecundity, host seeking behavior and ultimately blood feeding and disease transmission. Sugar feeding is not random; mosquitoes have clear preferences and are attracted to favorable sources over long distances. In the absence of nectar and fruit, some mosquito species are able to divert to plant tissue feeding exposing them and parasites in their gut to an array of phyto-chemicals including toxins. Another aspect of neglected adult mosquito behavior is diurnal “resting“ in vegetation. For mosquitoes, surviving the day in adverse conditions is not trivial. An important aspect of vector competence of mosquito populations is the percentage of mosquitoes “old enough” to transmit diseases. Especially in arid and semi-arid habitats, suitable sugar sources and resting sites are bottlenecks. Thus, ornamental and invasive plants can provide both sugar and shelter and may accordingly increase vector competence. Recent research shows that this neglected mosquito behavior provides new opportunities for control. A new promising paradigm is Attractive Toxic Sugar Baits (ATSB). This approach exploits the daily quest of mosquitoes for sugar. Plant based attractants, sugar as a feeding stimulant, and an oral toxin applied as a spray on non-flowering vegetation or enclosed within bait stations attract and kill mosquitoes.

Effect organic farming on the relationship between predator diet diversity and pest control services in vineyards

Authors: Muneret Lucile[7], Papura Daciana[1], Barraquand Frédéric[3], Sauve Alix[2], Aluome Christelle[4], Mouden Charlotte[5], Roux Pascale[1], Franck Pierre[6], Thiéry Denis[1], Vacher Corinne[5] and Rusch Adrien[1], [1]2- INRAE, Bordeaux Science Agro, UMR SAVE, Villenave d’Ornon, France, [2]3- University of Bordeaux, Integrative and Theoretical Ecology, LabEx COTE, Fran, [3]4- CNRS, Institute of Mathematics of Bordeaux, France, [4]5- INRAE, UMR 1391 ISPA, Bordeaux, France, [5]6- INRAE, Univ. Bordeaux, BIOGECO, Pessac,France, [6]7- INRAE, UR1115 PSH, Agroparc, France, [7]INRAE, France

Abstract: Evidence shows that pest control services are enhanced by natural enemy abundance and diversity, notably under organic fields. However, little is known about the mechanisms behind these relationships. Here, we investigated how the natural enemy diet variability expected under different landscape and local contexts can explain variation of pest control services. We collected and sequenced the gut content of 2880 arthropod predators in 10 French vineyards in 2015. Five vineyards were conducted under organic farming and the other ones under conventional farming, distributed along a gradient of proportion of semi-natural habitats (from 1 to 75%). We showed that the diet of predators is more diverse under organic farming, this can in turn explain the higher level of pest control services. In addition, we extrapolated the locally observed pattern of pest control services to estimate landscape-scale levels of natural pest control services.

The role of USAID in monitoring spread of Tuta absoluta and its management

Authors: Muniappan Rangaswamy[1] and Hendery Sara[2], [1]IPM IL, Virginia Tech, United States, [2]Virginia Tech, United States

Abstract: The South American tomato leafminer, Tuta absoluta, a native of South America, was accidentally introduced to Spain in 2006. Since then it has invaded most of Europe, Africa, Central Asia, Middle East, Afghanistan, India, Nepal, Bangladesh, and Myanmar. It also invaded Panama, Costa Rica, and Haiti in Central America and the Caribbean. Currently it is posing a serious threat to North American countries, even though they have posted some quarantine regulations to prevent its introduction. Since 2012, the IPM Innovation Lab, a USAID-funded program, has been involved in monitoring and modeling its spread and conducting awareness and management workshops in its host countries and in national, regional, and international conferences. One of the key findings of this program is that T. absoluta can spread long distances through infected tomato seedlings and fruits.

Implementation of IPM packages for tropical crops by the IPM Innovation Lab

Authors: Muniappan Rangaswamy[1] and Hendery Sara[2], [1]IPM IL, Virginia Tech, United States, [2]Virginia Tech, United States

Abstract: The Innovation Labs funded by USAID address agricultural and related problems in developing countries by connecting scientists from the U.S.A. and host countries for collaboration. The IPM Innovation Lab has been in operation since 1993; in the early years, it addressed individual components of different crops and institutionalized their development. For the past 15 years, however, it has been concentrating on IPM package development and implementation for selected crops. In this, scientists develop a matrix of problems of a crop faced by the farmers in a country and tackle the problems that do not have a local solution. This led to the concept of IPM package development for selected crops, tackling problems and incorporating components of solutions into it. The IPM Innovation Lab has developed IPM Packages for most tropical high value vegetable crops, and some cereal, fruit, and legume crops. In recent years, it has regionalized most and globalized some of them.

IPM package for the management of Mango pests and diseases in Bangladesh

Authors: Muniappan Rangaswamy[3], Hossain MD. Shahadath[1] and Yousuf Mian MD.[2], [1]Horticulture Research Centre, Bangladesh Agricultural Research Institute (BARI), Bangladesh, [2]IPM IL, Bangladesh Site, Gazipur, Bangladesh, [3]IPM IL, Virginia Tech, United States

Abstract: Mango (Mangifera indica L.) is a major fruit crop grown in the tropical and sub-tropical regions of the world including Bangladesh. Various insect pests and diseases affect mango production. About twenty arthropod pests, of which nineteen insect and one mite pests are reducing yield of mango in Bangladesh. Seven diseases causing pathogenic microorganisms are also responsible for the low yield of mango. Among the insects, mango hoppers (Idioscopus spp), mango fruit weevil (Sternochaetus frigidus), mango fruit fly (Bactrocera dorsalis) and mango mealy bug (Droshicha mangiferae) are major pests of mango. Among them mango hoppers and mango fruit fly are mainly responsible for most of the damage. The major diseases caused by pathogenic microorganisms include the anthracnose disease (Colletotrichum gloeosporioides) in the field conditions and fruit end rot (Lasiodiplodia theobromae) in post-harvest situations. These pests and diseases are causing both quantitative and qualitative losses and in addition act as export barrier. Excessive use of chemical pesticides leads to the development of pesticide resistance with various adverse effects on the environment and human health. In this paper, integrated pest management components widely practiced by farmers for mango production in Bangladesh are described. For instance, foliar spray of powder formulation of Beauveria bassiana @ 5.0g/L of water at flower initiation stage, Imidachloprid (Confidor 70WG) insecticide @ 0.2g/L of water before flower opening stage and again foliar spray of powder formulation of Beauveria bassiana @ 5.0g/L of water at pea stage; and fruit bagging with double layer brown paper bag before forty-two days of harvest found to effectively reduce hopper and fruit fly infestations, respectively. In addition, pruning of infected parts and spraying of Bavistin @2g/L 2-3 times at 15days intervals for anthracnose; three sprays of Mancozeb (Indofyl M-45) @2g/L of water for sooty mold; and hot water treatment for fruit end rot disease are successfully practiced in Bangladesh. This IPM package maximizes the marketable yield and marginal benefit cost ratio.

Tapping into existing networks or going it alone? Citizen science for plant health monitoring and surveillance

Authors: Murchie Archie[1], Fleming Colin[1], O'Hanlon Richard[1] and Jess Stephen[1], [1]Agri-food and Biosciences Institute, Belfast, Northern Ireland, United Kingdom

Abstract: Monitoring and surveillance of plant health, bee health pests or vectors of human and livestock pathogens is mostly the responsibility of Government. For plant health pests there are portal inspections and crop / forest surveys. These approaches fulfil two different roles. Portal inspections are normally to detect potential incursions of pests into the country; whilst, surveys are to demonstrate to authorities (in Europe the EU) that the country is free from certain pests. An example of the latter, would be surveys to maintain EU protected zone status. However, both approaches are akin to 'finding a needle in a haystack'. Resource limitations mean that only a very small proportion of plant imports or cropping / forestry area are examined.

Ireland as an island off of another island on the edge of Europe, should have good plant and animal health biosecurity. Most invasive species, with a few exceptions, move through Europe East to West. We can therefore prepare in advance for potential pest invasion and provide alerts to industry and the public. In recent years in Northern Ireland, plant health pests have been detected by entomological recorders and enthusiasts. These include: horse chestnut leaf miner (Cameraria ohridella) detected in 2014 by an ecological consultant, box tree moth (Cydalima perspectalis) collected in a moth trap in 2018 by a recorder and spotted wing drosophila (Drosophila suzukii) swept from the wild in 2019 by a museum curator. Due to local connections in the entomological community, these were rapidly reported to the authorities. Another example is that of ash sawfly (Tomostethus nigritus). This species, first recorded in Ireland in 2016, causes spectacular defoliation of ash trees and was brought to our attention through a BBC news television report. Subsequently, we have sought to use ash sawfly as an examplar for a tree pest invasion and to explore the value of citizen science to monitor both incursion and spread. Three approaches are being considered. The first is use of traditional media such as television, radio and newspaper articles. This approach was used with some success in Northern Ireland to map the distribution of the New Zealand flatworm, an invasive predator of earthworms commonly found in gardens. Second, is the use of existing networks reporting on Facebook or through national biodiversity recording apps. Lastly, is use of Tree Check (www.treecheck.net), which is a more tailored approach specific to tree health on the island of Ireland.

Economic burden of Tomato Leaf Miner Tuta absoluta in tomato production in Kenya and Uganda

Authors: Muriithi Beatrice, International Centre of Insect Physiology and Ecology, Kenya

Abstract: The significance of the effects of pests in Agricultural production cannot be underestimated. There have been several efforts of controlling these pests, chiefly the use of pesticides. However, the continuous use of synthetic chemicals not only causes pests resistance and resurgences but also, presents high human and environmental risks. This study aims at examining the economic, health and environmental impact of pests on smallholder farmers in selected counties in Kenya and Uganda. Economic Impact Quotient (EIQ) and gross margin analysis was used on a random sample of 316 farmers in Kenya and 345 farmers. The results showed the average gross income of a farmer was $3282 in Kenya and $895 in Uganda. The potential tomato production in both countries was seen to be affected by the invasion of Tuta absoluta. The opportunity cost lost was valued at $8 and $646 in Kenya and Uganda repectively using NPV through the most persimistic scenario, while BCR had $1 and $5 in Kenya and Uganda respectively.

Economic and Poverty Impacts of Biological Control of Cereal Stemborers in Kenya

Authors: Muriithi Beatrice[5], Ong'amo George[4], Affognon Hippolyte[1], Macharia Ibrahim[2] and Bruno LeRu[3], [1]CORAF, Senegal, [2]Department of Agribusiness Management & Trade, Kenyatta University, Nairobi, Kenya, [3]Institut de Recherche pour le Developpement, France, [4]International Centre of Insect Physiology and Ecology, Kenya, [5]International Centre of Insect Physiology and Ecology, Kenya

Abstract: A biological control (BC) program was initiated by icipe and partners to respond to severe stemborers invasion in cereal farming regions of sub-Saharan Africa including Kenya. Four natural enemies: Cotesia flavipes (Cameron), C. sesamiae (Cameron) (Hymenoptera: Braconidae), Telenomus isis (Polaszek) (Hymenoptera: Scelionidae) and Xanthopimpla stemmator (Thunberg) (Hymenoptera: Ichneumonidae) were released to suppress economically important stemborer pests; Busseola fusca (Fuller), Sesamia calamistis Hampson (Lepidoptera: Noctuidae) and Chilo partelus (Swinhoe) (Lepidoptera: Crambidae). An economic surplus model was applied, based on time-series data on production, market and, Geographical data (GIS), to evaluate the economic and poverty impact of the BC program in Kenya. Findings show that the BC intervention contributed to an aggregate monetary surplus of $US 0.74 billion to the economy. The net present benefit of $US 141.52 million, the Internal Rate of Return of 113.08% and the Benefit-Cost Ratio of 276:1 justify that the program was worthwhile. On average, the BC program gains would lift out of poverty 57,400 persons every yearly. Wide promotion and up-scaling of the BC program should, therefore, be encouraged.

Biogeography and diversification patterns in a hyper-diverse and worldwide distributed group of moths

Authors: Murillo-Ramos Leidys, PhD Student, Sweden

Abstract: Megadiverse insect groups hold great potential to understand the processes that have led to the current uneven distribution of biodiversity. Understanding how and why some groups have become more species-rich than other groups, and how past biogeography may have shaped their current distribution, are important questions that many evolutionary biologists have long tried to solve. We address how diversification patterns and biogeography may have played in favour of a hyper-diverse Lepidoptera lineage, the geometrid moths, by studying its most species-rich clade. The tribe Boarmiini contains c. c. 200 genera and c. 3000 species. We inferred the evolutionary relationships of Boarmiini based on a dataset of 346 taxa, with up to eight genetic markers under a Maximum Likelihood approach. Their biogeographic origin was inferred using the Dispersal-Extinction-Cladogenesis (DEC) model, and the estimation of diversification rates was studied using the Bayesian analysis of macroevolutionary mixtures (BAMM). The monophyly of Boarmiini is strongly supported. The results indicated that boarmiines probably appeared in Laurasia c. 52 Mya, followed by dispersions throughout the Oriental, Australasia, African and Neotropical regions. Given the current distribution of most of the genera, we suggest that multiple dispersals have played an important role in their biogeographic distribution. Most of the dispersion patterns have occurred in the Eocene, which was characterized by intense geological activity and climate changes. In addition, diversification analyses showed a relatively constant diversification rate for all Boarmiini, except in one clade leading to one of the species-rich geometrid genera, genus Cleora. The identification of such burst in diversification rate, which is geographically limited, allows focusing future research to understand the evolutionary properties that may explain such phenomenon. Extreme polyphagy and habitat restriction of Cleora may be among the most important success factors.

Beyond case studies: a meta-analysis to identify patterns of diversification in the Neotropics

Authors: Murillo-Ramos Leidys[3], Chazot Nicolas[2], Matos Maravi Pavel[1] and Freitas André V. L.[4], [1]Biology Centre of the Czech Academy of Sciences, [2]Swedish University of Agricultural Sciences, [3]Universidad de Sucre, [4]University of Campinas

Abstract: Biogeographic patterns of diversity in the Neotropics have long been characterised but their origin remains unclear and many hypotheses have been proposed. The so-called “Gentry-pattern” characterises groups which species richness either peaks in the Andes or instead peaks in the Amazon basin. Antonelli & Sanmartín (2011) suggested that this pattern could be explained by the presence of a barrier preventing exchanges between regions, which thereby diversified separately. Here, we explore the hypothesis that the large Pebas wetland that covered western Amazonia during the first half of the Miocene isolated Andean lineages from Amazonian lineages. Using 21 groups of Neotropical Nymphalidae butterflies we performed ancestral biogeographic state estimations under a unified model to assess 1- the dynamics of diversification in the Andes versus Amazonia, 2- the timing of interchanges between regions. According to Antonelli & Sanmartín (2011) we expected to the two regions to diversify in isolation until the Pebas started draining about 8-11 Ma.

Bottom-up and top-down effects are altered by interacting global change drivers: a case study in marine coastal habitats

Authors: Murphy Shannon[2], Wimp Gina[1], [1]Georgetown University, United States, [2]University of Denver, United States

Abstract: Anthropogenic disturbances, such as nutrient pollution and habitat fragmentation, have significant impacts on natural ecosystems and their associated food webs. Salt marsh coastal ecosystems are particularly threatened by human impacts and are being lost at an alarming rate. Salt marshes are important for conservation because of the critical ecosystem services they offer, including erosion control, water filtration, nurseries for fisheries, and carbon sequestration. Arthropod communities in saltmarsh ecosystems are threatened by human impacts, including sea level rise, habitat loss, nutrient subsidies, and extreme weather events, such as hurricanes. Some disturbances are felt throughout the food web (e.g. hurricanes), whereas other disturbances are mediated via effects on host plants (e.g. nutrient subsidies). Our studies over the past two decades have found that the impacts of these disturbances on insects/ spiders and their rate of recovery are dependent on trophic level, life history, and diet breadth. While we understand impacts of single disturbances relatively well, we have very little understanding of how multiple disturbances interact to affect insect communities.

We found that generalism in diet and habitat use can lead to stable predator populations across different kinds of anthropogenic disturbance. For example, nutrient inputs consistently lead to increased populations of generalist predators, but sustained, high-inputs of nutrients eventually lead to ecosystem collapse. Diet generalism also sustains predator populations in edge habitats, but only in combination habitat generalism. When predators have specific habitat requirements, they are negatively impacted by habitat edges even when their food can be found in abutting habitats. Finally, when predator diets are so general as to include different food webs (multichannel omnivory), this can increase population stability through disturbance events. After a hurricane, spiders that were multichannel omnivores recovered most quickly because they were able to switch over to epigeic prey when herbivores were not abundant. While fewer studies have examined the interactive effects of different anthropogenic factors on organisms, we found that recovery of multichannel omnivores after hurricanes is enhanced in fertilized plots. Predators are declining globally with ramifications for important ecosystem processes. Here we show that predator persistence in the face of global change is impacted by diet and habitat breadth.

Nutrient subsidies increase food web recovery following a major disturbance by a hurricane

Authors: Murphy Shannon[3], Wimp Gina[2], Lewis Danny[1], Hauri Kayleigh[1], Naugle Melissa[1] and Bansal Shweta[1], [3]United States, [2]Georgetown University, United States, [1]Georgetown University, United States

Abstract: Anthropogenic disturbances, such as nutrient pollution, have significant impacts on natural ecosystems and their associated food webs. In particular, the timing and amount of nutrient inputs can have variable effects on food web structure, particularly stability. However, how anthropogenic nutrient pollution interacts with recovery from natural disturbances is not well studied. In the midst of our multi-year experiment investigating the effects of long-term nutrient presses and short-term nutrient pulses on food web interactions, a natural disturbance, Hurricane Sandy, directly affected our study site. This unplanned hurricane event allowed us to measure how food web stability in the form of resilience to environmental perturbation interacted with nutrient loading. We found that food webs in all treatments were negatively affected by the hurricane disturbance, but that food webs in our nutrient subsidy plots recovered from the hurricane more quickly than control plots. Notably, we found no significant differences in recovery between our long-term nutrient press and short-term nutrient pulse treatments. We found that anthropogenic disturbances, such as nutrient pollution, affect how natural systems recover from a natural disturbance.

Phylogenomics of Chrysidoidea: will family relationships finally be resolved?

Authors: Murray Elizabeth, Smithsonian National Museum of Natural History, United States

Abstract: Chrysidoidea is one of the least-known superfamilies of Aculeata, and there has not yet been a molecular phylogenetic analysis that has included a representative from all seven extant families. Chrysidoidea is noteworthy in an evolutionary and ecological context in part due to the many differing feeding habits and life histories. Additionally, the phylogenetic placement of Chrysidoidea at the interface between ‘Parasitica’ and Aculeata places them at an interesting junction. I will explore practices in data choice and analysis, and show how methodological decisions can change the outcomes of analyses, affecting the evolutionary inferences we draw from phylogenomic data.

Distribution and integrated pest management options of Brown Marmorated Stink Bug Halyomorpha halys (Hemiptera: Pentatomidae) in hazelnut orchards in the Republic of Georgia

Authors: Murvanidze Maka[2], Inasaridze Nino[1], Krawczyk Greg[3], [1]I. Javakhishvili Tbilisi State University, Georgia; CNFA Georgia, Georgia, [2]Institute of Entomology. Agricultural University of Georgia, Georgia, Georgia, [3]The Pennsylvania State University, Department of Entomology, Fruit Research and Extension Center, Biglerville, PA, United States

Abstract: Distribution of Halyomorpha halys (BMSB) in commercial hazelnut orchard was investigated during two consecutive years in two commercial hazelnut orchards located in western Georgia (Samegrelo region). One of the orchards was surrounded by dense wild vegetation while the second orchard was bordered by a river, arable and open lands. Different BMSB management strategies including “Attract and Kill” (A&K) approach, border sprays (BRD) and grower’s standard management practices (GS) were compared at each site with untreated blocks used as a control treatment(CTR). Phenology of BMSB was similar during both years with the first BMSB adults observed near the end of April and adults and all instar nymphs observed from July 20 (950 DD13.9) to the end of September. Finding of the 2nd instar nymphs near the end of September supports hypothesis on the presence of minimum two generations of H. halys in Georgia. The A&K treatment was very effective in killing high numbers of stink bugs through the growing season and demonstrated higher effectiveness in management of BMSB than the Grower’s standard insecticide program. Similarly, applications of pyrethroid insecticides around the perimeter of the orchard also protected the interior better than Grower’s standard program. Effectiveness of evaluated management strategies was highly impacted by the orchard surrounding vegetation. The influx of bugs from outside of the orchards was documented by high numbers of captured BMSB in the monitoring traps placed outside and inside of experimental plots. Evaluation of hazelnut quality showed that percentage of healthy kernels increased from the orchard perimeter to the interior of managed blocks. Corking damage of nuts by H. halys was associated mostly with the perimeter of the orchard and was higher on nuts collected from trees located near the edge. Percentage of healthy kernels was the highest in the A&K blocks in both years; however the overall quality of nuts in all treatments during the 2019 season was better than in 2018. The BMSB management decisions in hazelnut orchards should be firmly based on the documented populations of bugs but growers should also factor in the potential influx of BMSB from surrounding areas. With wild vegetation around, the A&K stations placed around the orchard performed better while in case of open surroundings effective protection was achieved by A&K and/or border treatments.

Predator induced changes in insect-plant and pathogen plant interactions

Authors: Musaqaf Nimra[2] and Sigsgaard Lene[1], [1]University of Copenhagen Department of Plant and Environmental Sciences, Denmark, [2]University of Copenhagen, Denmark Punjab Education endowment Fund, Pakistan, Denmark

Abstract: Pests and diseases can seriously affect strawberry production. Anthocorids are major predators in strawberries, but can puncture the plant for water, and they insert their eggs in plant tissue. To test the hypotheses that predators can induce resistance in strawberry plants against specialist and generalist herbivores as well as against a fungal disease two experiments were done. In both experiments, plants that had had a 24-h exposure to O. majusculus, removed before the onset of the experiment, were compared to intact plants. In the herbivore experiment, fecundity of the aphid generalist Macrosiphum euphorbiae and the strawberry specialist, Chaetosiphon fragaefolii reared on preexposed or intact plants was assessed. In the second experiment, mildew growth on exposed or intact plants was assessed. In both experiments leaf samples were taken for gene expression analysis. The chemistry of intact and preexposed plants will be compared to understand if and how induce resistance may affect specialist and generalist aphid species and powdery mildew. It was found that predator preexposure reduced fecundity of M. euphorbiae, while no effect was found on C. fragaefolii. Mildew growth was not affect by predator preexposure treatment according to a visual assessment. Results of effects on pests and diseases as well as any changes in plant chemistry will be reported and discussed.

Geographic variation of photoperiodic control of nymphal development and adult diapause induction in native and invasive populations of the brown marmorated stink bug, Halyomorpha halys

Authors: Musolin Dmitrii[2], Haye Tim[1], Saulich Aida[5], Dolgovskaya Margarita[6], Karpun Natalia[3], Reznik Sergei[6], Zakharchenko Vilena[4], [1]CABI, Rue des Grillons 1, 2800 Delémont, Switzerland, [2]European and Mediterranean Plant Protection Organization (EPPO/OEPP), France, [3]Federal Research Centre the Subtropical Scientific Centre of the , Sochi, Russia, [4]Russian Research Institute of Floriculture and Subtropical Crops, Sochi, Russia, [5]Saint Petersburg State University, Saint Petersburg, Russia, [6]Zoological Institute of the Russian Academy of Sciences, Saint Petersburg, Russia

Abstract: Facultative winter adult diapause in Halyomorpha halys is regulated by a long-day photoperiodic response. Day length influences also nymphal development which slows down at the critical (near threshold) day lengths. We compared photoperiodic responses of one native (Andong, South Korea) and three invasive (Torino, Italy; Basel, Switzerland; and Sochi, Russia) populations in a laboratory common-garden experiment. Nymphs developed and emerging adults were reared at 24 °C and a range of photoperiods with day lengths 14.0, 14.5, 15.0, 15.5, and 16.0 h. The critical day lengths of the photoperiodic responses of both sexes fell between 14.5 and 15.0 h in the native Korean and between 15.0 and 15.5 h in the invasive European populations. The differences between three invasive populations were not significant, although populations originated from distant regions. Moreover, the difference between Korean and European populations was much smaller than it was expected. The microevolution was possibly 'too slow to keep up' with the rapid spread of the invader across Eurasia. It is expected that soon the critical day length of invasive H. halys populations will gradually change to adopt better to the local conditions. At present, the critical day length for diapause induction of 15 h 15 min can be used to model phenology, further spread, and response to climate change for all European populations of the pest.

The research was funded by the Russian Science Foundation (project No. 21-16-00050).

Evaluation of a combination of thiamethoxam and pirimiphos methyl for the control of insect pests in stored grain

Authors: Mutambuki Kimondo[1] and Likhayo Paddy[1], [1]Kenya Agricultural and Livestock Research Organisation, Kenya

Abstract: A study was conducted to determine the efficacy of a new dust formulation containing 0.36% thiomethoxam and1.6% pirimiphos-methyl (Simba) as active ingredients. The new formulation was tested against common storage insect pests of stored maize under laboratory and field conditions. In the laboratory trial 100g of maize and wheat held in 0.25 litre kilner jars were treated with doses of the cocktail thiamethoxam/pirimiphos methy at labeled rate of half dose 0.1 and 4.4 mg/kg, normal dose 0.2 and 8.9mg/kg, double dose 0.4 and 17.8 mg/kg respectively. A commercial product traded as Actellic Gold® with similar molecules as the test product but applied only as normal dose was used for comparison. The untreated controls of maize grain were prepared the same way but without insecticide The jars were arranged randomly on metal shelves in the controlled temperature room according to the insect species and storage period For the field trial, the same rates were applied in 10kg maize grains held in hessian mini jute bags. The bags were placed in a store simulating farmer storage conditions. All treatments plus control were replicated four times. In the laboratory bioassay trial exposure of Sitophilus zeamais (Motsch), Prostephanus truncatus (Horn) and Tribolium castaneum (Herbst) adults to all doses of test product in the 4,8,12,16,20,24 weeks interval resulted in mortality of 100% for all the species up to the end of the trial. No significant differences in the mortality between all dosage rates tested and the standard was detected giving a good comparison between the two products. During the entire storage period, practically no grain damage and weight loss were observed in the grains treated with either Actellic Gold® dust or normal and double dose rate of Simba dust. It is concluded that Simba dust was very effective against the three test insects at all the application rates tested in the laboratory and dosage rates of 0.2 and 8.9mg/kg and 0.4 and 17.8 mg/kg under field trial over the six month storage duration. The new product (Simba dust) is therefore recommended for registration as a potential grain protectant.

Fluctuating environments impact physiological fitness in an invasive insect species Bactrocera dorsalis (Diptera: Tephritidae)

Authors: Mutamiswa Reyard[3], Nyamukondiwa Casper[1], Chidawanyika Frank[2] and Tarusikirwa Vimbai[1], [1]Botswana International University of Science and Technology, Botswana, [2]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [3]University of the Free State, South Africa

Abstract: The incidence and severity of environmental stressors associated with global climate change are increasing and insects frequently face variability in temperature and moisture regimes at variable spatio-temporal scales. Coincidental with this, is increased thermal and hydric stress on insects as warming increases vapour pressure deficit (VPD), the drying power of the air. While the effects of mean temperatures on fitness are widely documented, fluctuations in both temperature and relative humidity (RH) are largely underexplored. Here, we investigated the effects of dynamic temperature and RH fluctuations (around the mean [28 °C; 65% RH]) on low and high thermal tolerance of laboratory reared adult invasive Bactrocera dorsalis (Hendel) (Diptera: Tephritidae), measured as lower and upper thermal activity limits, chill coma recovery time (CCRT) and heat knockdown time (HKDT). Our results show that increased environmental amplitude significantly influenced low and high temperature responses and varied across traits tested. The highest amplitude (d12°C; 28% RH) compromised lower thermal activity limits, CCRT and HKDT while enhancing upper thermal activity limits. Similarly, acclimation to d3°C; 7% RH compromised both low (lower thermal activity limits and CCRT) and high (upper thermal activity limits and HKDT) fitness traits. These variations in fitness indicate significant roles of combined thermal and moisture fluctuations on B. dorsalis survival under changing ambient environments. This likely suggests B. dorsalis thermal fitness losses under climate change. These results are significant for B. dorsalis population phenology, management, quantifying vulnerability to climate variability and may help modeling future biogeographical patterns.

Remote Detection of Powder-Tagged Insects with Hyperspectral Lidar

Authors: Månefjord Hampus[2], Müller Lauro[2], Li Meng[3], Salvador Jacobo[2], Runemark Anna[2], Kirkeby Carsten[1] and Brydegaard Mikkel[2], [1]Copenhagen University, [2]Lund University, Sweden

Abstract: We showcase a hyperspectral lidar used for in situ remote monitoring of powder-tagged honeybees, Apis mellifera. The experiment was ongoing from 08 to 20 o'clock for one day, and the insect activity over time and distance from the beehive was logged. Our ambition is to inspire for further entomological studies using similar technique.

Benefits of cooperation and its life-history costs in Pine Sawflies

Authors: Mäntylä Elina[1], Kokko Hanna[4], Lindstedt Carita[3], López-Sepulcre Andrés[7], Miettinen Antti[5], Valkonen Janne[6], Mappes Johanna[6], Gerber Nina[8] and Ketola Tarmo[2], [1]Biology Centre of the Czech Academy of Sciences University of South Bohemia, Czech Republic, [2]Department of Biological- and Environmental Sciences, University of Jyväskylä, Finland, [3]Department of Biological and Environmental Sciences, University of Jyväskylä, Finland, [4]Department of Evolutionary Biology and Environmental Studies, University of Zurich, 7 Switzerland, [5]Organismal and Evolutionary Biology Research Program, University of Helsinki, Finland, [6]University of Jyväskylä, Finland, [7]Washington University in St. Louis, United States, [8]Wildlife Sciences, Faculty of Forest Sciences and Forest Ecology, University of Goettingen, 9 Germany

Abstract: In many socially behaving organisms the costs and benefits of cooperation are likely to vary with changes in ecological and social conditions. However, these trade offs between contribution to cooperative act and life-history traits have rarely been quantified, especially under multiple biological interactions. We investigated these aspects experimentally with haplodiploid social Diprion pini pine sawfly larvae that perform cooperative chemical group defence. The benefit of this system is that there is genetic and phenotypic variation in the cooperative behaviour and relatedness among cooperating individuals. We can also manipulate the levels of cooperativeness as well as social and ecological environments experimentally, and measure responses in reproductive and life-history traits. In several factorial rearing experiments and behavioral assays, we tested investment to cooperative defense and its correlated fitness effects under various conditions by manipulating diet, attack intensity and social environment. We found that cooperation increases survival of the group against predators, but investing to cooperative defence behaviour imposes several lifehistory costs. Cooperative behaviour and the magnitude of its life-history costs are further shaped by interactive effects of host plant quality and social environment (kin-structure and sex-ratio of the group). Together these results provide much needed experimental evidence that both ecological and social interactions can shape the adaptive value of cooperative behaviour and maintain variation in cooperation and cheating. Thus, to form ecologically realistic syntheses of adaptive processes and persistence of cooperation, we need tighter integration of experimental and theoretical work that takes into account multiple interactions that comprise an individual's selective environment in nature.

How to make trees good or bad for herbivores?

Authors: Mäntylä Elina[5], Sam Katerina[1], Volf Martin[6], Weinhold Alexander[7], Sosanika Gibson[10], Luke Grace[10], Maraia Heveakore[4], Frouz Jan[2], Salminen Juha-Pekka[9], Sisol Mentap[10], Vojtech Novotny[8] and T. Segar Simon[3], [1](1) Biology Centre of Czech Academy of Sciences, Institute of Entomology, Ceske Budejovice (2) University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic, [2]Biology Centre of the Czech Academy of Sciences Charles University in Prague, Czech Republic, [3]Biology Centre of the Czech Academy of Sciences Harper Adams University, United Kingdom, [4]Biology Centre of the Czech Academy of Sciences University of South Bohemia The New Guinea Binatang Research Center, Czech Republic, [5]Biology Centre of the Czech Academy of Sciences University of South Bohemia, Czech Republic, [6]Biology Centre, Czech Academy of Sciences, Ceske Budejovice, CZ, Czech Republic, [7]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany, [8]Lab of Tropical Ecology Institute of Entomology Czech Academy of Science, Czech Republic, [9]Natural Chemistry Research Group, Department of Chemistry, University of Turku, Finland, [10]The New Guinea Binatang Research Center, Papua New Guinea

Abstract: A plant should be good for herbivore arthropods if it is nutritious, does not have too many defence chemicals and does not attract too many predators of the herbivores. A plant bad for herbivores would then be the opposite: low in nutrients, high in defence chemicals and frequently visited by the predators. We wanted to study is it possible to manipulate plants to be better or worse for herbivores. We did this experiment in lowland tropical primary rainforests of Papua New Guinea. We used as experimental trees several species of Ficus which differ in their constitutive and induced defences. We used various methods to manipulate the Ficus trees. We increased the emission of volatile organic compounds (VOCs) that attract predators by spraying methyl jasmonate (MeJA). We reduced the attraction of predators by applying an inhibitor of MeJA, diethyldithiocarbamic acid (DIECA). With nitrogen fertilization (ammonium sulphate) we increased the nutrients of the tree. Finally we prevented vertebrate predator access with exclosure cages, and access of ants with glue on tree stem and poisonous baits. We had five different method combinations as treatments which were in our hypothesis from best to worst: 1) DIECA + fertilization + cage, 2) DIECA + fertilization, 3) control, 4) MeJA + cage, 5) MeJA. We have so far finished two experiments lasting 6 months and involving each 4 Ficus species. We collected from the trees before, middle and after experiment samples of leaves, arthropods, VOCs and soil, measured plant growth, and estimated the amount of herbivory. The early results show that the treatments worked as we expected: the amount of herbivory was highest in trees which were made good for herbivores, and lowest in trees that had a treatment to make the tree bad for herbivores. These results did not depend on the original level of constitutive defence of the Ficus tree. At least in some Ficus species there seemed to be a trade-off between growth (stem diameter and height) and emitting more VOCs due to the MeJA treatment. There appeared to be much more variation within and between species if the increased herbivory of DIECA + fertilization treatments affected the tree growth. There were also differences between species and treatments in e.g. VOC emissions and arthropod communities. The answer to the question in the title is that with the treatments in this experiment we managed to make the Ficus trees better or worse for herbivorous arthropods.

Phytoseiid mites benefit from conventional and integrated management as well as from higher amount of vineyards in the landscape

Authors: Möth Stefan[3], Walzer Andreas[3], Rusch Adrien[1], Tolle Pauline[2], Richart-Cervera Sylvie[2] and Winter Silvia[3], [3]University of Natural Resources and Life Sciences, Vienna, [1]2- INRAE, Bordeaux Science Agro, UMR SAVE, Villenave d'Ornon, France, [2]INRAE, UMR 1065 SAVE

Abstract: Biodiversity and ecosystem services in vineyards are strongly influenced by viticultural practices and landscape composition. Phytoseiid mites are important natural enemies of pest mites and therefore deliver important pest control services in vineyards.

In this study, we examined the relative effects of local management (organic versus integrated in Leithaberg (Austria)/ conventional in Bordeaux (France)) and the landscape composition (proportions of vineyards and semi-natural habitats within a 500 m landscape buffer) on phytoseiid mite densities in vineyards.

Compared to organic vineyards, phytoseiid mites benefited from conventional management and integrated management, respectively in Bordeaux and Leithaberg. The population densities were promoted through higher proportions of vineyards in the surrounding landscape. The influence of the management type on phytoseiid mite populations was probably caused through the higher region-specific pesticide use in organic vineyards resulting in lower phytoseiid mite densities. Especially the frequent application of the fungicides copper and sulphur in organic vineyards was probably crucial, due to their well known detrimental non-target effects on phytoseiid mites. The positive effects of surrounding vineyards may result from relative stable and interconnected phytoseiid mite populations in viticultural landscapes, which facilitates the recovery of locally diminishing populations in single vineyards by aerial dispersal of the phytoseiid mites.

Taste sensing by the maxillary palp in silkworm larvae

Authors: Nagata Shinji[1], Endo Haruka[2], Shii Fimika[3] and Sato Ryoichi[3], [1]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Japan, [2]The University of Tokyo, Japan, [3]Tokyo University of Agriculture and Technology, Japan

Abstract: Taste sensing is essential for host-plant selection in herbivorous insects. Classical behavioral observations in the 1970s suggested that they select their diet at the surface of host plant leaves. Recently we found ultra-sensitive gustation by the maxillary palp of silkworm larvae, which enables them to identify the host mulberry leaves at the surface prior to biting (Tsuneto et al., bioRxiv). We also found that a subset of chemosensory neurons in the maxillary palp of silkworm larvae detects key mulberry compounds including chlorogenic acid, quercitrin glycosides, and ß-sitosterol with atto-/femtomolar sensitivity. Only if these three compounds are detected by the maxillary palp does the larva make a test bite, which is required for initiation of feeding. However, the neuronal and molecular basis of taste sensing by the maxillary palp still poorly understood.

Here we report the detail of taste responses by the maxillary palp towards feeding stimulants and deterrents. Electrophysiological recording reveals the ultra-sensitivities of the maxillary palp towards some sugars and secondary metabolites known as feeding deterrents. A test bite was inhibited when mulberry leaves treated with a leaf-surface extract from non-host plant leaves, suggesting that sensing of feeding deterrents by the maxillary palp inhibit test biting. Furthermore, we report a repertoire of chemosensory receptors in the maxillary palp revealed by RNA-seq. These results illuminate the role of the maxillary palp as an ultra-sensitive identifier for host-plant leaves. We also discuss the mechanism of host-plant selection by the maxillary palp that equips ~30 gustatory sensory neurons.

NPF signaling regulates feeding preference in the two-spotted cricket, Gryllus bimaculatus

Authors: Nagata Shinji[1], Seike Hitomi[2], [1]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Japan, [2]Graduate School of Frontier Sciences, the University of Tokyo, Japan

Abstract: Animals need to take appropriate nutrients by feeding to exert precise biological processes. In 1938, Richter and his colleagues have already proposed that animals can recognize their required deficient nutrient, which is called “self-selection”. So far, in both vertebrates and invertebrates, feeding behavior is thought to be regulated by endocrine control involving neuropeptides and biologically active peptides secreted from the central nervous system. As the vertebrate Neuropeptide Y (NPY) is a factor regulating feeding behavior, Neuropeptide F (NPF) is a homologue of NPY, which has been suggested to regulate feeding behavior in invertebrates including insects. In the desert locust, Schistocerca gregaria, the body-weight is decreased by NPF knockdown and increased by NPF injection as a consequence of changes in the amount of food intake. In the fruit fly, Drosophila melanogaster, the knockdown of NPF reduced the amount of sucralose intake. Together, NPF signaling regulates the amount of food intake and is involved in response to carbohydrates. However, it remains unclear whether or not NPF signaling is involved in the selection of nutrients. Here, we aim to elucidate the mechanism of feeding behavior, in particular, feeding preference, in the two-spotted cricket, Gryllus bimaculatus.

We firstly demonstrated the effect of a high-carbohydrate diet (C-rich diet) intake on NPF signaling. The transcriptional level of NPF was increased by C-rich diet intake but not only by normally fed diet. We next confirmed the effect of NPF signaling on the amount of food intake. RNAi-mediated silencing of NPF decreased the amount of C-rich diet intake. We further confirmed whether or not NPF signaling is involved in nutrient-selective behavior. The knockdown of NPF by RNAi reduced a proportion of the amount of C-rich diet to that of a high-protein diet (P-rich diet). In addition, we observed that locomotor activity was increased after dsRNA-treatment of NPF. The current data show that response to dietary carbohydrate is involved in NPF signaling in the crickets along with activation of NPF signaling. In conclusion, NPF is an important factor controlling the decision mechanisms of feeding preference, possibly involving the decision-making in the dietary choice between carbohydrate and protein accounting for the choice between herbivores and carnivores in the omnivorous insect.

Effects of Stunted on energy homeostasis in the two-spotted cricket, G. bimaculatus

Authors: Nagata Shinji[1], Zhou Yi-Jun[1], [1]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Chiba 277-8562, Japan

Abstract: As a heterotrophic organism, dietary products provide all the energy that is essential for digest, metabolisms and physiology activities. Fat body, where is the main peripheral tissue responsible for energy storage and expenditure, secretes several bioactive peptides for delivering energy-related information to central nervous system and triggers following systemically metabolic alterations. Stunted has been identified as one of the fat body-producing peptides, delivering signals by triggering insulin release. However, the roles of Stunted and its receptor in energy homeostasis are not clarified yet.

Here we report that the role of Stunted and its receptor, Methuselah, in energy homeostasis was addressed. RNA-sequencing revealed the strong abundance of Methuselah in the corpora cardiaca. As indicated in the fruit fly Drosophila melanogaster, Stunted is involved in the metabolic processes including insulin signaling in insect, possibly accompanied by AKH signaling, leading to the idea that reinforces the importance of fat body-brain axis in insect metabolisms.

Corpora cardiaca, a key organ regulating feeding behavior by Adipokinetic hormone and its high homologous peptide in the two-spotted cricket, Gryllus bimaculatus

Authors: Nagata Shinji[2], Zhou Yi-Jun[2] and Fukumura Keisuke[1], [1]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Japan, [2]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Japan

Abstract: Like most heterotrophic organisms, feeding behavior of insects is generated by the appropriate composition and amount of energy uptake and energy expenditure. Self-selection, proposed by Curt P. Richter in 1942, described a close relationship between appetite and dietary needs in many animals, which make insects perfect targets to study on energy requirements and its regulatory mechanism in vivo by observing feeding behavior individually. Adipokinetic hormone (AKH) is a neuropeptide that regulates feeding behavior and energy homeostasis in insects by supporting the mobilization of lipids. Our previous report revealed that knockdown of AKH receptor in the two spotted cricket, Gryllus bimaculatus, altered feeding behavior in the following aspects, 1) enhancement of starvation tolerance; 2) increase of feeding frequency and food intake; 3) decrease of locomotor activity in the cricket. However, the influences of feeding behavior by alteration of AKH itself has not been elucidated yet.

In this study, we identified cDNAs encoding AKH (GbAKH) and its high homologous hormone AKH/Corazonin-related peptide (GbACP) and found their predominant expression in the Corpora cardiaca (CC). Injection of synthetic GbAKH and GbACP altered feeding behavior accompanied by the following aspects, 1) inhibition on food intake and excretion; 2) elevation of carbohydrate level in the hemolymph; 3) moderate alteration in food preference. Interestingly, single knockdown of GbAKH or GbACP precursor did not alter lipid mobilization, which is possibly due to their collaborative contribution to control feeding behavior. Besides, interferences of GbAKH and GbACP signals seemed to regulate other neuropeptide signals in the midgut, which would be eventually involved in feeding behavior as observed in other insect enteroendocrine control. Here we hypothesized that the hemolymph carbohydrate elevation induced by GbAKH and GbACP signals in CC, consequently leading to alterations of neuropeptides expression in the midgut and following adjustment of feeding behavior in order to maintain energy homeostasis. In this study, we proved the possibility of the CC-midgut axis in the two-spotted cricket to regulate feeding behavior that is mainly directed by GbAKH and GbACP signals.

Nutrient selective behavior under endocrine control in the cricket

Authors: Nagata Shinji[1], Zhou Yi-Jun[1], Seike Hitomi[2], Fukumura Keisuke[1], Oka Sayuki[2] and Tsukamoto Yusuke[2], [1]Department of Integrated Biosciences, Graduate School of Frontier Sciences, The University of Tokyo, Japan, [2]Graduate School of Frontier Sciences, the University of Tokyo, Japan

Abstract: Animals are needed appropriate diets for normal growth and development. The omnivorous insects such as orthopteran species exert the nutrient selective behavior. Bioassays of macro-nutrient selective behavior using the two-spotted cricket Gryllus bimaculatus were carried out by the application of synthetic peptides and by RNA-interference knockdown of the neuropeptide signaling. Data revealed that Insulin-like peptide, Adipokinetic hormone (AKH), and Neuropeptide F, among all identified neuropeptides, play central roles in the nutrient selective behavior in this species. For example, protein selective behavior, as observed in the mated female, is regulated by insulin-like peptide, and lipid selective behavior is regulated by AKH. Further, such biased requirements for specific macro-nutrients are modified by the metabolisms in the fat body in addition to the endocrine control in the central nervous system including brain and corpora cardiaca (CC). These facts indicate that interplay between peripheral tissues such as fat body and central nervous system including brain-CC is crucial for successful nutrient selection. In addition, systemic nutrient conditions might be perceived by lipid and carbohydrate levels in the hemolymph via CC where produces AKH. Taken together, CC might be a hub tissue generating an endocrine network to maintain energy homeostasis involving nutrient selective behavior.

Imidacloprid toxicity in a dipteran pollinator, Eristalis tenax, supports trends of higher toxin tolerance among dipterans

Authors: Nagloo Nicolas[1], Rigosi Elisa[1] and O'Carroll David[1], [1]Lund University, Sweden

Abstract: Imidacloprid is a neonicotinoid neurotoxin that remains the most used insecticide worldwide. It persists in the environment long after the initial application, resulting in chronic exposure to non-target insects. To accurately map the dose-dependent effects of these exposures across taxa, toxicological assays need to assess various natural modes of exposure across relevant indicator species. However, due to the difficulty of these experiments, contact bioassays are frequently used to quantify dose. Dipterans remain underrepresented, despite their importance as pollinators. Here, we developed a novel naturalistic feeding bioassay to precisely measure imidacloprid ingestion and its toxicity for acute and chronic exposures in a dipteran pollinator, Eristalis tenax. We found them to be 2 to 3 orders of magnitude less sensitive than honeybees to acute exposure. Severe locomotive impairment (likely to be fatal in the wild) or death is only seen at much higher dosages than imidacloprid residues measured in nectar and pollen. Flies which ingested dosages lower than 12.1 ng/mg still showed consistent intake volumes and learned improved feeding efficiency over successive feeding sessions. Feeding ability was compromised at higher dosages due to severe locomotive impairment, but no direct antifeedant effect was observed. The similar imidacloprid sensitivity to other dipterans such as the fruitfly and housefly suggests a phylogenetically conserved component to pesticide tolerance that merits further investigation. The absence of obvious adverse effects at sublethal dosages also underscores a need to develop better tools for quantifying animal behaviour to evaluate the impact of insecticides on foraging efficiency in economically important species.

Role of circadian clocks in dopaminergic neurodegeneration

Authors: Nagoshi Emi[1], Majcin Dorcikova Michaëla, Pottié Emma, Lou Duret, [1]University of Geneva, Switzerland

Abstract: Patients suffering from neurodegenerative disorders, including Parkinson's disease (PD), frequently report circadian dysregulations and sleep problems. However, no causal link from circadian disturbances to vulnerability of dopaminergic (DA) neurons and PD has been demonstrated. Overarching goal of this study is therefore to understand the effect the circadian clock in Drosophila melanogaster exerts on the DA system and its underlying mechanisms. We have previously shown that DA neurons in the protocerebral anterior medial (PAM) subcluster are selectively vulnerable to oxidative stress in a toxin-induced model of DA neurodegeneration using H2O2. Based on this knowledge, here we establish time-of-day-dependent vulnerability of PAM neurons to oxidative insults and dissect underlying genetic and neuronal mechanisms. Our results demonstrate the critical role of circadian clocks in modulating dopaminergic neurodegeneration via specific neural circuit.

The global distribution of fall armyworm haplotypes and their implications to migration behavior

Authors: Nagoshi Rodney, Center for Medical, Agricultural, and Veterinary Medicine USDA-ARS Gainesville, FL, United States

Abstract: Fall armyworm, Spodoptera frugiperda (J. E. Smith), is an important agricultural pest native to the Americas that has recently been introduced into the Eastern Hemisphere where it has rapidly spread through most of Africa and much of Asia. The long-term economic consequences of this invasion will depend on how the species and important subpopulations become distributed upon reaching equilibrium, which is expected to be influenced by a number of factors including climate, geography, agricultural practices, seasonal winds, among others. Much of our understanding of fall armyworm movements have come from the mapping genetically defined subpopulations in the Western Hemisphere, particularly in North America where annual long-distance migrations of thousands of kilometers have been documented and modeled. In contrast, fall armyworm mapping in much of the rest of the world is relatively incomplete. Here we describe the global distribution of selected genetic markers and haplotypes relative to seasonal wind patterns and climate suitability estimates in order to assess the migratory relationships between populations.

Established non-native forest pests and pathogens in Australia — accumulation, response to detection, and impact

Authors: Nahrung Helen[2] and Carnegie Angus[1], [1]Forest Health & Biosecurity - Forest Science NSW Department of Primary Industries, [2]Forest Industries Research Centre, The University of the Sunshine Coast, Queensland, Australia

Abstract: Geographic isolation and a robust biosecurity system render Australia free from many devastating exotic pests and pathogens found in other countries. Nevertheless, around 260 non-native pests and pathogens of arborescent hosts have established in Australia since 1885. Although the risk of invasive species arriving and establishing in Australia is increasing through increased trade and travel, the rate of establishment of non-native forest pests and pathogens has remained relatively constant over the last 130 years, with non-native species accumulating at a rate of about two per year. The majority of these affect host genera exotic to Australia, including the main plantation species, Pinus radiata; few are pests of Australian native genera. Eighteen percent of these pests and pathogens have caused moderate to significant impact or resulted in ongoing management costs in commercial plantations, native forests or amenity trees. Asian and European species accounted for two-thirds of Australia's non-native forest pests, and were equivalently represented numberically, temporally and compositionally. Asian species were more polyphagous and more frequently established in northern Australia. Earlier-establishing species were more polyphagous and had broader Australian and global non-native distributions. Thirty-four new detections of forest pests and pathogens were made since 1996, the majority (71%) via passive surveillance: 24% by public, 12% by industry, and 34% by researchers. This highlights the need for ongoing awareness campaigns and adequate systems for passive surveillance detection, reporting and response. There has been an increase in detections in recent years from active surveillance, but the majority of exotic forest pests and pathogens were not detected early enough to attempt eradication. Early detection is key to successful eradication, yet only one pest of arborescent hosts has been successfully eradicated from Australia, the nematode Bursaphelenchus hunanensis. All forest/tree stakeholders (industry, all levels of government & environment) need to be involved for forest biosecurity to be effective.

Associates of Megastigmus spp. (Hymenoptera: Megastigmidae) in eucalypt galls: a Leptocybe spp. biocontrol perspective

Authors: Nahrung Helen[3], Lawson Simon[2], Le Ngoc Hoan[4] and Morgan Jess[1], [3]Forest Industries Research Centre, The University of the Sunshine Coast, Queensland, Australia, [2]Forest Industries Research Centre (FIRC), University of the Sunshine Coast, Brisbane, Queensland, Australia, [4]University of the Sunshine Coast, Australia, [1]Department of Agriculture and Fisheries, , Australia

Abstract: Species of Megastigmus Dalman (Hymenoptera: Megastigmidae) have been identified as potential biocontrol agents against Leptocybe spp., worldwide eucalypt galling pests originating from Australia. During the last two decades, Megastigmus zvimendeli and M. lawsoni from Australia have established as biocontrol agents in the invasive range of Leptocybe spp.; and many non-Australian species have been recorded in Africa, Asia, Europe and South America as local associates of Leptocybe spp. We conducted a survey of Megastigmus species and their co-inhabitants from eucalypt galls in Australia. Molecular data identified at least sixteen Megastigmus species associated with eucalypt galls, and with several chalcid wasp families (e.g. Eulophidae, Mymaridae, Eurytomidae) and gall midges (Cecidomyiidae). The abundance and geographical distribution of Megastigmus species associated with Leptocybe spp. was determined based on our field collections. A combination of molecular and morphological results revealed that some of the recently described non-Australian species are synonyms of M. zvimendeli, accounting for the unrecorded spread of this species outside of Australia. Our work contributes to the understanding of eucalypt galling insect communities in Australia, Megastigmus biodiversity and the potential of these species as biocontrol agents for Leptocybe and other eucalypt galling species.

Hidden interactions as revealed by metabarcoding on internal DNA of herbivore larvae

Authors: Nakadai Ryosuke, Department of Environmental and Biological Sciences, University of Eastern Finland; Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan

Abstract: In nature, various interactions have occurred in a fraction of a second. To reveal those interactions, researchers have spent a lot of time on field observations. However, to get all information about interactions is technically difficult only by field observations, thus quite a lot of hidden interactions still exist. The recent development of metabarcoding methods now makes us possible to reveal the interactions intensively. In this presentation, I will talk about a study that has applied metabarcoding to study a terrestrial tri-trophic interaction (i.e., a plant-herbivore-parasitoid association). Specifically, the study examined whether partitioning of phenology or natural enemies may explain the coexistence of leaf cone moths (Caloptilia; Gracillariidae) associated with maples (Acer; Sapindaceae). Larval activity of 10 sympatric Caloptilia species found on nine maple species was monitored every 2–3 weeks for a total of 13 sampling events, and an exhaustive search for internal parasitoid wasps was conducted using high–throughput sequencing. Also, blocking primers were used to facilitate the detection of wasp larvae inside moth tissue. The result clearly showed considerable phenological overlap among Caloptilia species, with two clear peaks in July and September–October. Coexisting Caloptilia species also had largely overlapping parasitoid communities; a total of 13 chalcid and ichneumon wasp species attacked Caloptilia in a nonspecific fashion at an overall parasitism rate of 46.4%. In the last of my presentation, I will discuss the future possibility to apply this method for monitoring parasitoid effects on insect outbreaks.

Seasonal occurrences and species composition of Orius spp. (Hemiptera: Anthocoridae) on eggplants planted in okra fields at Kawasaki City Japan

Authors: Nakamura Akinobu[1] and Itoyama Kyo[1], [1]Meiji University, Japan

Abstract: Conservation biological control is the practice to conserve and enhance the resident populations of natural enemies through modification of the environment or of existing practices, and its importance has been increasing in recent years. Conservation of natural enemies within cropland is possible by means of insectary plants which provide them with the resources they need to survive. For example, the introduction of flowering plants in agricultural systems increases nectar and pollen resources that are required by some natural enemies. However, it is difficult to secure enough space to plant insectary plants in urban agriculture where the agricultural land is limited.

It is known that Orius spp. occur and settle in Abelmoschus esculentus (L.) Moench, when cultivated in open eggplant fields, and effects of suppressing the density of thrips in eggplant can be expected. We also have shown that Orius spp. can be found and colonized in okra field in Kawasaki City, Kanagawa prefecture, Japan, there is engaged in urban agriculture.

But the effects on other crops grown nearby okra have not been clarified. In this study, we compared the occurrence and species composition of Orius spp. in the test plot where eggplant was planted in the okra field and the control plot where only eggplant was planted. The occurrence of Orius spp. in eggplants was earlier than in the surrounding okra. The occurrence of Orius spp. in the test plot was higher than that in the control plot. In the test plot, the population of thrips was also large, but it decreased after the occurrence and establishment of Orius spp., confirming the density suppression effect on thrips. Dominant species was Orius sauteri at each plot and the surrounding okra in July, but Orius minutus replaced Orius sauteri in September. Our results would give important information about the application of okra as insectary plants in urban agriculture.

Hazard rating of Japanese larch forests for larch bark beetle (Ips subelongatus) using self-organizing map (SOM) and random forest approaches

Authors: Nam Youngwoo[1], Young Lee Cha[1], Il Choi Won[2], [1]Division of Forest Diseases & Insect Pests National Institute of Forest Science Korea, South Korea, [2]Division of Forest Ecology and Climate Change, National Institute of Forest Science, South Korea

Abstract: The objective of this study was to evaluate the hazard ratings of Japanese larch forests to Ips subelongatus by considering environmental factors. Factors related to thinning, geographical factors and forest stand condition were collected at 16 study sites in Japanese larch stands where thinning was implemented. Using machine learning approaches, self-organizing map (SOM), one of the unsupervised classification methods, and random forest model, which predicted the probability of the tree mortality caused by I. subelongatus, hazard rating of Japanese larch forests after thinning was analyzed. Our results showed that stand age, thinning history, slope orientation, and soil moisture are the major factors influencing on abundance of dead trees killed by the beetles after thinning. There were more dead trees killed by in older forests than in younger forests, suggesting that tree vigor can influence outbreak of the beetles. The slope orientation was related to occurrence of dead trees, which was more on southeast-facing slope than at sites facing other directions. Also, the dead trees were more occurred in the forests with dry soil during the first 3 years after thinning. These results can provide useful information for improved the Japanese larch forests management against I. subelongatus after thinning.

Using Social Media to Communicate Scientific Research as a Public Health Entomologist

Authors: Natasha Agramonte, University of Florida - Emerging Pathogens Institute: Gainesville, FL, USA DeKalb County Board of Health: Atlanta, GA, United States

Abstract: Scientific research has several tried and true outlets for communication, such as publishing in scientific journals or presenting at national and international conferences, however scientists often struggle to communicate their work to the general public. Some organizations encourage outreach to local and state communities in the form of classroom visits, educator trainings, state fairs, and extension publications. While very helpful for establishing ties to the local community, these outreach efforts typically reach fairly small audiences. With the aid of social media, scientists can now reach much larger, international audiences easily. More importantly, social media platforms like Facebook and Twitter allow for a dialogue between scientists and non-scientists, which encourages nuance into the interpretation of research that is often lacking when science research is presented via news broadcasts or popular media. I document my own journey from science researcher uncomfortable in my interactions with the general public to communicating my research on Twitter, Reddit, and even on the Bill Nye show.

Economic and Social Impacts of Arthropod Biological Control

Authors: Naranjo Steve[3], Frisvold George[1] and Ellsworth Peter[2], [1]Department of Agricultural and Resource Economics, University of Arizona, Tucson, Arizona, United States, [2]Department of Entomology, University of Arizona, Maricopa Agricultural Center, Maricopa, Arizona, United States, [3]USDA-ARS, Arid-Land Agricultural Research Center, Maricopa, Arizona, United States

Abstract: Biological control of insect pests is an integral tactic of modern integrated pest management. The number of studies quantifying the economic benefits of biological control remains small, yet estimates suggest biological control has immense value. Here we present economic concepts and discuss methods for placing an economic value on biological control services. We then summarize and synthesize the extant studies that have attempted to quantify the economic outcomes of the biological control of arthropod pest with natural enemies, with particular focus on introductory (classical) biological control. Introductory biological control projects targeting arthropod pests have an average benefit to cost ratio of 61:1 with an estimated net present value of $37.3M per successful project.

Temporal and spatial change in Phytophagous mite populations of Varanasi region

Authors: Nath Singh Rajendra[1], Zainab Shafia[1], [1]Department of Entomology and Agricultural Zoology, Institute of Agricultural Sciences, Banaras Hindu University, Varanasi, India

Abstract: The past few decades have witnessed poignant changes in global climatic conditions. The major factor attributed to this is the elevated CO2 levels in the atmosphere. It has been observed that there has been an unprecedented rise in the CO2 concentration from 280ppm (pre-industrial era) to 400+ ppm in current times. Though CO2 forms an integral part of the carbon cycle on earth and it is an essential component for synthesizing the photosynthates by the plant; global warming is yet another result of the elevated CO2 levels triggering various catastrophic phenomenon leading to climatic variabilities like erratic rainfall, extended drought, and flood conditions. These altercations disturb the diversity, population dynamics, and status of pests and their natural enemies. In this light, we studied the dynamics of plant mite population in and around Varanasi district of eastern Uttar Pradesh, India. The phytophagous mites hold economic significance in agricultural crops and vegetables. The Varanasi district (1,535 square kilometers) predominantly is a major vegetable growing region. The first report of plant mites by Singh (1976) as an emerging pest in eastern Uttar Pradesh was in the early 1980s. Approximately four decades later since it was reported, the obvious climate change coupled with faulty agricultural practices has lead mites to invade different localities across the Varanasi district. Previously it was concentrated in and around the farms of Bishanpura locality but now it has gradually dispersed and established itself in other distant localities as well. The probable hotspots observed were Raja Talab, Rohaniya, Susuwahi, Mundadih, Lalpura, Pindra, Umraha and Tikri to name a few. The mites belonging to family Tetranychidae have been found in abundance in the above-mentioned areas. The major being Tetranychus ludeni, T. urticae, T. macfarlanei, T. neocalidonicus on different host crops. Another mite belonging to family Tarsonemidae, Polyphagotarsonemus latus, is a major pest on chili crop in this region. Eutetranychus orientalis has also become a major threat to locally grown fruits like papaya and guava. Among family Eriophyidae, Aceria cajani on Pigeonpea and Aceria mangiferae on Mango is causing severe damage around the district. Over the years it has been observed that the incidence of the above-mentioned mites has increased substantially in different seasons with more spatial expansion within the Varanasi region. The point here to consider is that previously these mites were not a major concern but various factors over the years have led to a considerable surge in their population causing greater economic losses to the farming community.

Beneficial Predators for Integrated Pest Management - a Bioinformatics Approach

Authors: Nauen Ralf[1], Bailey Emma[3], Crossthwaite Andrew[4], Rawlings Chris[3], Hassani-Pak Keywan[3], Field Linda[2], Williamson Martin[3] and King Robert[3], [1]Bayer AG, Crop Science Division, Germany, [2]Department of Biointeractions and Crop Protection, Rothamsted Research, Harpenden, United Kingdom, [3]Rothamsted Research, United Kingdom, [4]Syngenta, United Kingdom

Abstract: Insect pests contribute significantly to crop yield losses every year, and with a rapidly growing population to feed, finding ways to increase or maintain crop yields amongst insecticide resistance and restrictions has become increasingly challenging.

Biological control – the use of beneficial predators to keep pest populations under control – is a highly effective and therefore key component of Integrated Pest Management (IPM) strategies. Unfortunately, there is a knowledge gap surrounding beneficial predators, with much of the focus to date being on pest species. More information is needed with regards to the impact of insecticides on beneficial predators in order to implement sustainable IPM programmes. Insecticides are an unavoidable element of such programmes and so a better understanding of their interaction with beneficial predators would be advantageous. An added bonus of this increased understanding could be a potential decrease in the use of insecticides and consequently an increased longevity of their action in the field.

The aim of this project is to help fill this knowledge gap through the development of predator genomes. Many genomes are already publicly available for pest species, but very few beneficial predator genomes have been released. The first step will therefore be to sequence and assemble the genomes of key beneficial predators using the latest technologies. The genomes of these beneficial predators will then be compared to pest genomes. A novel insect-specific biological network will be developed for use with 'KnetMiner' (an application to explore large biological knowledge networks), which will identify novel links between species not necessary directly observed.

This comparison will allow us to look for evidence of co-evolution between predators and their prey and learn more about how they interact. For example, it has been theorised that predators may have evolved odour binding proteins to detect pheromones released by the pests, and the expansion of related gene families may provide evidence for this. Particular focus will also be given to genes/pathways which have been linked to insecticide mode of action and resistance. Identifying and exploiting genetic differences related to these pathways could help to design more targeted IPM approaches with the aim to leave the beneficial predator populations unharmed.

The knowledge gained from this project could contribute to the development of successful IPM strategies and help increase crop yields to feed a growing world population.

The alfalfa leafcutter bee, Megachile rotundata is more sensitive to N-cyano neonicotinoid, pyrethroid and butanolide insecticides than other managed bees

Authors: Nauen Ralf[1], Bass Chris[2], Hayward Angela[2], [1]Bayer AG, Crop Science Division, Germany, [2]The University of Exeter, United Kingdom

Abstract: Recent research has shown that several managed bee species have specific P450 enzymes that are preadapted to confer intrinsic tolerance to some insecticides including certain neonicotinoids. However, the universality of this finding across managed bee pollinators is unclear. In this talk I will outline work that demonstrates that the leafcutter bee, Megachile rotundata, lacks such P450s, and is >2500-fold more sensitive to the neonicotinoid thiacloprid and >100 fold more sensitive to the pyrethroid tau-fluvalinate and the butenolide flupyradifurone than other bee species. These findings have significant implications for the safe use of insecticides in crops where M. rotundata is used for pollination, and for ensuring that regulatory pesticide risk assessment frameworks are protective of this species.

Mechanisms of pyrethroid resistance and potential cross-resistance issues in clonal cultures of pea aphid, Acyrthosiphon pisum

Authors: Nauen Ralf[1], Müller Viola[3], Rottmann Antje[2], Buer Benjamin[2] and Lueke Bettina[2], [1]Bayer AG, Crop Science Division, Germany, [2]Bayer Crop Science, Germany, [3]University of Bonn, Germany

Abstract: Insecticide resistance is quite common in green peach aphid, Myzus persicae, and cotton aphid, Aphis gossypii, a fact reflected by 750 documented cases found in the Arthropod Pesticide Resistance Database (https://www.pesticideresistance.org). In total this database lists 922 aphid resistance cases for 27 species, but strikingly not listing any entry for the pea aphid, Acyrthosiphon pisum. The pea aphid is known as a global sucking pest of leguminous plants including peas, broad beans and alfalfa. It is also a model aphid species and its genome has been recently sequenced and annotated.

We recently collected a French population of A. pisum showing a significantly lower susceptibility to pyrethroids when compared to an insecticide susceptible reference strain. After separating and testing a number of clonal cultures we obtained a strain, PYR-R1, exhibiting high levels of pyrethroid resistance (RR>100-fold), but lacking any cross-resistance to other chemical classes of insecticides.

We investigated the molecular mechanism confering pyrethroid resistance in strain PYR-R1 by analysing the involvement of detoxification enzymes as well as possible target-site mutations in the voltage-gated sodium channel, known as the pyrethroid target site. Here we describe the molecular mechanism of resistance and its implications for resistance management.

Target-site and metabolic mechanisms of resistance in fall armyworm

Authors: Nauen Ralf[2], Boaventura Debora[1], [1]Bayer AG & University of Bonn, Germany, [2]Bayer AG, Crop Science Division, Germany

Abstract: Fall armyworm (Spodoptera frugiperda) is a polyphagous lepidopteran species, causing significant damage in several economically important crops, particularly corn. It is a major pest in North and South America, but very recently invaded the African continent and East Asia.

The control of this pest relies on synthetic insecticides and genetically engineered crops expressing Bacillus thuringiensis (Bt) crystal (Cry) toxins. However, fall armyworm developed resistance to different insecticide chemical classes and since 2014, field-evolved Cry1F-resistance has been observed in Brazil.

In this study, the molecular mechanisms conferring resistant to Cry1F was characterized in fall armyworm populations collected in Brazil and cross-resistance pattern with chemical insecticides and Bt toxins were investigated. Moreover, the involvement of detoxification enzymes as well as possible target-site mutations in different insecticides targets were analyzed and new gDNA-based diagnostic tools developed to support fall armyworm resistance management strategies.

Molecular and allelic variation of field evolved mechanisms of resistance to Cry proteins in fall armyworm

Authors: Nauen Ralf[2], Franz Laura[3], Mehlhorn Sonja[1], Horikoshi Renato[1], Boaventura Debora[1] and Head Graham[1], [1]Bayer AG, [2]Bayer AG, Crop Science Division, Germany, [3]Bayer AG, Germany

Abstract: Fall armyworm (FAW), Spodoptera frugiperda (Lepidoptera: Noctuidae), is a highly-destructive moth pest native to the tropical and subtropical Americas that preferably feeds on corn plants. FAW pest management strategies largely rely on the use of synthetic insecticides and transgenic crops, e.g., corn expressing Bacillus thuringiensis (Bt) insecticidal Cry proteins such as Cry1F. Corn hybrids expressing Bt proteins remain a cornerstone in FAW control in North/South America, though resistance is on the move. Resistance to Cry1F is rather widespread and in some cases cross-resistance to Cry1A.105, Cry1Ab and Cry1Ac was described. Cry1F resistance in FAW was shown to be linked to mutations in the ATP-binding cassette transporter C2 (ABCC2) gene. In Brazilian FAW populations we detected by pooled population sequencing several mutations at high frequency in the ABCC2 extracellular loop domain 4 (ECL4), including deletions, insertions, and amino acid substitutions. Other ABBC2 mutations such as splice disruption sites or premature stop codons resulting in a truncated ABCC2 have been described in North American FAW populations. Recent whole genome sequencing approaches revealed the absence of such mutations in invasive populations collected in Eastern Hemisphere countries. Here we discuss the molecular and allelic variation of ABCC2 mutations in FAW and their functional validation.

Beyond Apis mellifera – Using a phylogenomics approach to identify putative detoxification enzymes in different bee species

Authors: Nauen Ralf[2], Haas Julian[3], Buer Benjamin[1], Teresa Almanza Maria[1] and Exeler Nina[1], [1]Bayer AG, Crop Science Division, Germany, [2]Bayer AG, Crop Science Division, Germany, [3]Rheinische Friedrich-Wilhelms University Bonn Bayer AG, Crop Science Division, Germany

Abstract: Insect and especially pollinator declines are a topic of great concern and debate in modern society. Although reasons are manifold, the use of pesticides has been heavily criticized and often blamed for decreases in pollinator diversity and abundance. Historically, risk assessment of crop protection products to bees relied on the honey bee Apis mellifera as a model organism due to its importance, broad availability and standardized methodology. Recently, the question arose whether or not the honey bee is a good surrogate species in risk assessment for the very diverse and complex clade of Anthophila.

Although huge effort is invested into developing new bioassays for different bee species, a problem remains the practicability and/or validity of these test systems as well as the availability of rare species for laboratory testing. This gap in methodology can in parts be filled by using the rapidly advancing field of genomics.

Leveraging the increasing amount of published genomic data, we conducted a phylogenetic approach to identify close relatives of the A. mellifera CYP9Q enzymes – a P450 subfamily previously shown to effectively detoxify certain bee-friendly insecticides – in different bee species and families. After functional expression of several candidate genes we investigated their activity against a range of fluorescent model substrates to compare substrate profiles and tested their ability to metabolize different chemical classes of insecticides.

These results provide us insights into the comparability of detoxification systems between different bee species and families, helping us to better understand and assess intrinsic toxicity of insecticides to bees covering a broad phylogenetic range.

A Genetic Understanding of Transporters Implicated in Insecticide Resistance and Toxicology

Authors: Nauen Ralf[2], Vontas John[1], Denecke Shane Michael[1], Vogelsang Kathrin[4], Vorgia Elena[1], Bao Hang Luong Ngoc[1] and Geibel Sven[3], [1]Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology-Hellas, Heraklion, Greece, [2]Bayer AG, Crop Science Division, Germany, [3]Division Crop Science, Research and Development, Bayer AG, Monheim, Germany, [4]Division Crop Science, Research and Development, Bayer AG, Monheim, Germany

Abstract: Small molecule pesticides are currently the most effective way of controlling damaging arthropod pest species in both public health and agriculture. As a result, genes that alter the toxicity of these compounds due to target site alterations and over-expression of drug metabolizing enzymes have been the subject of intense investigation. Other detoxification mechanisms such as pesticide transport have been less well-studied. While rarely associated with high levels of resistance, various studies have shown that transporters can play roles in basal levels of detoxification even in susceptible populations by preventing compounds from reaching their targets. Furthermore, it can be inferred from pharmaceutical studies that certain transporters may be critical in helping compounds be effectively absorbed into the body. Here, we describe our recent progress on studying transporter proteins that act on insecticides. Through a combination of in silico, in vivo, and in vitro approaches we identify insect transporters that act on pesticides and in what tissue they mediate their effect. It is hoped that these data can begin to establish insects as a model for pharmacokinetic research and provide for a more rational pesticide design strategy.

Pyrethroid efficacy and P450-mediated resistance in the Malaria mosquito Anopheles funestus with special reference to transfluthrin

Authors: Nauen Ralf[3], Nolden Melanie[1], Paine Mark[4] and Horstmann Sebastian[2], [1]Bayer AG, Crop Science Division Liverpool School of Tropical Medicine (LSTM), Germany, [2]Bayer Ag, Crop Science Division, Germany, [3]Bayer AG, Crop Science Division, Germany, [4]Liverpool School of Tropical Medicine (LSTM), United Kingdom

Abstract: Insecticide based control of mosquitoes contributed globally to two-third of the malaria cases which have been averted between 2000 and 2015. However, chemical control heavily relies on pyrethroids, a class of insecticides acting on voltage-gated sodium channels (VGSC). Pyrethroids are frequently applied as indoor residual sprays, space sprays and incorporated in bednets, leading to high levels of resistance.

Resistance is driven by two major mechanisms: Target-site resistance based on mutations in the VGSC, and metabolic resistance based on elevated levels of detoxification enzymes. One enzyme class, cytochrome P450-monooxygenases (P450s) has been shown to be overexpressed in resistant mosquitoes such as Anopheles funestus where the duplicated P450 variants CYP6P9a and CYP6P9b were identified and shown to confer resistance to common pyrethroids, e.g., deltamethrin and permethrin. Whereas the volatile pyrethroid transfluthrin has been shown to be resilient to oxidative metabolism by these P450s due to a highly fluorinated benzene-ring instead of the common phenoxybenzyl-structure.

In contact bioassays we found that An. funestus FUMOZ-R is highly resistant to common pyrethroids such as deltamethrin and permethrin, whereas almost no cross-resistance towards transfluthrin was detected. We recombinantly expressed CYP6P9a and CYP6P9b using a baculovirus expression system and evaluated the oxidative metabolism of various pyrethroids. Our studies revealed sequential metabolism by hydroxylation and subsequent cleavage of the phenoxy-benzyl ether by both CYP6P9 variants. No such oxidative metabolic fate was observed for transfluthrin, suggesting that it is protected by its high fluorination and the lack of the phenoxybenzyl-ether. Indeed, in transfluthrin-metabolism assays no hydroxylated metabolites were found and we unveiled alternative routes of metabolism for this molecule. Furthermore, we elucidated the low RRs observed for permethrin, likely due to its enantiomeric composition. These novel findings will help to refine resistance management tactics to control highly resistant malaria vectors.

Exploring the genetic diversity of the predatory mite Amblyseius swirskii: biological control in a context of climate change

Authors: Navajas Maria[2], Lopes Ivinho[3], Migeon Alain[1], Tixier Marie-Stéphane[4] and Douin Martial[4], [1]INRAE, France, [2]INRAE, France, [3]Institut Agro Montpellier, [4]UMR CBGP, Institut Agro, INRAE, CIRAD, IRD, Univ. Montpellier

Abstract: Genetic variability is an important element for organisms to face variable field conditions. Phytoseiidae are predatory mites, well- known for their efficiency in biological control. In a recent study we show that climate change is affecting predators and preys fitness and distribution, which in turn affect biocontrol performance. Here we focus on Amblyseius swirskii, a mite used in biological control of small insect and mite pests and commercialized since 2005. Our study combines 12S rRNA, CytB and COI mtDNA sequences obtained from (i) mites issued from commercial rearing (several companies), (ii) mites collected in Israel (where the material source now commercially marketed is originated), and (iii) mites collected in several other countries where the species naturally occurs. A very low genetic diversity was observed in and between all populations except the one from Cape Verde that clearly differs. This suggests that (i) commercialized and natural populations now co-occur widely, even in natural environments and/or (ii) that commercialized populations have probably overpassed the natural ones except in remote areas (here Cape Verde) where commercial releases have not occurred. How much observed genetic differentiation results in different biological features needs deeper analysis, however the detection of diversity in remote natural populations may provide a source of novel traits useful to improve performance of this natural enemy. More broadly, this study questions the role of natural enemies' diversity to face new environmental situations as for example the capacity of resilience adapting to climate change.

Bacterial symbionts from the gut of the coffee berry borer Hypothenemus hampei (Coleoptera: Curculionidae): identification of potential “Trojan horses” for insect pest management

Authors: Navarro-Escalante Lucio[3], Benavides Pablo[1], Grueso Nathalie[5], Góngora Carmenza[3], Acuña Ricardo[4] and Mejía Santiago[2], [1]FNC-CENICAFE, Colombia, [2]Graduate Research Assistant Department of Entomology Colombia National Coffee Research Center - CENICAFE, Colombia, [3]Research Scientist Department of Entomology Colombia National Coffee Research Center - CENICAFE, Colombia, [4]Research Scientist Department of Plant Physiology Colombia National Coffee Research Center - CENICAFE, Colombia, [5]Universidad de Caldas

Abstract: The coffee berry borer (CBB) is an important insect pest of coffee crops worldwide. Despite the use of current integrated pest management strategies focused on cultural and chemical control, CBB is a permanent threat for coffee production, urging for more effective and safer insect control strategies. Since microbial symbionts play important roles in the biology of insects, there is a growing interest for understanding this complex insect-symbiont interactions and the application of this knowledge to develop future pest control methods, including delivery of RNA interference. Here, we described the diversity and dynamics of bacterial symbionts within the gut across life stages of CBB using high-throughput DNA sequencing of the 16SrRNA gene (metabarcoding) and culture-dependent methods in order to identify species with potential use for pest control. Additionally, we developed a proof of concept for the RNAi-mediated gene silencing in CBB using bacteria as delivery system. Metabarcoding analysis revealed a diverse bacterial microbiota dominated by genera Ochrobactrum (15.1%), Pantoea (6.6%), Erwinia (5.7%), Lactobacillus (4.3%), Acinetobacter (3.4%), Stenotrophomonas (3.1%), Akkermansia (3.0%), Agrobacterium (2.9%), Curtobacterium (2.7%), and Clostridium (2.7%). From these microbiota, we isolated 21 bacteria strains, including some of the most abundant genera above. We also show that bacteria-delivered RNAi effectors are able to silence CBB genes and offer an opportunity to develop a symbiont-mediated pest control for CBB.

RNA interference of PgCadh gene in Pink Bollworm (Pectinophora gossypiella) enhanced its mortality and suppressed resistance evolution against Cry1Ac

Authors: Nazeer Ahmad Jam[1], Jam Nazeer Ahmad Samina[1], Majeed Dilawar[1], [1]University of Agriculture Faisalabad, Pakistan

Abstract: Gene silencing through RNA interference in different insect pests has been targeted from previous few years. It has been exploited to inhibit growth of insect, induce mortality, avoids resistance evolution and increases the chances of insect susceptibility to Cry1Ac and pesticides. Here, two field collected populations of Pectinophora gossypiella (Multan and Faisalabad) and one susceptible and other resistant laboratory population was used for investigation. All populations were examined for PgCad1 gene expression that is involved in Bt resistance against P. gossypiella. The double stranded RNA (dsRNA) specific for PgCad1 gene in Pectinophora gossypiella was developed and employed through micro-injection using different concentration (1-3 ul/sample) to knockdown it in resistant population. The results showed that expression of PgCadh1 was up regulated in Multan, and laboratory reared resistant population as compared to Faisalabad and laboratory reared susceptible population. Down regulation of PgCad1 gene was observed in 3rd instar larvae upon application of PgCad1-dsRNA RT-PCR and real time PCR. Increased mortality was observed in 3rd instar larvae treated with dsRNA as compared to control insects treated with water and dsGFP. Present study showed that dsRNA can cause severe effect on the P. gossypiella and persuade RNA interference. The findings also confirmed that RNAi application is appropriate tool to cause mortality and to reduce the evolution of Cry1Ac resistance in P.gossypiella.

Insecticide Resistance management in Red Palm Weevil (Rhynchophorus ferruginous) management through RNAi

Authors: Nazeer Ahmad Jam[2], Manzoor Mujahid[1] and Jam Nazeer Ahmad Samina[2], [1]Punjab university, Lahore, Pakistan, [2]University of Agriculture Faisalabad, Pakistan

Abstract: Molecular and proteomic study was conducted on field evolved resistance of Red Palm Weevil (Rhynchophorus ferruginous) against Parathyroid group of insecticide (Cypermethrin). Cytochrome P450 genes have been associated with insecticides resistance. Field collected population of R. ferruginous from different provinces of Pakistan was investigated for insecticides resistance development against P450 gene. Insect bioassay indicated highly significant level of LC50 values among laboratory reared and field collected population against Cypermethrin. The laboratory reared resistant population, Sindh and South Punjab collected population showed high LC50 values as compared to susceptible, Baluchistan and KPK population. The expression of P450 gene through PCR showed enhanced level of P450 gene in different Instars as well as collected population. The dsRNA specific for CYP450 gene was designed and targeted through dsRNA in thoracic region of R. ferruginous through micro-injection. Gene expression and proteomic study confirmed the down regulation of P450 gene and associated protein in dsRNA treated population. The application of ds RNA specific for CYP450 also reduced insecticide resistance in R. ferruginous. The developmental parameters were highly affected in RPW treated with dsRNA as compared to control samples treated with water or dsGFP. These results support the RNAi application as a suitable tool for the management of insecticide resistance and control of R. ferruginous

Enhanced efficacy of sub-lethal dose response of native Polyhedroviruses and Spinosad for economical and sustainable management of Sopodoptera litura in Pakistan

Authors: Nazeer Ahmad Jam[3], M Bones Atle[1], Ahuja Ishita[1], Ahmad Malik Mubashar[2], Mushtaq Rashid[2] and Jam Nazeer Ahmad Samina[2], [1]NTNU, Norway, [2]University of Agriculture Faisalabad, Pakistan

Abstract: In the present investigation, laboratory trials were conducted to investigate the synergistic, additive or antagonistic effect of three sub-lethal dose rates (2 x 103, 4.5 x 103, and 6 x 103 PIB/Larva) of native isolated Nucleopolyhydrovirus (NPV) from Spodoptera litura and Spinosad (0.01 ppm) against 3rd and 4th instar larvae collected from three different geographical areas of Punjab (Pakistan). The difference in larval mortality, pupation, adult emergence and egg ecluson occurred. The higher but sub-lethal dose rate of NPV with Spinosad exhibited synergistic interaction, while the rest of combinations were additive in all the tested populations, showing the population of S. litura from Rahim Yar Khan Region least susceptible, and that of Faisalabad highly susceptible. It may be inferred that the mixtures of the correct sub-lethal doses of Spinoad + NPV can be a proven potential pest and insecticides resistance management (IRPM) strategy against S. litura in vegetable and major crop growing areas of Pakistan.

On the morphology of male genitalia in Onciderini (Coleoptera: Cerambycidae: Lamiinae)

Authors: Nearns Eugenio, USDA APHIS National Identification Services (NIS), National Museum of Natural History, Smithsonian Institution, Washington, DC, United States

Abstract: Male genitallic structures for representatives of 81 genera of Onciderini (Coleoptera: Cerambycidae: Lamiinae) were dissected and illustrated. Several distinct types of parameres were discovered. A cladistic analysis based on morpohological characters is discussed.

Avoidance and toxicity of ladybirds (Coleoptera: Coccinellidae)

Authors: Nedved Olda[1], Sakaki Samane[1], [1]University of South Bohemia, Czech Republic

Abstract: Avoidance reaction of ants Lasius niger to the extracts from Adalia bipunctata, Hippodamia undecimnotata, Coccinella septempunctata, Harmonia axyridis, Halyzia sedecimguttata and Tytthaspis sedecimpunctata differed slightly. Fresh carcasses of toxic and aposematic insect species remained longer than 24 hours: firebugs Pyrrhocoris apterus and ladybirds C. septempunctata, H. undecimnotata, H. axyridis (adults and larvae) and T. sedecimpunctata. Extracts from the invasive alien ladybirds H. axyridis were more toxic for fleas Daphnia magna than native European species: aposematic A. bipunctata > cryptic Cynegetis impunctata > aposematic C. septempunctata > slightly aposematic Calvia quatuordecimguttata. Three months old ladybirds H. axyridis were 3.8x more toxic than 2 and 4 weeks old. Melanic and non-melanic forms of H. axyridis were equally toxic. Extracts from one week old H. axyridis decreased the root length of germinating seeds of Sinapis alba to one third and from three-month-old ladybirds to one tenth of the control. Differences in toxicity among 13 colour forms of H. axyridis were small. Insectivorous tits Parus major showed strong avoidance of various adult ladybirds, larvae and pupae, but not the granivorous sparrows Passer montanus. Artificial plasticine larvae resembling real larvae confirmed less attack rate of aposematically coloured prey than of black and green larvae.

Assessing the conservation status of ladybirds: A roadmap towards conservation

Authors: Nedved Oldrich[8], Haelewaters Danny[4], Roy Helen E.[7], Losey John E.[5], Brown Peter M.J.[1], Pervez Ahmad[2], Soares António Onofre[3], Mishra Geetanjali[6] and Omkar Omkar[6], [1]Anglia Ruskin University, United Kingdom, [2]Biocontrol Laboratory, Department of Zoology, Radhey Hari Govt. P.G. College, Chamoli, Uttarakhand., India, [3]CE3C, Centre for Ecology, Evolution and Environmental Changes, Azorean Biodiversity Group, Faculty of Sciences and Technology, University of the Azores., Portug, [4]Ghent University, Czech Republic, [5]IUCN SSC Ladybird Specialist Group, [6]Ladybird Research Laboratory, Department of Zoology, University of Lucknow, India, [7]UK Centre for Ecology & Hydrology, [8]University of South Bohemia

Abstract: Insects face many human-mediated threats, including climate change, agricultural intensification, habitat loss, pollution, and biological invasions. Ecological impacts from these threats have altered the richness, abundance, and distribution of insect species, impacting their survival and compromising the numerous services they provide. The development and implementation of conservation strategies for beneficial insects such as ladybirds (Coleoptera: Coccinellidae) is hindered by a lack of knowledge of the conservation status of most species and the factors driving their population dynamics. Here we review the ecological threats faced by ladybirds, and current projects and actions that should aid the conservation and recovery of their populations. We also identify knowledge gaps in biodiversity assessment and conservation approaches, and suggest mitigating actions following Harvey et al. (2020) as a roadmap for ladybird conservation and recovery over short-, intermediate-, and long-term timescales.

Fire: death by a thousand cuts in aquatic insect community assembly of streams in western North America, concerted and confounded variables in space and time.

Authors: Nelson C. Riley[1], Frandsen Paul[2], Abbott Ben W.[3], Errigo Isabella M.[3] and Eichert Anna L.[3], [1]Department of Biology, Brigham Young University, United States, [2]Department of Plant and Wildlife Sciences, Brigham Young Univ, Provo, UT, USA, United States, [3]Department of Plant and Wildlife Sciences, Brigham Young University

Abstract: Megafires have burned vast stretches of wildlands in western North America in recent years during unprecedented drought. The summer of 2018 was particularly devastating in central Utah where several huge fires merged into one encompassing 610 km2 in the southern Wasatch Mountains. Within weeks remnants of an intense tropical storm dumped unseasonable amounts of rain on the fire scar in this arid watershed, triggering extensive flash flooding. These streams are tributaries of Utah Lake, the third largest freshwater lake in the contiguous western United States, whose ecology is currently a focus of renewed public scrutiny. All streams in the lake's southern watershed were impacted to varying degrees and a sampling regime for quickly documenting changes in both abiotic (86 sites) and biotic communities (18 sites) put in place. In this report we summarize progress on measuring macroinvertebrate recovery in these streams over the past three years using species effort analyses, rapid bioassessment protocols, and community estimates using environmental DNA. Asymmetric methodologies with confounded variables for judging community decline and recovery are briefly reviewed in a context of global insect apocalypse and climate change.

New insecticidal proteins with potential applications in future genetically engineered crops

Authors: Nelson Mark, Corteva Agriscience, United States

Abstract: Genetically engineered insect resistant crops have provided growers with valuable tools for protecting yield for more than two decades. The insecticidal proteins derived from Bacillus thuringiensis have served as the cornerstone for establishing this technology leading to widespread adoption. However, the ongoing risk of insects developing resistance to the proteins in these crops has continued to drive the discovery of new proteins that can replace or augment those currently in use. This talk will briefly review the history of transgenic insect control and highlight the discovery of new insecticidal proteins with the potential for transgenic insect control applications in the future.

Roofing the forest to learn more about drought-induced bark beetle attack

Authors: Netherer Sigrid, Institute of Forest Entomology, Forest Pathology and Forest Protection Department of Forest and Soil Sciences BOKU - University of Natural Resources and Life Sc, Austria

Abstract: Drought episodes are widely considered to stress host conifer trees and render them highly susceptible to scolytid attack. The Eurasian spruce bark beetle Ips typographus is the main biotic disturbance agent in European Norway spruce forests, causing vast amounts of salvaged timber in the recent decades. The constellations of predisposing factors differ with geographical region; yet, temperature sums available for generation development and drought variables have turned out to be relevant for bark beetle infestations at all sites. Predisposition assessment, simulation of bark beetle phenology and of drought proxies such as the transpiration deficit are useful tools in bark beetle risk assessment. The fundamental questions however remain, how primary attack of Norway spruce depends on finding and acceptance of trees as hosts by bark beetles and in which way drought mediates tree defence capability. An ongoing drought manipulation experiment addresses constitutive and induced resistance against biotic attack, including resin flow, hypersensitive reaction on blue stain fungus inoculation, and the accumulation of defence compounds such as terpenes and monophenols in the bark. Volatile compounds, in particular the composition and concentration of terpenes, are gustatory and olfactory cues strongly affecting beetle attraction and repulsion. In my talk I will present novel results gained from the field experiments involving measurement of climate and soil parameters, tree physiological stress and tree defence markers, in particular bark and volatile compounds, as well as bark beetle attack under controlled test conditions.

When moon and sun intertwine: Characterizing the role of the circadian clock in endogenous lunar timekeeping of a marine midge

Authors: Neumann Jule[2] and Kaiser Tobias S.[1], [2]Max Planck Institute for Evolutionary Biology, Germany, [1]Max Planck Institute for Evolutionary Biology

Abstract: Life on earth evolved in recurring environmental cycles caused by the sun and the moon creating predictable, fluctuating environments. In anticipation of these regular changes, organisms have developed their own timekeepers – so-called biological clocks. Marine midges of the genus Clunio (Diptera, Chironomidae) time adult emergence to the lunar cycle by a circalunar clock. However, mechanism of such endogenous (semi)lunar timekeeping remains elusive. Three functional principles of the circa(semi)lunar clock have been proposed – two of which involve the circadian system: (1) A counting mechanism based on light-dark (LD) cycles, (2) a beat wave resulting from the superposition of a circadian and a circatidal rhythm, and (3) A (semi)lunar oscillator running independently of the circadian system. In our experiments, we find evidence that the semilunar period changes linearly with non-24h T-cycles, suggesting involvement of a counter mechanism in Clunio. Experiments conducted in LD 6:6 indicate that Clunio counts endogenous circadian oscillations rather than LD-cycles. In a broader evolutionary context these results strengthen the idea that circalunar clocks are based on different functional principles when comparing circalunar clocks of dipterous insects with those of marine annelids. These divergent clock principles may indicate multiple evolutionary origins of circalunar clocks.

Role of a Niemann-Pick type C2 transcript (Vd40090) in Varroa-honey bee interaction

Authors: Nganso Beatrice

Abstract: Chemical cues are well-known to play a crucial role in the interactions between the honeybee and its most devastating parasite, the invasive ecto-parasitic Varroa destructor mite. However, the chemosensory machinery that mediates this interaction remains unknown. Recently, via transcriptomic and proteomic analyses, we identified twelve putative soluble carrier and membrane-bound chemosensory proteins. Specifically, three transcripts were found to be foreleg-specific, while the other two transcripts were expressed in both the forelegs and gnathosoma. Silencing highly expressed and foreleg-specific transcript (Vd40090), which encodes a Niemann-Pick disease protein type C2 (NPC2) protein using RNA interference caused significant behavioral and physiological changes. Silencing effectively disrupted Varroa host selection, acceptance and feeding as well as significantly impaired the expression of reproduction-related genes leading to reduced mite reproduction within worker brood cells. Overall, our results clearly indicate the crucial role of this putative odorant carrier protein in Varroa-honeybee interaction.

Beyond Scientific Journals: Broadening the societal impact of entomological science discoveries

Authors: Ngumbi Esther, University of Illinois at Urbana-Champaign, United States

Abstract: Science continues to provide answers to the most persistent challenges our global societies face, including climate change, public health, and food insecurity. Yet, many of these novel scientific solutions, including those arising from entomological research, are only meaningful to the science community. Approximately 3 million scientific articles are published every year. Yet, on average, only ten people read a given scientific article in its entirety, so clearly, the public is not being reached. Considering this disconnect, it is crucial for graduate students, post-docs, early career, and seasoned scientists to learn the art of sharing their research findings beyond the scientific journals. In this talk, I will explore other avenues researchers can use to disseminate their findings widely and outline the art of writing and pitching impact-full science-related opinion pieces. By widely spreading our scientific results, we can build bridges between entomological research and society and allow communities, activists, private industries, and policymakers to build on our findings and discoveries.

How honest signaling and co-evolution between bees and their hornet predators has shaped bee communication

Authors: Nieh James, UCSD, United States

Abstract: Predators have shaped the evolution of multiple bee signals and how bees can detect signals. These adaptations include alarm communication, stop signals, and olfactory eavesdropping. I present recent work by my collaborators and myself on how predators affect the signaling of different honey bee species (Apis cerana, Apis florea, and Apis dorsata) to understand how important selective pressures, predation and peril, have shaped the evolution of honey bee communication.

Use of vibratory signals as mating disruption strategy for pest control

Authors: Nieri Rachele[3], Berardo Alice[2], Pugno Nicola M.[3], Mazzoni Valerio[1], [1]Fondazione Edmund Mach Center for Research & Innovation, Italy, [2]University of Padua, [3]University of Trento

Abstract: Mating disruption is normally associated with pheromones and for this reason it is considered a typical chemical ecology strategy. However, recent progresses in the field of biotremology are conveying research in the use of mechanical stimuli (i.e., semiophysicals) for pest manipulation. Vibrational inputs are less impacting on the environment than pesticides and for this reason they are suitable for organic and integrated pest management. Since 2017, a 1 ha vineyard of Cabernet Franc is managed with vibrational signals to disrupt the mating behavior of two noxious leafhoppers, Scaphoideus titanus Ball and Empoasca vitis Göthe. The 24h/day transmission of vibrations with frequency pattern overlapping the two pests' mating signals, by means of special electromagnetic transducers, caused a significant reduction (30-50%) of both populations in the treated area, in comparison with an adjacent control vineyard. Similarly, the leaf damage was much lower in the treated area compared to the control. On the contrary, no negative effects were observed on predators (e.g. spiders and lacewings). A numerical approach on the mechanics of the problem has indicated the optimal trellis system setup (i.e., poles and wires characteristics) to maximize the signal transmission along the row and thus reduce the overall costs (i.e., to increase the active space and thus to reduce the number of transducers per row). This is the first demonstration of the efficacy of the vibrational mating disruption method in the field. In future, we aim at extending the experimental area to other European vine regions, in order to further validate the method.

Endogenous viral elements are abundant in arthropod genomes and give rise to piRNAs

Authors: Nigg Jared[1], Falk Bryce[1], [1]University of California Davis, United States

Abstract: Endogenous viral elements (EVEs) are genomic sequences derived from partial integrations of DNA and non-retroviral RNA viruses. In Aedes aegypti and Aedes albopictus, EVEs give rise to Piwi-interacting RNAs (piRNAs), raising the possibility that EVE-derived piRNAs may prime ping-pong amplification of virus-derived piRNAs during infection with corresponding exogenous viruses. We conducted a comprehensive survey of 48 arthropod species and found that while EVEs are abundant in arthropod genomes and often give rise to piRNAs, limited nucleotide identity between the majority of EVEs and currently described viruses likely limits the extent to which EVE-derived piRNAs direct ping-pong-dependent cleavage events during infection with these viruses. Nevertheless, a small number of EVEs share stretches of >20 uninterrupted nucleotides with corresponding viruses. In one such case, we found that the Diaphorina citri genome contains a 654 nt EVE with 86% nucleotide identity to Diaphorina citri densovirus (DcDV). Furthemore, we found that DcDV is targeted by ping-pong-dependent piRNAs during infection in D. citri. To further explore the potential roles of EVE-derived piRNAs, we constructed a recombinant cricket paralysis virus (CrPV) mutant by inserting 57 nt of sequence derived from DcDV and corresponding to the DcDV-derived EVE into the CrPV genome. We found that the presence of DcDV-derived sequence within the CrPV genome was not sufficient to permit targeting of the recombinant CrPV by EVE-derived piRNAs during infections in D. citri initiated either by microinjection or oral inoculation. Moreover, we found that DcDV was targeted by ping-pong-dependent piRNAs in D. citri populations lacking the DcDV-derived EVE. Our results represent the first report of ping-pong-dependent virus-derived piRNAs outside of mosquitoes and do not support the hypothesis that EVE-derived piRNAs are capable of targeting corresponding exogenous viruses.

Of monarchs and mitochondria: Effects of starvation and infection on flight physiology in the monarch butterfly

Authors: Niitepõld Kristjan[2], N. Kavazis Andreas[1], G. Appel Arthur[1], A. Parry Hailey[1], de Roode Jacobus[3] and R. Hood Wendy[1], [1]Auburn University, United States, [2]Department of Biological Sciences, Auburn University, United States, Finland, [3]Emory University, United States

Abstract: Migration poses an extreme energetic and physiological challenge to animals. Flying insects, in particular, consume energy at very high rates during migration. Thus, any disruption by external and internal stressors has the potential to hinder an insect’s ability to maintain physiological performance. Mitochondrial function lies at the base of organismal performance, health and fitness, but has been little studied in the context of migration. Here, we focused on two stressors, starvation and parasite infection, and assessed how they affect physiological performance at two levels: at the whole-animal level and at the level of mitochondria. Our study species, the North American monarch butterfly (Danaus plexippus) is well known for its annual migration between northern breeding sites and southern overwintering sites. The monarch suffers from infection by the protozoan parasite Ophryocystis elektroscirrha, which has been shown to reduce survival and flight performance. We subjected infected and uninfected lab-reared female monarchs either to an ad lib diet or 7 days of starvation, and then measured whole-animal resting (RMR) and flight metabolic rates, and after quick dissection of flight muscles, mitochondrial oxygen consumption. We measured maximum oxygen consumption rate (State 3), resting rate (State 4), and the respiratory control ratio, indicating mitochondrial coupling. All results were corrected for body size. Starvation had a strong negative effect on whole-animal resting metabolic rate, which may reflect reduced capacity to maintain basal physiological functions. Starved individuals also showed reduced peak flight metabolic rate, indicating poor flight performance. In contrast, infection did not affect RMR or peak flight metabolic rate. Starvation lowered mitochondrial maximum (State 3) oxygen consumption of muscle whereas resting oxygen consumption did not change, leading to lowered respiratory control ratio. Infection did not affect mitochondrial respiration. A correlation analysis showed that mass-independent mitochondrial maximum respiration significantly predicted mass-independent whole-animal flight metabolic rate at the individual level, supporting the hypothesis of a clear link between mitochondrial and organismal performance. Many of the results showed trends suggesting additive effects of starvation and infection, but these were statistically nonsignificant. Nevertheless, as infection may lead to lower resource intake, it may ultimately reduce physiological flight performance via energy shortage. In summary, monarch flight physiology is sensitive to nutritional stress, highlighting the importance of natural food resources prior to energetically expensive undertakings, such as migration. Compromised mitochondrial function may serve as a mechanism leading to reduced survival and fitness in flying insects in general.

Evolution of developmental patterns in the sex-specific wing reduction in Lepidoptera: a perspective from developmental constraints

Authors: Niitsu Shuhei[3], Sugimoto Takafumi[2] and Kamito Takehiko[1], [1]International Christian University, Japan, [2]National Agriculture and Food Research Organization, Japan, [3]Tokyo Metropolitan University, Japan

Abstract: The acquisition of wings is the most important evolutionary event in insects, and thus pterygotan insects have become the most flourish animals in the world. Flight-loss has occurred in nearly all winged orders. Such flightlessness or winglessness have evolved many times in neopteran insects in a response to a change according to ecological conditions. Wing reduction in insects has received considerable attention regarding its processes and mechanisms in group such as Orthoptera, Homoptera, Hymenoptera, Coleoptera and Diptera. In lepidoptera, female-specific wing degeneration occurs in many groups; that is, brachypterous (vestigial wing) and apterous (no wing) forms occur in 26 of approximately 120 moth families. It has been well known that sex-specific vestigial wing type, which shows normal development of pupal wing but after adult development, pupal wing sheet degenerates due to sex-specific programmed cell death. While the developmental processes that led to these wingless females is well known, why and how such similar processes are caused in each different lepidopteran family still remain to be understood. To elucidate this issue, we compare the developmental processes of wing reduction in several lepidopteran families, e.g., Psychidae, Lymantriidae and Geometridae. Through our study, we found that these developmental processes of wing reduction were quite similar among different lineages in Lepidoptera. Based on these results, we propose that similar developmental patterns were caused by developmental constraints which limited evolutionary changes and were originated from parallel evolution of winglessness in Lepidoptera.

RNA viruses in spider mites and potential interactions with the host RNAi

Authors: Niu Jinzhi[1], Wang Jinjun[1], [1]Key Laboratory of Entomology and Pest Control Engineering, College of Plant Protection, Southwest University, Chongqing, China; State Cultivation Base of Crop S

Abstract: RNA viruses are abundant and diverse in eukaryotic organisms, and evolved as a main biological factor in ecosystem. Currently, only a small proportion of RNA viruses has been characterized, and this is unknown in a key agricultural pest family-spider mites (Acari: Tetranychidae). In order to investigate RNA virome in spider mites, we used a polyphagous species (Tetranychus urticae) and two species preferred to infest on citrus (Panonychus citri and Eotetranychus kankitus). Based on rRNA-removed RNA-seq data of three mite species, we identified eight (six new and two known) RNA viruses, including one of Kitaviridae, two of Dicistroviridae, two of Chuviridae, and three picorna-like viruses (Picornavirales: unassigned). Screening of virus-derived sequences in multiple species of citrus pests (n=10 per species) showed that Eotetranychus kankitus picorna-like virus and Tetranychus urticae mivirus may be present in multiple citrus pests. These results may reflect spillover of this virus to different arthropod species in this citrus-based ecosystem. To further investigate the impact of viruses to host RNA interference pathway, we sequenced small RNAs of three spider mites. All identified viruses of Kitaviridae, Dicistroviridae, and picorna-like viruses (Picornavirales: unassigned), showed 20-21 bp peaks of virus-derived small RNAs, and these small RNAs also had symmetrical distribution patterns in the genome and antigenome, implying that viral infections may trigger the RNAi responses as an antiviral defense mechanism in spider mites. Our study highlight the importance to investigate RNA viromes in spider mites and the interactions between viruses and mites as well as interactions among pest species in an ecosystem via viruses.

Neuronal control of juvenile hormone biosynthesis to regulate reproductive dormancy in the fruit fly Drosophila melanogaster

Authors: Niwa Ryusuke[6], Kurogi Yoshitomo[5], Imura Eisuke[5], Hoshino Ryo[5], Mizuno Yosuke[5], Nouzova Marcela[2], Matsuyama Shigeru[5], Mizoguchi Akira[1], Kondo Shu[4], Tanimoto Hiromu[3] and Noriega Fernando[2], [1]Aichi Gakuin University, [2]Florida International University, [3]Tohoku University, [4]Tokyo University of Science, [5]University of Tsukuba, [6]University of Tsukuba, Japan

Abstract: Reproductive dormancy is a process to suppress oogenesis and save energy in adverse environmental changes, such as low temperature and short-day conditions. In many insects including the fruit flies Drosophila melanogaster, reproductive dormancy is induced by downregulation of juvenile hormone (JH) biosynthesis in the corpus allatum (CA). However, it is still largely unclear how JH biosynthesis is downregulated under dormancy-inducing conditions at the molecular and cellular levels. In this study, we report that a subset of neurons projecting to the CA plays an indispensable role in JH-dependent reproductive dormancy in Drosophila melanogaster. When a transgenic RNAi specifically impaired a neuropeptide expressed in the CA-projecting neurons, oogenesis was not suppressed, leading to mature egg production even in dormancy-inducing conditions. In addition, we also found that the neuropeptide receptor is highly expressed in the CA. Knockdown of the neuropeptide receptor in the CA also produced mature eggs in dormancy-inducing conditions. Consistent with these results, the hemolymph JH titer was upregulated by the knockdown of the neuropeptide receptor in the CA. Collectively, we propose that dormancy-inducing conditions activate the CA-projecting neurons to downregulate JH biosynthesis in the CA, leading to reproductive dormancy.

Developing behaviorally-compatible monitoring traps for the invasive spotted lanternfly, Lycorma delicatula

Authors: Nixon Laura J.[2], Ludwick Dalton[2], Leach Heather[1] and C. Leskey Tracy[2], [1]Department of Entomology, Penn State University, University Park, PA 16802, United States, [2]USDA-ARS, Appalachian Fruit Research Station, Kearneysville, WV 25430, United States

Abstract: The invasive spotted lanternfly, Lycorma delicatula, has been officially detected in a number of states in the USA. To date, it has been recorded feeding on important specialty crops including grapevines and apple and peach trees, with recent reports of vine death attributed to their feeding. To enable more sensitive and reliable monitoring efforts for this invasive pest species, we have studied dispersal behavior of both adults and nymphs and developed novel trap designs based on their movement patterns that not only reliably capture L. delicatula, but also reduce non-target captures.

Contrasting light environments bias attacks by predators on white and yellow colour morphs of the aposematic wood tiger moth

Authors: Nokelainen Ossi[1], de Moraes Rezende Francisko[2], Valkonen Janne[2] and Mappes Johanna[2], [1]University of Jyvaskyla & Helsinki, Finland, [2]University of Jyväskylä, Finland

Abstract: The wood tiger moth warns predators on its unprofitability by its conspicuous coloration. It comes in many varieties including white and yellow, often co-occurring within a population. As predators are expected to select for the locally most efficient warning signal, there is a perplexing range of polymorphism present in this species and as such, it presents an evolutionary puzzle. One explanation that could maintain such polymorphism, is the light influence of variable light environments. As predators use visual perception to process luminance and chromatic information in their environment, different light environments may alter visual cues and bias their decision making. Here we recorded natural forest irradiance profiles and created two contrasting light environments and tested the impact of light on the survival of an aposematic, colour polymorphic wood tiger moth (Arctia plantaginis) using blue tits (Cyanistes caeruleus) as predators. To assess bird decisions in a simultaneous choice test with real prey, we offered yellow and white moths to blue tits under conditions simulating open (i.e. bright) and/or forested (i.e. shady) light environments. Yellow moths were more likely to get attacked first in low light conditions whereas white moths got more often attacked in bright light conditions. Our findings suggest that deviance in chromatic and luminance information and light conditions can influence predators' decision making, and thus facilitate the maintenance of anti-predatory colour polymorphism in the wild.

The existence of a new cryptic species of Japanese pygmy mole cricket (Orthoptera: Tridactylidae) revealed by morphological study and mitochondrial DNA analysis

Authors: Nomura Masashi[2] and Sato Rie[1], [1]Laboratory of Applied Entomology, Graduate School of Entomology, Chiba University, Japan, [2]Laboratory of Applied Entomology, Graduate School of Horticulture, Chiba University, Japan

Abstract: Pygmy mole crickets (Orthoptera: Tridactylidae) are small, blackish, grasshopper-like insects that have several interesting morphological characters. In Japanese fauna, four species are described within the genus Xya, namely alcicornis, nitobe, japonica and riparia. Among these species, in Honshu, the mainland of Japan, there are two species of pygmy mole crickets: Xya japonica that are widely distributed, and X. riparia that show limited distribution. In 2014, we found a new pygmy mole cricket with similar morphological features to X. riparia in a southwestern area of Japan. Thereupon, we performed a morphological comparison and a molecular phylogenetic analysis using the mitochondrial DNA of all of the pygmy mole cricket species, including the unknown species we found.

As a result, the morphological characteristics of the genitalia in the unknown species was similar to X. riparia, and was quite different from the other three species. However, the unknown species was different from the individuals in the Southwestern Islands due to an external white pattern on the legs and wings. Molecular phylogenetic analysis using mitochondrial COI and COII genes of 971bp by the Maximum Likelihood Method revealed that the unknown species holds a close relationship with X. riparia in Honshu, but belongs a different group from the X.riparia in the Southwestern islands. In this study, we have concluded that the unknown species is a new cryptic species of pygmy mole cricket, and is different from the X.riparia where it was found in the Southwestern islands.

On the generality of the diploid male vortex in parasitoid wasps with single-locus complementary sex determination

Authors: Nonaka Etsuko[1] and Kaitala Veijo[2], [1]Sweden, [2]University of Helsinki, Finland

Abstract: Most parasitoid wasps have complementary sex determination (CSD), which produces sterile or inviable males when homozygous at sex determining loci. Zayed and Packer (2005) have theoretically shown that small populations have elevated risks of extinction due to positive feedback between inbreeding and small population size, referred to as the diploid male vortex. Consistent with limited empirical support, a few modeling papers have suggested that diploid male vortices may not be as common as indicated by Zayed and Packer because balancing selection at sex determining loci tends to maintain high allelic diversity and because immigrants can introduce locally new alleles in spatially structured populations. However, the generality of the conclusion is yet uncertain, as these models were either developed for a particular system or based on models atypical for host-parasitoid interactions. The objective of our paper is to attest the conclusion in several well-studied host-parasitoid models. We derived analytical expressions of the conditions for a diploid male vortex in a single population. Then, we developed stochastic individual-based versions of the models and tested the effects of various behaviors, diploid male fertility, temporal fluctuation in host populations, and spatial population structure on the likelihood of a diploid male vortex. We found that a small increase in dispersal probability, diploid male fertility, and female discrimination against diploid males as a mate and a small decrease in primary sex ratio can alleviate the risk of a diploid male vortex, even when host populations fluctuate with high amplitudes and synchronously. However, populations become more prone to extinction when the temporal dynamics of host abundance are autocorrelated. We conclude that spatially connected parasitoid populations may be more robust to a diploid male vortex than anticipated by Zayed and Packer. However, if future climate change induces more temporally autocorrelated host abundance, the likelihood of a diploid male vortex could increase substantially.

Revealing the bacterial diversity associated with Platypus cylindrus (Coleoptera: Curculionidae) on Portuguese cork oaks

Authors: Nones Stefano[1], Matos José, Fernandes Camila[3], Sousa Edmundo[3], Simões Fernanda[3], Cruz Leonor[2] and Serra Octavio[3], [1]1 Instituto Nacional de Investigação Agraria e Veterinaria (INIAV), Av. da Republica, Quinta do Marques, Oeiras, Portugal; 2 Instituto de Tecnologia, Italy, [2]1 Instituto Nacional de Investigação Agraria e Veterinaria (INIAV), Av. da Republica, Quinta do Marques, Oeiras, Portugal; 3 Instituto de Biossistema, [3]1 Instituto Nacional de Investigação Agraria e Veterinaria (INIAV), Av. da Republica, Quinta do Marques, Oeiras, Portugal

Abstract: The oak pinhole borer Platypus cylindrus Fab. (Coleoptera: Curculionidae) is an ambrosia beetle distributed across Eurasia and the Mediterranean area. In Portugal, it colonizes the trunks of the major forest tree species Quercus suber (Fagaceae). P. cylindrus was traditionally recorded as a secondary pest, with damages limited to dead and weakened trees. In recent decades, it has promoted cork tree death within a few years and been part of a complex multifactorial process of decline affecting cork oak forests involving several microorganisms. The associated fungi are well studied, and it is known that they can have an important adverse effect on the tree, but no knowledge exists about the bacteria in this specific interaction. The cause of the beetle outbreak remains still unknown leading to the formulation of the hypothesis of a new insect-symbionts interaction. The aim of this study is assessing the presence and the putative role in oak decline of the bacteria associated with cork oak and P. cylindrus. We provide an in-depth overview of the bacteria associated with this pathosystem by means of a culture dependent approach for strain isolation and phylogenetic identification of bacterial strains with 16S rRNA gene sequencing and multilocus sequence analysis (gyrB, atpD, infB), along with independent methods. The P. cylindrus bored galleries from five different cork oak trees, as well as the body and mycangia from male and female beetles were investigated. The whole set of wood and beetle samples revealed the presence of 68 distinct bacterial isolates, which were collected and used for sequencing. These allowed the construction of the phylogenetic tree, with the majority of the isolates belonging to two taxonomic groups: the Enterobacterales and the Actinobacteria. The largest set of Enterobacterales isolates were present only in the tree galleries and were allocated in a major group together with pathogenic strains from the Pectobacteriaceae family including Dickeya, Brenneria and Lonsdalea spp., collected from other Quercus spp. Beetle strains displayed high similarity levels with Curtobacterium sp., Microbacterium sp., and Brevibacterium sp. Furthermore, 16S metabarcoding complemented with a detailed overview of the bacteria, revealing specific ecological roles related to both the beetle and trees. The results highlighted a small sexual differentiation for the bacteria in the mycangia. Comparison between ASVs and full 16S sequences allowed the identification of a group of Pectobacteriaceae carried by the beetle. Lastly, prediction of metabolic pathways revealed upregulation in the galleries of carbohydrate and virulence factors. This study reports for the first time the bacterial community associated with the pathosystem Q. suber - P. cylindrus, contributing to highlight unique features of the cork oak-oak pinhole borer interaction in Portugal and compare them with other wood-boring beetle outbreaks and oak declines in different countries.

Pesticide-induced food and macronutrient limitation in beneficial predatory beetles in agroecosystems

Authors: Noreika Norbertas, Estonian University of Life Sciences, Estonia

Abstract: Pesticide usage is claimed as the main cause of insect declines. Beneficial predatory beetles are also exposed to indirect pesticide effects arising from reduced prey availability and quality. Our main aim was to investigate if higher food and macronutrient limitation in carabids are related to conventional agro-practices (especially pesticides). Individuals of different carabid species were collected by hand from 8 conventional and 8 organic oat fields scattered around Tartu, Estonia (three times). In the laboratory beetles were served with three semi-artificial diets: lipid-rich, protein-rich, sugar-rich. Consumption of each diet was evaluated after 24 hours (=test1). Afterwards, beetles were fed ad libitum for a week until full satiation. The procedure of test1 was repeated (=test2). The differences of consumed diets among two tests showed the level of food and macronutrient limitations in carabids within assemblages. Separately, pesticide residue analyses in beetle bodies were performed. Food and macronutrient limitations were more expressed in larger bodied, poorly dispersing species and for carabids from conventional rather than organic fields. 11 different pesticide residues were detected in carabid bodies from conventional fields. We conclude that reduced pesticide usage would improve carabid nutrition and fitness thus leading to higher efficiency in providing biocontrol service.

Approaches and tools to study the role of Juvenile Hormone in modulating insect behavior

Authors: Noriega Fernando G.[1], Nouzova Marcela[1], [1]Florida International University, United States

Abstract: Juvenile hormones (JHs) are sesquiterpenoids synthesized by the corpora allata (CA). They play critical roles during insect development and reproduction. JH titers in insects are often in the femtomole to picomole range, which makes it challenging to measure them by most typical analytical techniques. In addition, to study processes that are controlled by JH, researchers need tools that can increase or decrease JH titers in vitro and in vivo. JH titers in insects can be easily increased by topical application of JH analogs (JHA), such as methoprene. On the other hand, purposely decreasing JH titers has been more difficult. In this presentation we will summarize the current knowledge on 1) Detection and quantification of JH from insect samples. 2) Approaches to manipulate JH titers. 3) New "omic-approaches" to modulate JH action and behaviour.

Epoxidation of juvenile hormone was a key innovation improving insect reproductive fitness

Authors: Noriega Fernando G.[1], Nouzova Marcela[1], Ramirez Cesar[1], Fernandez Lima Francisco[1], Areiza Maria[1], DeGennaro Matthew[1] and Michalkova Veronika[1], [1]Florida International University, United States

Abstract: Methyl farnesoate (MF) plays hormonal regulatory roles in crustaceans. An epoxidated form of MF, known as juvenile hormone (JH), controls metamorphosis and stimulates reproduction in insects. To address the evolutionary significance of MF epoxidation, we generated mosquitoes completely lacking the enzyme that catalyzes the last step of JH biosynthesis, the P450 epoxidase CYP15 (EPOX). Strikingly, epox-/- mutants, which synthesized MF but no JH, completed the entire life cycle. While epox-/- adults were fertile, the reproductive performance of both sexes was dramatically reduced. Our results suggest that although MF can substitute for the absence of JH in mosquitoes, it is with a significant fitness cost. We propose that MF can fulfill most roles of JH, but its epoxidation to JH was a key innovation providing insects with a reproductive advantage.

Does thiamethoxam reduce circadian rhythmicity and lower activity in Bombus impatiens?

Authors: North Heather[1], Bowsher Julia[1], Yocum George[3], [1]North Dakota State University, [2]USDA Ed. T. Schafer Agricultural Research center

Abstract: Bumblebees (Bombus impatiens) are economically and ecologically important wild pollinators in temperate regions of North America and recent declines are of major concern. One reason for the decline is agrochemical use affecting non-target organisms like bumblebees. Bumblebees can be exposed to agrochemicals either directly by coming in contact with treated crops or indirectly by drift from agricultural fields. An agrochemical class of concern for the bumblebees are the neonicotinoids and specifically thiamethoxam which has become a popular choice among farmers in recent years. Neonicotinoids act as agonists of insect nicotinic acetylcholine receptors (nAChR) within the central nervous system. One possible target of neonicotinoids poisoning is the nAChR dependent neurons regulating the bumblebee's circadian rhythm. . We investigate activity and the circadian rhythms of bumblebees after chronic ingestion of field realistic levels of thiamethoxam. Thiamethoxam treatments included 0nM, 1nM, 10nM, 100nM. Although we did not observe an effect on circadian rhythmicity, we observed declines in activity in all treatment groups with significant reductions in activity at the highest dose of thiamethoxam. Our results suggest that thiamethoxam concentration at high does may reduce pollination efficiency through a reduction in overall activity levels.

The Impact of Glyphosate on Mitochondrial Function in Honey Bee Spermatozoa

Authors: North Heather[2], Bowsher Julia[2], Rajamohan Arun[1] and Mortenson Brett[2] [1]Ed. T. Shafer Agricultural Research Center USDA,ARS, Fargo, ND, United States, [2]North Dakota State University, United States

Abstract: The western honey bee is the most commercially managed bee, because of its value to agriculture. During the last few years, colony declines have been being recorded worldwide. Agrochemicals can act as inadvertent contraceptives among bees, affecting multiple reproductive mechanisms in the male, resulting in lowered sperm count, sperm viability and sperm motility. However, there are no studies demonstrating the effect of agrochemical exposure to changes in male reproduction at the cellular level. Mitochondrial activity can be indicative of the spermatozoa longevity, motility, and its ability to capacitate. We hypothesized that mitochondrial activity will decrease with increasing concentrations of N-(phosphonomethyl)glycine (glyphosate) exposure. We used the mitochondrial stain MitoTrackerTM (green) to measure mitochondrial function after exposure to glyphosate at three different near field-level doses (3.2 nmol, 32 nmol, and 320 nmol) as would be noted in the nectar or pollen. MitoTrackerTM stains indirectly assesses mitochondrial activity, mass, cysteine abundant proteins (thiol proteins), certain glycoproteins and the impact of reactive oxygen species (ROS). Thus, higher MitoTrackerTM (green) stain intensity can be construed an index of mitochondrial activity in the spermatozoa. Our Results indicate that in the presence of glyphosate there is increased mitochondrial activity in the presence of glyphosate, compared control to treatments. However, this finding is independent of increasing glyphosate dosages in the range of 3.2 - 320 nM. Since MitoTrackerTM accumulation is independent of the membrane potential, we believe that near field-level doses glyphosate exposure results in significant stress and elevated production of ROS. The effects of glyphosate on the membrane potential will be considered in future studies on honey bee reproductive stressors.

Triatominae symbiosis: unique after all?

Authors: Nováková Eva[4], Poosakkannu Anbu[3], Batani Giampiero[3], J. Brown Joel[1] and Rodríguez-Ruano Sonia[2], [1]Biology Centre of the Czech Academy of Sciences, Institute of Entomology, Ceske Budejovice, Czech Republic, [2]Department of Parasitology, Faculty of Science, University of South Bohemia, Ceské Budejovice, Czech Republic, [3]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic, [4]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic

Abstract: Kissing bugs (Triatominae) are obligate hematophagous (blood-feeding) insects and the only known vector of Chagas' disease (Trypanasoma cruzi). Like many organisms, kissing bugs host symbiotic bacteria within their guts (the gut microbiome) that are important modulators of host phenotype. However, compared to our comprehensive understanding of other symbiotic systems involving obligate blood feeders like tsetse flies, keds and lice, current research have not yet provided much insight into the symbiotic associations established by kissing bugs. The findings published so far often contradicts each other and fail to identify common drivers shaping Triatominae symbiosis. In our project, we have succeeded to sample over 500 Triatoma individuals of all life stages from their natural environment, i.e. pack rat (Neotoma albigula) nests, in Texas and southern Arizona. Using this extensive sample set, 16S rRNA gene amplicon sequencing, genomics and advanced visualisation techniques including TEM and confocal microscopy, we have investigated the natural host-microbiome relationship in multiple species of kissing bug. Our results bring the first visualisation of the microbiome assembly along with the identification of intracellular symbionts. Furthermore, being able to study individual microhabitats. i.e. pack rat nests, we conclude that ontogeny, species identity, and location are the primary factors influencing gut microbiome community composition. Contrary to previous reports on triatomine microbiomes, we demonstrate that there is a high degree of species-specific effect on the microbiome composition coupled with a positive correlation between microbiome dissimilarities and host phylogeny.

Microbiome convergency in kissing bugs and their predator relatives (Heteroptera: Reduviidae)

Authors: Nováková Eva[5], Poosakkannu Anbu[4], Zima Jan[4], J. Brown Joel[1], O. Schmidt Justin[3] and Rodríguez-Ruano Sonia[2], [1]Biology Centre of the Czech Academy of Sciences, Institute of Entomology, Ceske Budejovice, Czech Republic, [2]Department of Parasitology, Faculty of Science, University of South Bohemia, Ceské Budejovice, Czech Republic, [3]Southwestern Biological Institute, Tucson, Arizona, United States, [4]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic, [5]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic

Abstract: Reduvinae subfamily are the predator relatives to Triatominae (Heteroptera: Reduviidae), the vectors of Trypanosoma cruzi causing Chagas disease in humans and dogs. Phylogeny suggests that the obligate blood feeding strategy of triatomines evolved from the predatory habit of reduvids feeding on hemolymph of other invertebrates. Along with our attention to the epidemiologiacally important triatomins, we have decided to investigate one of the plesiomorfic traits of the reduvid ancestors that presumably facilitated the evolution of hematophagy, i.e. symbiosis with bacteria. In particular, we have sampled these two closely related bugs from sympatric populations and the exact same microhabitat, i.e. the nest of white-throated woodrats (Neotoma albigula), and profiled their microbiome using 16S rRNA gene amplicon sequencing. Microbiomes from Reduvius sp. (n=20) and two species of Triatoma (T. rubida and T. protracta; n=7) collected from Southern Arizona, US, were analyzed to explore the first hand knowledge on Reduvius-associated bacteria. Our results showed the presence of specific and shared taxa between Reduvius and Triatoma bugs. Compared to the triatomins, the predator microbiome however displayed a higher complexity and distinct dynamics. While the microbiome richness and diversity generally increase from the first to higher instars of Reduvius bugs, Triatoma species show significant decrease in the diversity indices throughout their ontogeny. Furthermore, beta-diversity analyses showed that Reduvius bugs have highly similar bacterial communities across the instars which is not the case in Triatoma.

Latitudinal life-cycle variations and their change in relation to climate warming in two Japanese crickets

Authors: Numata Hideharu, Graduate School of Science, Kyoto University, Japan

Abstract: Recent climate warming has affected some life-history traits of insects, including the number of annual generations and body size. The magnitude of changes in these traits may differ with latitudes within a species because of the differing cumulative effective temperatures for growth. In the present study, we estimated the change in the number of annual generations in Polionemobius mikado and Dianemobius nigrofasciatus over the last four and five decades, respectively, by comparing the body size of adults collected from a wide range of latitudes in Japan. These species are closely related in the family Trigonidiidae (Orthoptera), and distributed broadly in low-elevation grasslands in the Japanese archipelago. They have univoltine life cycles in northern Japan, but bivoltine ones in southern Japan with embryonic winter diapause.

The body size of P. mikado and D. nigrofasciatus collected in recent years showed a latitudinal saw-tooth cline, in the same way as the body size did four and five decades ago, respectively. The adult body size increases with decreasing latitude, but sharply decreases at a latitude where the number of annual generations increases.

In P. mikado, the cline shifted northward by 1-2° from 1970s to 2010s. The sum of effective temperatures for postdiapause embryonic development was greater in 2010s than in 1970s by approximately 200-400 day-degrees within each site because of global warming and heat island phenomenon. This difference of the sum of effective temperatures was comparable to that caused by an increase by 1-2° of latitude. Taken together, these findings suggested that the latitudinal range suitable for the bivoltine life cycle of P. mikado has expanded northward over the last four decades because of climate warming. In D. nigrofasciatus, however, no significant temporal change was observed in the cline between 1960s and 2010s, suggesting that the bivoltine life cycle had not expanded in the last five decades. Therefore, the effect of climate warming is not so simple and varies even between two closely related species with similar life cycles.

Transgenerational seasonal timer as an adaptation to spring short days in the pea aphid

Authors: Numata Hideharu[2], Endo Jun[2], Akimoto Shin-ichi[1] and Kanbe Takashi[1], [1]Graduate School of Agriculture, Hokkaido University, Japan, [2]Graduate School of Science, Kyoto University, Japan

Abstract: Most aphid species adapt to seasonal environmental changes, by switching from viviparous parthenogenesis in spring and summer to oviparous sexual reproduction in autumn. Sexual generations are induced by short days. Under short-day conditions in the laboratory, however, the appearance of sexual morphs is suppressed by a transgenerational seasonal timer after hatching of stem mothers from sexually produced eggs.

In the present study, we examined whether the seasonal timer measures the number of days or the number of generations from hatching in the pea aphid, Acyrthosiphon pisum. To distinguish the number of days and generations, we reared two lineages in which either early-born or late-born progenies were allowed to produce the next generation. The ability to produce sexual morphs was completely suppressed in stem mothers, and gradually recovered over successive generations produced during a few months. It was shown that the duration of the seasonal timer depended on the number of days from hatching, but not on the number of generations from hatching, by comparing the duration until the recovery of the ability to produce sexual morphs between early-born and late-born lineages. Moreover, the duration of the seasonal timer depended on temperature, but not on photoperiod.

Then we tested a hypothesis that the seasonal timer suppresses an unseasonal appearance of sexual generations which is induced by short days in spring, by rearing A. pisum under natural photoperiods and temperatures.

Stem mothers with the operative seasonal timer produced only parthenogenetic progenies in spring. In contrast, parthenogenetic females with the expired seasonal timer produced sexual progenies besides parthenogenetic ones in spring. These results show that photoperiods in spring induce sexual morph production as those in autumn, and the seasonal timer suppresses unseasonal appearance of sexual generations in spring.

Climate variability differentially impacts thermal fitness traits in three coprophagic beetle species

Authors: Nyamukondiwa Casper[1], Chidawanyika Frank[3], Machekano Honest[2], Mgidiswa Neludo[1] and Mutamiswa Reyard[4], [1]Botswana International University of Science and Technology, Botswana, [2]Department of Biological Sciences and Biotechnology, Botswana International University of Science and Technology (BIUST), Private Bag 16, Palapye, Botswana, Bot, [3]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [4]University of the Free State, South Africa

Abstract: While the impacts of extreme and rising mean temperatures are well documented, increased thermal variability associated with climate change may also threaten ectotherm fitness and survival, but remains poorly explored. Using three wild collected coprophagic species Copris elphenor, Metacatharsius opacus and Scarabaeus zambezianus, we explored the effects of thermal amplitude around the mean on thermal tolerance. Using standardized protocols, we measured traits of high- (critical thermal maxima [CTmax] and heat knockdown time [HKDT]) and -low temperature tolerance (critical thermal minima [CTmin], chill coma recovery time [CCRT] and supercooling points [SCPs]) following variable temperature pulses (d0, d3, d6 and d9°C) around the mean (27°C). Our results show that increased temperature variability may offset basal and plastic responses to temperature and differs across species and metrics tested. Furthermore, we also show differential effects of body mass, body water content (BWC) and body lipid content (BLC) on traits of thermal tolerance. For example, body mass significantly influenced C. elphenor and S. zambezianus CTmax and S. zambezianus HKDT but not CTmin and CCRT. BWC significantly affected M. opacus and C. elphenor CTmax and in only M. opacus HKDT, CTmin and CCRT. Similarly, BLC only had a significant effect for M opacus CTmin. These results suggest differential and species dependent effects of climate variability of thermal fitness traits. It is therefore likely that the ecological services provided by these species may be constrained in the face of climate change. This implies that, to develop more realistic predictions for the effects of climate change on insect biodiversity and ecosystem function, thermal variability is a significant determinant.

The diversity and ecology of viruses in the Drosophilidae, a ‘model’ insect family.

Authors: Obbard Darren[1], Wallace Megan[1] and Kuyateh Oumie[1], [1]University of Edinburgh, United Kingdom

Abstract: Drosophila have been model for insect-virus interaction since the symptoms of Drosophila sigma virus were first recognised in 1937. Drosophila experiments have since been instrumental in defining all of the major antiviral immune pathways of insects. However, the advent of high-throughput metagenomic sequencing has only recently allowed us to appreciate the diversity of viruses associated with the Drosophilidae. We have now identified over 100 RNA viruses - and around a dozen DNA viruses - associated with more than 20 species of Drosophila in the wild. These include virus lineages not previously recognised to infect insects (the dsRNA Partitiviruses) and entirely new virus families (the segmented +ssRNA Quenyaviruses).

We have used targeted metagenomics and PCR surveys to show that some of these viruses are highly prevalent (Galbut Partitivirus infects more than 50% of wild D. melanogaster and is detectable in all populations examined); some have naturally wide host ranges (Prestney burn virus has been seen in 12/15 Drosophila species surveyed); and some can have extremely high titres (over 50% of the coding RNA in a fly). However, we still know little of the costs associated with infection. Our experiments suggest a 20-30% reduction in lifetime offspring production is not unusual for females under laboratory conditions, but it is necessarily hard to estimate fitness effects smaller than a few percent - the magnitude that likely shapes evolution in the wild.

Honeybee colony strength is affected by spatial scale in fragmented landscapes in eastern Kenya

Authors: Ochungo Pamela[1], Abdel-Rahman Elfatih[2], Muli Eliud[6], Ng’ang’a James[4], Veldtman Ruan[5] and Landmann Tobias[3], [1]1. International Centre of Insect Physiology and Ecology (ICIPE), Kenya 2. Department of Conservation Ecology and Entomology, Stellenbosch, [2]1. Department of Conservation Ecology and Entomology, Stellenbosch University, South Africa 3. South African National Biodiver, [6]South Eastern Kenya University/International centre of insect physiology and ecology, Kenya

Abstract: Landscape fragmentation at multiple scales and habitat loss has a direct effect on species persistence, productivity and survival. Little is known about the effect of the surrounding landscape structure on honeybee colony performance in Kenya. Here we focus on how patch size, shape, connectivity, composition and configuration affect honeybee (Apis Mellifera) colony strength characteristics in a semi-arid agro-ecological landscape in eastern Kenya. The research was done within 6 study sites of varying degrees of degradation, during the period from 2017 to 2018; mapped using high resolution fused bi-temporal Sentinel-1A and Sentinel-2A satellite systems with an optimized random forest algorithm. The influence of the surrounding landscape matrix was constrained to spatial scales with a radius of up to 3km around the apiary to mimic average foraging distances of honeybees. The results of linear mixed effects models showed that adult honeybee population, amount of pollen and amount of brood increased with landscape homogeneity comprised of semi-natural vegetation at short distances from the apiary (500m), while simpler patch geometries at 1km radius from the apiary also had a similar effect on the same hive parameters. Amount of honey increased during the long rainy season that occurs in May, whereas during the driest month of the year (January), pollen amounts largely decreased, demonstrating that seasonality had a role to play for honey and pollen production. There were hardly any eggs in January, in contrast to May which had a large increment in the number of eggs. In contrast to expectations, honeybees in moderately degraded landscapes demonstrated the most consistently strong colonies throughout the study period, perhaps due the heterogeneity of the landscape, therefore availing forage from grasslands, croplands, weeds as well as natural woody vegetation. Colonies in the least degraded areas exhibited the highest rate of absconding, probably due to the presence of large hive beetles which were found in large numbers in the hives. Our results suggest that semi-natural landscape homogeneity, as well as proportion of croplands were most influential at short distances from the apiary (<= 1km), while complexity of patch geometries was most influential at longer distances from the apiary (2km). These results have important implications on hive placement and location for optimal hive productivity as well as pest control in least degraded areas for improved honeybee colony strength.

Flowers, florivores, and floral visitors across elevation gradients

Authors: Ode Paul, Colorado State University, United States

Abstract: The pervasive effects of climate change on the biosphere are increasingly evident with many well-documented impacts on species ranges and phenological events. As ectotherms, the phenologies of plants and insects are highly sensitive to changes in temperature. The vast majority of studies of climate change effects on terrestrial organisms have focused on the responses of individual organisms to changes in temperature and precipitation patterns. Far fewer studies have examined the effects of climate change on biotic interactions, yet studies are vital for our understanding of how climate change has (and will continue to) alter communities and ecosystems. This talk explores how changing temperatures differentially alter the phenologies of members of a simple trophic community (cowparsnip – Heracleum maximum, insect herbivore – parsnip webworm, its parasitoid wasp – Copidosoma sosares, and the suite of insect pollinators) across elevational gradients, resulting in phenological matches in warmer years and mismatches in colder years. In cooler years, cow parsnips at higher elevations largely escape herbivory; in warmer years, cowparsnip populations at higher elevations experience reduced fitness due to substantially increased levels of herbivory.

Determining the genetics of diapause termination in the codling moth (Cydia pomonella L.)

Authors: Oehlmann Christian[2], Neulichedl Peter[3], Wennmann Jörg[1], Janik Katrin[4], Heckel David[5], Jehle Johannes[1] and Zelger Roland[3], [1]Julius Kühn Institute, Federal Research Centre for Cultivated Plants, [2]Julius Kühn Institute, Germany, [3]Laimburg Research Centre, Entomology, [4]Laimburg Research Centre, Functional Genomics, [5]Max Planck Institute for Chemical Ecology

Abstract: Codling moth (Cydia pomonella L.) hibernates in a larval diapause stage and terminates diapause temporally heterogeneous during spring. Individuals terminating earlier in the season have a higher chance of completing several generations before returning into diapause, whereas individuals terminating their diapause later in the year have a lower chance of doing so. In the studies conducted at Laimburg Research Centre, two different codling moth populations were selected by inbreeding, which showed diapause termination which differed by several weeks (early and late), indicating an inherited genetic basis for these phenotypes.

As most studies are looking at downstream processes like transcriptomic or hormonal changes depending on the already started diapause termination, these studies are only meaningful to a limited extend for determining the environmental signal for diapause termination in the codling moth. Investigation of our selected populations populations showed, that the diapause termination signal is dependent on photoperiod and temperature. Crossing of distinct diapause-termination phenotype populations and genome sequencing can give valuable insights about genetic mechanisms responsible of diapause termination. Elucidating the genetic background of diapause termination in codling moth can help keeping track of the population dynamics in the field and therefore help pome fruit growers to adapt control treatments.

Re-surveys reveal biotic homogenization of Orthoptera assemblages as a consequence of environmental change

Authors: Ogan Sophie, Trier University (Germany)

Abstract: Biodiversity loss is a major global challenge. While population trends of vertebrates are well documented, insect declines have not been sufficiently studied and their drivers are still not fully understood. Repeating historical surveys can help to reveal the patterns and drivers of insect declines. We resurveyed 199 study sites in which Orthoptera assemblages had been recorded between 1986 and 1999 in south-west Germany. Our results show a significant increase in species per site (α-diversity), but simultaneously a homogenization of species communities (decreasing β-diversity). Habitat generalists became more frequent than specialized species and highly mobile species significantly increased in site occupancy compared to species with low mobility. Some Orthoptera species showed significant altitudinal range shifts, including species with positive trends (i.e. expansion to higher altitudes) and negative trends (i.e. extinction at lower altitudes). Protected areas had a high efficacy for conservation as trends in site occupancy were generally more positive in protected areas than in unprotected sites. Our results provide insights into the patterns and drivers of orthopteran assemblage turnover, including major effects of agricultural land use change and climate change. It is therefore critical to repeat historical surveys in order to understand global biodiversity change and implement the necessary actions.

Violet light increases Nesidiocoris tenuis population on crops.

Authors: Ogino Takumi, Shimoda Masami[2], Uehara Takuya[3], Uehara Takuya[4] and Kainoh Yooichi[1], [1]Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan, [2]Institute of Agrobiological Sciences, NARO, Japan, [3]Institute of Agrobiological Sciences, NARO, Japan, [4]National Agriculture and Food Research Organization (NARO), Japan

Abstract: Introduction: The minute pirate bug Orius sauteri and zoophytophagous plant bug Nesidiocoris tenuis have received attention as effective biological control agents against micropests. Banker plants are used to increase and maintain the populations of biological control agents by providing food resources. However, higher preference for banker plants can prevent the establishment of populations on cultivated crops. To develop a strategy for promoting attraction to cultivated crops, we previously investigated wavelength preference in O. sauteri. In a cultivated field, violet light promoted an increase in O. sauteri populations on cultivated crops and suppressed thrips density (Ogino et al., 2016), demonstrating that light illumination is a promising candidate for naturally attracting and maintaining natural enemies. In the present study, we examined attraction to light in N. tenuis to improve the establishment of its populations on cultivated crops.

Methods: We examined wavelength preference in N. tenuis using a six-arm arena equipped with six monochromatic light-emitting diodes (LEDs): ultraviolet (wavelength, 365 nm), violet (405 nm), blue (450 nm), green (525 nm), orange (590 nm), and red (660 nm). The behavior of the bugs on the arena was observed, and the wavelength for attraction was determined. Attraction to light was also investigated in tomato greenhouses. Banker plants were planted just inside each greenhouse entrance, and an LED was located at the innermost part of the greenhouse. N. tenuis adults were then released on the banker plants. The attraction effect in N. tenuis was evaluated by monitoring their movement toward tomato plants.

Results/Conclusion: 1) More N. tenuis individuals selected ultraviolet and violet light than other types of light. We assumed that violet light would selectively attract natural enemies, because it differs from the spectral preferences of most pest species. 2) More N. tenuis individuals were found on tomato plants in the LED-illuminated greenhouses than in the conventional greenhouses. In addition, more N. tenuis individuals remained near banker plants in the non-illuminated greenhouse, whereas in the illuminated greenhouse, bugs immediately dispersed from banker plants to crops and became uniformly distributed. In conclusion, light illumination is a promising strategy for attracting N. tenuis, which can promote controlling crop pests.

Wavelength preferences differ significantly among four species of thrips

Authors: Ohki Hiroto[5], Ogino Takumi[3], Yamaguchi Terumi[5], Shimoda Masami[5], Yoshida-Noro Chikako[1], Arikawa Kentaro[4] and Kainoh Yooichi[2], [1]Department of Applied Molecular Chemistry, College of Industrial Technology, Nihon University, Izumi-Cho, Narashino, Chiba 275-8575, Japan, [2]Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan, [3]Institute of Agrobiological Sciences, NARO, [4]Laboratory of Neuroethology, SOKENDAI (The Graduate University for Advanced Studies), Shonan Village, Hayama, 240-0115, Japan, [5]University of Tokyo

Abstract: [Introduction] Thrips are major pests of many agricultural crops. They cause severe damage by transmitting viral plant diseases. Since thrips have developed pesticide resistance, other pest control methods are necessary for successful integrated pest management. Exploiting the phototactic behavior of thrips by using colored sticky traps (i.e., yellow, blue, green) for monitoring thrips density, offers one possible approach. However, ideal color compositions for such traps are not known because the phototactic responses to specific light wavelengths have not been adequately studied in thrips species yet. This study analyzed wavelength preferences of four thrips species, Frankliniella occidentalis, Thrips palmi Karny, Thrips tabaci Lindeman, and Frankliniella intonsa, and elucidated the reasons for diversity in their wavelength preferences.

[Methods] Wavelength choice tests were conducted by illuminating a hexagonal arena with six monochromatic LEDs that covered the visible light spectrum of thrips. Phototactic behavior was evaluated using tracking analysis after recording the phototactic attraction to each wavelength. The spectral sensitivity of compound eyes was determined with the electroretinographic (ERG) method. A molecular phylogenetic tree based on the amino acid sequence of mitochondrial COI was constructed using neighbor joining. The implications of diversity in wavelength preference among thrips species were discussed.

[Results] Wavelength preferences: Four thrips species exhibited clear differences in their wavelength preferences. F. occidentalis and F. intonsa preferred shorter wavelengths (365–450 nm), including ultraviolet, whereas T. palmi and T. tabaci preferred the green wavelength (525 nm).

Spectral sensitivity of compound eyes: All four thrips species had bimodal spectral sensitivity curves that peaked at both ultraviolet and green wavelengths. The spectral sensitivity was consistent with the wavelength preference of T. palmi, but there was no correlation in other species.

Phylogenetic relationships: The phylogenetic tree indicated that F. occidentalis and F. intonsa are closely related, as are T. palmi and T. tabaci.

[Discussion] We found notable differences in wavelength preference among the four thrips species. However, spectral sensitivity did not correlate with wavelength preferences in F. occidentalis, F. intonsa, or T. tabaci. This indicates that the wavelength preference of thrips is related to the neural processing of light input signals from photoreceptors. The four thrips species have a wide range of host plants, and are common pests for many of them. The species that preferred ultraviolet wavelengths, F. occidentalis and F. intonsa, are often found on flowers, whereas those that preferred green, T. palmi and T. tabaci, are found almost exclusively on foliage. Therefore, our results indicate that wavelength preference is related to whether feeding is on flower nectar or leaf sap, rather than the host plant species.

Aggregation of host plants attract the specialist leaf beetle through change of the leaf chemicals

Authors: Ohsaki Haruna[2], Atsuko Miyagi[4], Kawai-Yamada Maki[3] and Yamawo Akira[1], [2]Hirosaki University, Japan, [4]Yamagata University, [3]Saitama University, [1]Hirosaki University

Abstract: Recent many studies have strongly suggested that plant-plant interactions affect resource utilization in herbivores through change in leaf traits of host plants. Here, we investigated the effects of phenotypic plasticity in leaves of Rumex obtusifolius (host plant) in response to intraspecific and interspecific interactions on the distribution of Gastrophysa atrocyanea (specialist herbivore).

In the field, the presence of G. atrocyanea was positively correlated with the local population density of R. obtusifolius. In the cultivation experiments, plants in the intraspecific interaction treatment increased their leaf concentrations of condensed tannins and total phenolics, and G. atrocyanea consumed more of these leaves than leaves in interspecific or no interaction treatments. Similar results were observed in the field. In the mesocosm experiments, larger numbers of G. atrocyanea were distributed on R. obtusifolius exposed to intraspecific interaction than on plants not exposed to intraspecific interaction.

The previous understanding of the resource concentration hypothesis was that a high density of host plants makes it easier to find them, i.e. that ‘resource quantity’ is important. However, our results show that changes in the chemical composition of leaves due to intraspecific interaction with neighbouring plants, i.e. ‘resource quality’, is an important factor in determining the distribution of herbivores.

Object Detection of Camouflaged Insect by Artificial Intelligence

Authors: Okamoto Ryoma[2] and Mori Naoki[1], [1]Osaka Prefecture University, Japan

Abstract: Insects are found everywhere and often blend into nature to protect themselves from their enemies or to ambush prey. Insects hiding in this way are often difficult to spot at a glance, not only by their natural enemies and preys but also by humans. On the other hand, the performance of artificial intelligence (AI) in image recognition has been improving dramatically. In this context, image recognition of camouflaged objects, which detects hard-to-find objects in an image, has been attracting attention. There have been few experiments on image recognition of camouflaged objects, focusing only on insects. In this study, we tried to recognize camouflaged insects by AI in object detection, an image recognition method. Specifically, we investigated the prediction accuracy of AI for camouflaged insects in experiments using a combination of YOLOX, the latest model of YOLO, a typical machine learning model for object detection, and TDGA AA, one of the methods for image data augmentation for AI. As a result of the experiment, we obtained promising results by the proposed method as a COD10K as an example.

Diversity of fungus gnat-pollination systems and the fine-tuned convergence in floral characters: a new pollination syndrome

Authors: Okamoto Tomoko[1], Kawakita Atsushi[3] and Wang Chun-Neng[2], [1]Gifu University, Japan, [2]Institute of Ecology and Evolutionary Biology, National Taiwan University, Taiwan, [3]The Botanical Gardens, Graduate School of Science, The University of Tokyo, Tokyo, Japan

Abstract: Dipteran insects are among the most common visitor to the flowers, yet the communications and its consequence on floral adaptation is less understood compared to those involving other pollinators such as bees. The fungus gnat is the groups of tiny fly families belonging to Nematocera. As they feed on fungi, moss, and plant litter, they are abundant in humid forest. Because of their tiny body, fungus gnats are often regarded as ineffective as pollen carriers, though in recent years, it has been found that several plant families shares fungus gnats as pollinators, forming a pollinator guild in the Japanese flora (Mochizuki and Kawakita, 2018 Ann. Bot.). Notably, plants also shares floral characters: dark red display, flat flowers, exposed nectary, short stamen, and fermented scent.

In this study, we hypothesized the set of shared floral traits to be convergence towards fungus gnats, namely floral syndrome involving fungus gnat pollinators. To test the hypothesis, we investigated the pollinators of the species in the genus Euonymus and its evolutionary relationship to floral traits in a phylogenetic context. All the investigated five species with dark red flowers were pollinated predominantly fungus gnats, and five greenish-flowered Euonymus species and the outgroup white-flowered Tripterigium species were pollinated by bees, beetles, and Brachyceran flies. There were strong correlation among pollinators, flower color, morphology (stamen length), and floral volatile. Ancestral reconstruction suggested that fungus gnat-pollinated has originated at least four-times, each time the dark red flower has evolved, and the floral scent bouquet mainly composed of acetoin has occurred three-times. These result indicate that adaptation towards fungus gnat pollination drives unique floral syndrome.

The floral scent bouquet dominated by acetoin is not common in angiosperms, suggesting that fungus gnats are functional group of pollinators distinct from any other pollinator taxa. As sensory and preference of the flies may be diverse corresponding to their diverse life history, flies may contain several functional pollinator groups and involve distinctive, fine-tuned floral adaptations.

Coexistence of honeybees with distinct mitochondrial haplotypes and hybridized nuclear genomes on Comoros Islands

Authors: Okwaro Allan[1], Muli Eliud[3], Lattorff Michael[4] and Runo Steven[2], [1]International centre for insect physiology and ecology, Kenya, [2]Kenyatta University, Kenya, [3]South Eastern Kenya University/International centre of insect physiology and ecology, Kenya, [4]University of Nairobi; Martin-Luther-University Halle-Wittenberg

Abstract: The Western honeybee, Apis mellifera, is a globally distributed species which has spread both naturally and by humans. Well-defined population sub-structure exist with different evolutionary lineages defined via the divergence in their mtDNA genotypes. The divergent lineages can interact through naturally occurring overlap in distribution ranges or secondary contact via human-mediated transport. Such contacts are characterized by preferential replacement of specific mtDNA genotypes. For instance, the Africanized honeybees in the Americas are characterized by complete replacement of the European bee mtDNA genotypes with African genotypes despite showing complete hybridization in the nuclear genome. Similar cases of preferential replacement of specific mitotypes are reported in La Réunion, an island located south-west of the Indian ocean, where European genotypes have been imported 30 years ago. However, few studies have investigated the population structure and diversity of honeybee populations existing as feral colonies with minimum human interference. Here, we are investigating the genetic diversity, genetic differentiation and population structure of isolated honeybee populations existing as wild colonies on Comoros islands, which is best suited as beekeeping is not well established and the islands are isolated from the continental plate. Using genotyping and phenotypic markers, we show that the wild honeybees of the Comoros Islands consist of two coexisting mitochondrial haplotypes. One belongs to the A-lineage, Apis mellifera unicolor, typical for the African continent, the other, the newly described L-lineage, is closely related to Apis koschevnikovi, a honeybee species native to Southeast Asia. The nuclear genomes of A. mellifera show complete hybridization with slight differentiation according to the island of origin, as evidenced by microsatellite markers and wing shape as a phenotypic trait. Our results suggest that the Asian honeybee has been introduced in Comoros islands. This introduction could have occurred during the human migrations of Southeast Asian people to Africa which occurred 6,000 years ago, reaching Madagascar and the Comoros Islands. The transported honeybee has since hybridized with African honeybees at the nuclear genome but still maintain the original mtDNA genome.

Diseases and pests emerging in domestication of some African stingless bees in East sub-Sahara Africa

Authors: Okwaro Allan[2], Nkoba Kiatoko[1], van Langevelde Frank[4], Odhiambo Obura[1] and Raina Suresh[3], [1]International Centre for Insect Physiology and Ecology, icipe, Kenya, [2]International centre for insect physiology and ecology, Kenya, [3]Nagpur University, India, [4]Resource Ecology group, Wageningen University, Netherlands

Abstract: We conducted a surveillance at 5 meliponicultures sites around the Eastern remnant rainforest in the East sub-sahara Africa to identify diseases and pests damaging managed colonies of five stingless bee species. Domesticated stingless bees included, H. gribodoi, M. ferruginea, M. togoensis, M. lendliana and M. bocandei. Using microbiology technics, we identify yeast or fungal infesting colonies nest. We also used molecular biology techniques, to tested for the presence of eight common honeybee pathogens among the reared stingless bee colonies. Furthermore, pests or predators infesting, and robbing colonies where also determine. Susceptibility to yeast or fungal pathogens, we isolated a disease-causing fungal Peyronellaea pomorum affecting involucrum and pillar in nest of M. ferruginea, M. togoensis, M. bocandei and M. lendliana. The fungal infestation mostly occurred during heavy raining season and infested nests dehydrates causing collapse of the colony. Nest absconding rate due to infestation was moderately higher in M. lendliana colonies (56.3±12.4) and proportion of damaged colonies was 33%. Susceptibility to eight common honeybee pathogens (Deformed Wing Virus, Black Queen Cell Virus, Kashmir Bee Virus, Israeli Acute Paralysis Virus, Chronic Bee Paralysis Virus, Acute Bee Paralysis Virus, Sacbrood Virus and Nosema microsporidia) showed presence only of Black Queen Cell Virus, in three stingless bee species (Hypotrigona gribodoi, Meliponula bocandei and Meliponula lendiliana). Black Queen Cell Virus was reported in 14.14% of all the sampled colonies; which support the notion that honeybee pathogens can possibly be transmitted to stingless bees. However, it remains unclear whether the pathogen has a detrimental effect on the stingless bee colonies. Susceptibility to pests, we identified two species of insects namely Aethina tumida and Megaselia scalaris. Olfactometer bioassays of both sexes of Aethina tumida adults to stingless bee species odors from intact colonies and separate hive components revealed both sexes strongly preferred intact colony, pot honey, and pot pollen odors, rather than propolis and cerumen odors. This result provides substantial evidence of the host potential of African meliponine bees for the Small hive beetles. Aethina tumida larvaes infestation was higher in M. togoensis (34.6±5.6) and M. bocandei (31.7±4.8) but absent in H. gribodoi colonies. The proportion of damaged colonies due to infestation by Aethina tumida larvaes was 100% in M. togoensis colonies and moderated in other species. Similarly, colonies infestation rate by Megaselia scalaris larvaes was higher in M. togoensis (30.4±6.1). The proportion of damaged colonies due to infestation was mainly higher by 75% in H. gribodoi, 68.75% in M. togoensis and 50% in M. lendliana colonies. Susceptibility to predators, three enemies were identified namely Apis mellifera, Philanthus sp (wasp), Elminia longicauda teresita (bird) preying on honey and forager bees.

Pollen or commercial diets? The honey bee response in presence of pesticides

Authors: Olden Farida[1] and Palmer Joseph[1], [1]Kentucky State University, United States

Abstract: The European honey bee (Apis mellifera) is primarily reared for honey production, but its benefits are substantially higher considering it is the most important pollinator of crops. This tremendous insect is confronting several environmental challenges, including the intermingled effects of malnutrition and pesticide exposure. Pollen is intuitively the healthiest choice for honey bee nutrition, but commercial substitutes are widely used to offset pollen shortages despite their unclear nutritional value. In the present study, we examined if honey bee reaction to chemical exposure is impacted by feeding pollen versus an artificial diet. Newly emerging bees were distributed into 3 groups of 6 cages, with each group receiving one of the following diets: pollen / sucrose, MegaBee / sucrose or sucrose only. On day-5, for each diet, 3 cages were kept pesticide-free to constitute the controls while the remaining cages were fed a mixture of chlorpyriphos and fluvalinate for 5 consecutive days to constitute the chronic chemical exposure treatment. To investigate if and how the different diets influence the honey bee reaction to pesticide exposure, we measured several physiological traits (body weight, fat body mass, hypopharyngeal gland development, hemolymph protein concentration, midgut proteolytic enzyme activity, hindgut protein content, and vitellogenin expression). We also examined the transcription levels of nutrition response genes, primary and secondary antioxidants, detoxification genes, immunity genes as well as acetylcholinesterase (AChE) which is the target of the organophosphate chlorpyriphos. Finally, to gain insight on the extent of alternative splicing in honey bee in response to environmental stress, we investigated the alternative splicing of few genes known to be highly spliced in drosophila.

Inter-drone competition drives the evolution of paternally-biassed gene expression related to female reproductive traits in the Cape honey bee Apis mellifera capensis

Authors: Oldroyd Ben[1] and Smith Nicholas[1], [1]Behaviour and Genetics of Social Insects Lab, Macleay Building University of Sydney, Australia

Abstract: The Kinship Theory of Genomic Imprinting (KTGI) posits that, in species where females mate with multiple males, there is strong selection for a male to enhance the reproductive success of his offspring at the expense of other males and his mating partner. Reciprocal crosses between honey bee subspecies show strong parent-of-origin effects for reproductive traits, suggesting that males epigenetically modify the expression of genes related to female function in their female offspring. This effect is likely to be strongest in the Cape honey bee (Apis mellifera capensis), because a male's daughters have the unique ability to produce female offspring that can develop into reproductive workers or the next queen without mating. We used RNA-seq to identify transcripts that are over- or under-expressed in Capensis embryos, depending on the parental origin of the gene. As predicted, 21 genes showed expression bias towards the Capensis father's allele in colonies with a Capensis father, with no such bias in the reciprocal cross. A further six genes (0.003% of informative genes) showed a consistent bias towards expression of the father's allele across all eight colonies examined, regardless of the direction of the cross.

Consistent with predictions of the KTGI, two of the six genes are associated with female reproduction and one with gametogenesis.

On springtails (Hexapoda: Collembola): A morphofunctional study of the jumping apparatus

Authors: Oliveira Fabio, Universität Rostock Institut für Biowissenschaften, Germany

Abstract: Springtails (Hexapoda: Collembola) are tiny organisms that lead a hidden life,style (e.g. they occurring deeper in the soil and in leaf litter). Springtails have a variety of interesting body morphology patterns, the most famous of which is their catapult-like structure that enables them to jump and flee from predators. This highly specialized jumping apparatus consists of the a mobile furca, which when at rest fits into a trigger, "the "retinaculum", on the ventral side of the abdomen. In this study, the morphology of the jumping apparatus of Orchesella cincta was investigated in detail using confocal laser scanning microscopy (cLSM) and MicroCT techniques for 3D reconstructions. In the following, the morphology of O. cincta with both flexed and extended furca was is analysed and described step by step. With the data obtained in this study, hypotheses can be made about 1) where and how the spring and hydrostatic pressure mechanisms are constructed originate; 2) which muscles act on the extension and flexion of the furca and 3) which muscles act on the retinaculum.

Characterising the epigenetic landscape of the Anopheles gambiae complex

Authors: Oliver Shüné[2], Carlin Sousa Neves Jeanrenaud Alexander[3], Brooke Basil[1] and Patel Nashrin[3], [1]Centre for Emerging Zoonotic and Parasitic Diseases, National Institute for Communicable Diseases, National Health Laboratory Service, Johannesburg, South Africa, [2]Vector Control Reference Laboratory, Centre for Emerging Zoonotic and Parasitic Diseases, National Institute for Communicable Diseases. Wits Research Institut, South Africa, [3]Wits Research Institute for Malaria, School of Pathology, Faculty of Health Sciences, University of the Witwatersrand & Vector Control Reference Laboratory

Abstract: Epigenetics is the study of inheritance coded outside of the genome. Although this field has grown rapidly in the field of cancer and diseases, it lags in entomology. In this study, we aimed to explore the little-known epigenetic landscape of the Anopheles gambiae complex, which contains several malaria vector mosquito species. This was done by examining whether larval heavy metal exposure would alter epigenetic markers in the accruing adults. This is because one member of the An. gambiae complex in particular, An. arabiensis, is adapting to breeding in polluted waters. Finally, we examined whether immune responses in the An. gambiae complex had an epigenetic basis, as the immune system underlies vector competence.

The epigenetic modulator and metal studies were limited to two laboratory strains of An. arabiensis, the insecticide susceptible SENN strain and the insecticide resistant strain selected from it, SENN-DDT. An. arabiensis larvae were reared in cadmium chloride, copper nitrate or lead nitrate treated water. In accruing adults, the m6A RNA methylation levels, and 5mC and 5hmC DNA methylation and Histone acetyl transferase activities were assessed using commercial kits. For the immune studies, two additional strains were included; the minor vector An. merus (MAFUS) and the non-vector An. quadriannulatus (SANGWE). Adult females of these two strains, in addition to SENN and SENN-DDT, were stimulated by being fed either a Gram-positive bacterium or a Gram-negative bacterium-spiked blood, and epigenetic markers were assessed by commercial calorimetric kits.

Under control conditions, RNA methylation differed significantly between males and females of the SENN and SENN-DDT strains. There were significant differences between the 5mC levels of males and females in the SENN strain. The SENN strain was also generally more sensitive to changes in methylation levels. HAT activity levels were also markedly affected by larval metal exposure, with a clear suppression of HAT activity in SENN and a marked increase in SENN-DDT.

Within the An. gambiae complex, basal RNA methylation levels differed in all three species, although there were no significant differences after immune stimulation. MAFUS had the highest basal and blood meal-induced levels of 5mC. SANGWE displayed the highest level of 5mC methylation in response to Gram-positive blood. 5hmC methylation, which is associated with demethylation and therefore gene activation, did not differ between strains at basal levels. SANGWE had the greatest amount of methylation in response to blood and Gram-negative stimulation. Differences in HAT activity, which also correlates with gene activation, was greatest in response to blood. Upon Gram-positive stimulation, the two An. arabiensis strains had significantly higher levels of HAT activity than the An. merus and An. quadriannulatus strains. This study provides some of the first evidence of the role of epigenetic architecture in the An. gambiae complex.

A survey of ticks and tick borne parasites in commercial cattle at Lafia, Nasarawa State, Nigeria

Authors: Ombugadu Akwashiki[1], Adejoh Victor[1], Asabe Yohanna Jael[3], G Rwang Pam[1], Ndubuisi Uzoigwe Raph[1], Naphtali Rebecca[2] and Pam Victoria[1], [1]Federal University of Lafia, Lafia Nasarawa State Nigeria, [2]Modibo Adamawa University Bauchi, Nigeria, [3]University of Jos, Jos Plateau State Nigeria

Abstract: Ticks and tick borne parasites are a major constrain to good livestock productivity in the Sub-Saharan Africa including Nigeria. This study aimed at determining the prevalence of ticks and tick borne parasites in cattle at Shinge Livestock Market Lafia Nasarawa State Nigeria. Ticks and blood collected from randomly selected cattle were examined using standard entomological, parasitological and haematological procedures. Out of the 200 cattle examined 112(56.0%) were tick infested. A total of 1,152 ticks were collected from all cattle examined. Rhipicephalus (Boophilus) decoloratus 948(62.3%) was the most abundant species infesting cattle breeds followed by Amblyomma variegatum 383(25.2%), then Hyalomma rufipes 184(12.1%), while Rhipicephalus sanguineus 7(0.5%) was the least tick species encountered. There was a very high significant difference ($P < 0.00001$) on species abundance. The bovine blood examined showed a 70.5% parasitic infection by two genera (Babesia and Anaplasma). Babesia bigemina 80(36.0%) was most prevalent, followed by Anaplasma marginale 77(34.7%), while Babesia bovis 65(29.3%) was the least prevalent. There was no significant difference ($P = 0.6848$) in prevalence rate between tick borne parasites. Haematological investigation showed that blood indices examined were within standard ranges. It is therefore recommended that dips be introduced at strategic points to herders for easy access to de-tick their animals.

Larvicidal Efficacy of Capsicum chinensis (Hot Pepper) Powder Against Mosquitoes Larvae in Lafia Local Government Area, Nasarawa State, Nigeria

Authors: Ombugadu Akwashiki[2], Aliyu Alhasan[2], Pam Dung[3], Micah Esla[2], Ahmed Hussein[2], Maikenti James[1], Njila Livinus[3], Isah Luka[3], Aimankhu Peter[2], Ayuba Scholastica[2], Odey Simon[2], Adejoh Victor[2] and Pam Victoria[2], [1]Department of Zoology Faculty of Science Federal University of Lafia Nasarawa State, Nigeria, [2]Federal University of Lafia, Lafia Nasarawa State Nigeria, [3]University of Jos, Plateau State, Nigeria

Abstract: Mosquitoes spread more diseases than any other known arthropod and have shown resistance to conventional insecticides despite several control efforts prompting the need to explore alternative control measures such as the use of bio-larvicides which are environmentally friendly. To this end, the study on larvicidal efficacy of Capsicum chinensis powder against mosquitoes larvae in Lafia Local Government Area, Nasarawa State, Nigeria was carried out through collection of wild field mosquitoes larvae from May to July, 2018. Fresh Capsicum chinensis fruits were collected from a farmland and dried under room temperature and further processed to fine powder from which varying concentrations were used against the larvae including the control group. The larvae were exposed at 24, 48 and 72 hours respectively based on WHO susceptibility protocol. Anopheles gambiae larvae were susceptible (100% mortality) to the various concentrations of the powder at the end of the 72 hours exposure period while Culex quinquefasciatus were resistant (0% mortality). There was significant difference ($P < 0.0001$) in mortality rate of An. gambiae larvae in relation to concentrations while there was no significant difference ($P = 1$) in mortality rate of Cx. quinquefasciatus across concentrations. LD50 and LD90 values for An. gambiae at 24 hours were 2.4mg/mL and 0.10mg/mL respectively; 0.1mg/mL and 0.26mg/mL respectively at 48 hours and 0.00mg/mL and 0.01/mL respectively at 72 hours. This study shows that Capsicum chinensis powder is a promising bio-larvicide for controlling An. gambiae while Cx. quinquefasciatus will require higher doses of Capsicum chinensis before they may be susceptible.

Survey of mosquitoes in students hostels of Federal University of Lafia, Nasarawa State, Nigeria

Authors: Ombugadu Akwashiki[1], Adejoh Victor[1], Asabe Yohanna Jael[3], G Rwang Pam[1], Ndubuisi Uzoigwe Raph[1], Naphtali Rebecca[2] and Pam Victoria[1], [1]Federal University of Lafia, Lafia Nasarawa State Nigeria, [2]Modibo Adamawa University Bauchi, Nigeria, [3]University of Jos, Jos Plateau State Nigeria

Abstract: The presence of mosquitoes in academic environment is a great threat to students well-being due to transmission of mosquito-borne diseases. Thus, the study survey of mosquitoes in students hostels of Federal University of Lafia was carried out between August and October, 2019 using Prokopack Aspirator. A total of 114 mosquitoes species belonging to 4 genera: Anopheles, Culex, Aedes and Mansonia. The predominant was Culex quinquefasciatus 65 (57.0%) followed by Anopheles gambiae 41 (36.0%) then 3 (2.6%) Aedes aegypti and Mansonia uniformis respectively while Anopheles squamosus and Anopheles coustani were the least 1 (0.9%), showing a high significance difference between the six species ($P < 0.0001$). The abundance of mosquitoes was more in male hostel 79 (69.3%) than in female hostel 35 (30.7%). Therefore, the mean abundance of mosquitoes between female and male hostels showed a significant difference ($P = 0.03636$). Blood fed female mosquitoes collected were 72 (69.2%) followed by those gravid 20 (19.2%) then unfed 9 (8.7%) while the least was half gravid individuals 3 (2.9%). Hence, the abundance of female mosquitoes in relation to their abdominal conditions showed a very high significant difference ($P < 0.0001$). The number of mosquito specimens collected during the study period was relatively low due high amount of rainfall flooding breeding sites in the area. This is the first study on mosquitoes population in the Institution's students hostels which will serve as a baseline data for mosquitoes control in the University environment. Students should avoid human-vectors contact through constant use of insecticides and treated bed nets.

Bioecology and qualitative analysis of the likelihood of Introduction of Tuta absoluta Meyrich (Lepidoptera: Gelechidae) via Export of Tomatoes from Nigeria to the USA

Authors: Omoloye Adebayo, Department of Crop Protection and Environmental Biology, Faculty of Agriculture, University of Ibadan, Nigeria

Abstract: The bioecology, damage characteristics of the tomato leaf miner, Tuta absoluta and the phyto-sanitary risks associated with export of fresh tomatoes fruits from Nigeria into the mainland USA was investigated. This pest is neither known to occur nor has been previously established in the USA although a closely related species, Keiferia lycopersicella (tomato pinworm) is present. Tuta absoluta is highly polyphagous and damaging on solanaceous crops and can survive in all tropical and sub-tropical conditions in the USA; presenting a potential risk to established vegetable crops in Florida, Texas and Alabama as well other states with similar environments. The impact of the pest could be very severe causing up to 100% yield loss and leading to increased tomato prices, bans on trade of tomatoes including seedlings, increase in synthetic insecticide applications, disruption of integrated management programmes of other tomato pests and general increase in crop protection cost. The high biotic potential, adaptability to various climatic conditions and the speed of spread could impact heavily on the livelihood of local tomato growers if introduced. The female T. absoluta lays about 260 eggs during its life time and it infests the apical buds and tomato leaves with visible mines. Egg eclosion at 26-30ºC and 60-75 % RH occurs in 5-7 days and the emergent larvae under these conditions pass through four instars in about 20 days and thereafter pupates in the soil. The consequence of introduction and entry potential through imported fresh fruits are high and the outbreak risks based on climatic conditions marching the pest etiology and host biotics as well as pest survival between crops could also be high. However, outbreak risks can be greatly reduced to the level meeting the phytosanitary protection of the importing country, USA; given application and enforcement of appropriate mitigation especially quality assurance and sorting, storehouse and pre-shipment treatment with environmentally safe pyrethroid insecticide and single point mitigation by gamma irradiation at approved dosimetry at the port of exit.

Neuroendocrine studies for the identification of target sites for next-generation insecticides

Authors: Ons Sheila, Insect Neurobiology Laboratory. Regional Center for Genomic Studies. Faculty of Exact Sciences. National University of La Plata. Buenos Aires, Argentina

Abstract: The persistent and excessive use of synthetic neurotoxic pesticides in agriculture, silviculture, animal husbandry and vector management created several difficulties on pest control: insecticide resistance, negative ecological impact, accumulation in the environment and food, etc. The use of many compounds has been phased out given their high environmental impact and/or the spreading of resistant populations. This is an alarming situation, given the reduction of the available options for the control of harmful arthropod species. Hence, there is an urgency in the development of novel eco-sustainable compounds for their use in integrated pest-management strategies, in order to replace or complement synthetic insecticides. A promising avenue in the development of novel compounds is the research in insect neuroendocrine system (neuropeptides and their receptors). It has been proposed that they are a source of targets for new-generation insecticides, given that neuropeptides play central roles in vital physiological processes in arthropods. The first step in a neuropeptide-based control strategy is the structural and functional characterization of neuroendocrine system from harmful species.

Our group performed comprehensive characterization of neuroendocrine complement in harmful species such as kissing bugs (Rhodnius prolixus, Triatoma spp), stinkbugs (Halyomorpha halys, Nezara viridula) and a lepidopteran species that is a pest of stored food (Plodia interpunctella). Using transcriptomic and genomic approaches, we were able to identify conserved features and particular characteristics for groups and/or species. Furthermore, we used RNAi-mediated gene silencing in hemipteran species to study the physiological roles of understudied neuropeptide families such as Orcokinins, CCHamide and ITG-like. Interestingly, we found that these poorly studied neuropeptide families have fundamental physiological roles in the regulation of either post-embryonic development, reproduction, diuresis or stress response. Even though we performed basic entomology, we are able to propose that some of the studied neuropeptides could be good targets for further studies in the development of next-generation tools for the control of hemipteran pests.

Reduced pollen return to commercial bumblebee colonies poses threats to nest provision and long-term health after exposure to field realistic levels of a pyrethroid and an organophosphate

Authors: O'Reilly Alison[2] and Stanley Dara[1], [2]University College Dublin, Ireland, [1]University College Dublin

Abstract: Bumblebees are important pollinators of crops and wild plants and threats to their decline poses a risk to the sustained provision of the they provide. Evidence suggests that exposure to field realistic levels of insecticides can affect bumblebee health and foraging behaviour, however most of these studies have investigated neonicotinoids only, with fewer investigating impacts on pollination services.

We exposed commercial bumblebee colonies to two widely used insecticide compounds; lambda-cyhalothrin (pyrethroid) and dimethoate (organophosphate) before foraging on potted oilseed rape plants in large exclusion cages. The results indicate that treatment didn't significantly affect individual foraging behaviour, visitation rates to the crop, or the yield of plants pollinated by bees from each treatment. There was, however, a significant effect of treatment on activity, with fewer bees leaving to forage from dimethoate colonies than from lambda-cyhalothrin and control. Additionally, significantly fewer bees from dimethoate and lambda-cyhalothrin colonies returned with pollen than control colonies. This suggests that over time, the health of colonies exposed to field realistic doses of these insecticides may deteriorate due to reduced activity and return of crucial pollen resources to the nest. Consequently, this may also pose a threat to the long-term sustained provision of important pollination services.

Weevil’s PGRP-LB circumvents endosymbiont immunogenicity and maintains host immune homeostasis

Authors: Orlans Julien[2], Heddi Abdelaziz[3], Butryn Agata[1], Vallier Agnès[2], Orville Allen[1], Zaidman-Remy Anna[2], Vincent-Monegat Carole[2], Sivignon Catherine[2], Rahioui Isabelle[2], Maire Justin[2], Galvao Ferrarini Mariana[2], Parisot Nicolas[2], Da Silva Pedro[2], Aller Pierre[1], Rebollo Rita[2] and Balmand Séverine[2], [1]Diamond Light Source Ltd., Didcot, Oxfordshire, United Kingdom, [2]UMR0203, Biologie Fonctionnelle, Insectes et Interactions (BF2i); Institut National des Sciences Appliquées de Lyon (INSA Lyon); Institut National de Recherche, [34]Univ. Lyon, UMR 203 INRAE/INSA-Lyon BF2i, France

Abstract: Peptidoglycan recognition proteins (PGRPs) represent a large protein family that is widespread from insects to mammals and play a pivotal role in immune response activation and regulation. However, while this family has been well investigated in pathogenic systems and conditions, little is known about their function in mutualistic associations. The cereal weevils Sitophilus harbors a Gram-negative intracellular bacterium, Sodalis pierantonius, which complements weevil’s diet with components lacking or in few amounts in cereal grains, and improves insect biological traits and invasive power. This bacterium is compartmentalized within specific host cells, the bacteriocytes, which form an organ around the gut, the bacteriome. This organ allows a fine-tuned regulation of host immune genes involved in endosymbiont control and host immune homeostasis.

We discovered recently in this association that pgrp-lb gene generates three transcripts with different cellular localization: A secreted isoform (extracellular) that is only expressed under pathogenic infection conditions; and, an intracellular and a transmembrane isoforms that are produced in the bacteriome. These last two isoforms specifically cleave the tracheal cytotoxin (TCT), an immunogenic peptidoglycan monomer released by the endosymbiont. The pgrp-lb silencing by RNAi results in TCT escape from the bacteriome to other insect tissues, where it chronically activates the host systemic immunity. To understand structural and functional specificities of the weevil’s PGRP-LB we recently have conducted X-ray crystallography and enzymatic studies of different PGRP-LB from endosymbiotic and non-endosymbiotic insect species. In this talk, I will present the main molecular and biochemical data obtained on this model system, and discuss how symbiotic evolutionary constraints may drive immune gene shaping and their adaptation to endosymbiosis.

Socioeconomic changes transform the pattern of biological invasions: history of invasions of beetles (Coleoptera) to Russian empire, Soviet Union and Russian Federation

Authors: Orlova-Bienkowskaja Marina, A.N. Severtsov Institute of Ecology and Evolution, Russian Academy of Sciences, Russia

Abstract: Our research group has compiled the first inventory of alien beetles of European Russia (ER) (https://www.researchgate.net/publication/334279194_Inventory_of_alien_beetles_of_European_Russia). Using this information, I analyzed beetle invasions to ER in three historical periods: before 1917 (when this territory was a part of Russian empire), in 1917-1991 (USSR) and after 1991 (Russian Federation). These periods drastically differ from each other in socioeconomic characters and I have found out that the pattern of beetle invasions was also quite different. The main sources of alien species established before 1917 were Europe, W. Asia and N. Africa. Many beetle species spread because of import of goods from Mediterranean region. Then, in 1917-1991, the main sources were Central Asia and East Asia. It could be probably connected with the transportation of goods within the USSR: from the republics of C. Asia and from the Far East. The main source of beetle invasions after 1991 is China, which is obviously connected with the dramatic increase of import from this country. 54 species were first recorded before 1917, 45 species in 1917-1991and 85 species after 1991. In general, the number of newly established alien species grew from decade to decade, but decreased in the period of the decrease of import to the USSR in 1917-1960. The distribution of newly established alien beetle species depended on the structure of the country and on features of historical development. St.-Petersburg was the capital of Russian Empire and had the first place in number of alien species newly recorded for the ER before 1917. Then after the transfer of the capital to Moscow, the first place belonged to Moscow. Now the first place belongs to the city of Sochi. This resort region is now developing quickly, and alien beetle species are often introduced with imported planting material. The main pathways of beetle invasions were different in different periods. The overwhelming majority of species established in the period of Russian Empire were unintentionally introduced with stored products and organic substrates. Then the increase of international plant trade caused the increase in introductions with planting material (seeds, seedlings, potted plants etc.): 24% of alien beetle species firstly recorded in ER in 1917-1991 and 41% - after 1991 were unintentionally introduced with planting material. The ratio of introductions connected with the import of wood also increased from 4% (before 1917) to 12% (in 1917-1991) and 14% (after 1991). Alien beetle species established in the previous periods are connected mainly with stored products and occur mainly indoors. But many of currently established beetle species are connected with living plants, establish in the wild and can potentially affect native ecosystems. This current tendency increases the possible negative ecological impact of invasions of beetles. The study was supported by Russian Science Foundation, project ?16-14-10031

Improving our knowledge of global bee distribution

Authors: Orr Michael[3], Hughes Alice[4], Zhu Chao-Dong[3], Chesters Douglas[3], Ascher John[1] and Pickering John[2], [1]Department of Biological Sciences, National University of Singapore, Singapore, [2]DiscoverLife.org, United States, [3]Key Laboratory of Zoological Systematics and Evolution, Institute of Zoology, Chinese Academy of Sciences, China, [4]Landscape Ecology Group, Centre for Integrative Conservation, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, China

Abstract: Insects, especially hyper-diverse lineages such as Hymenoptera, constitute the foundation of many ecosystems. We must know where insects live to conserve them, given recently-reported declines, lest we risk irreversible ecological damage. However, even bees, invaluable pollinators, lack a modern distributional synthesis based on empirical data. Here, we combine >5,800,000 public bee records with a uniquely-comprehensive 168,618-entry checklist of the ~20,000 bee species' distributions to reveal the global patterns of bee biodiversity while also examining the pervasive sampling biases which obscured this knowledge until now.

The route of infection influences the contribution of key immunity genes to antibacterial defense in the malaria vector Anopheles gambiae

Authors: Osta Mike A.[1] and San Dekmak Amira[1], [1]Department of Biology, Faculty of Arts and Sciences, American University of Beirut, Lebanon

Abstract: Insects deploy several humoral and cellular innate immune effector mechanisms to clear bacterial infections. While antimicrobial peptides, melanization, phagocytosis and complement-mediated attack are often described as the main players in different contexts, several knowledge gaps remain as to their regulation, specificity and relative contribution to microbial clearance. This is further complicated by the fact that the vast majority of bacterial challenges in model insects have been established through an artificial route by pricking the cuticle to introduce microbes directly into the hemocoel. While this mode of infection has allowed the dissection of systemic anti-microbial immune responses at different levels, it is associated with two major pitfalls. First, microbes are often introduced at large numbers which might blur the readouts from distinct effector programs due to saturation effects; low dose infections are most likely the norm in field conditions. Second, this mode of infection may not allow sufficient priming of the systemic response whether humoral or cellular. Here, we will address the contribution of key immune genes to tolerance and resistance of A. gambiae mosquitoes to systemic Serratia marcescens (Sm) infections established through direct injection into the hemocoel or through oral feeding. Sm is a Gram-negative bacterium with a broad host range including plants, vertebrates and invertebrates, and its ability to efficiently colonize the midguts of insects and to invade the midgut epithelium reaching into the hemolymph makes it an attractive microbe to address whether the route of infection alters the contribution of key immunity genes to the systemic immune response. We will also address by RNA seq analysis what functional gene groups are differentially regulated in the midgut and fat body in response to oral Sm infections relative to infections established by cuticular pricking

Clip-domain serine protease homologs: key players in the proteolytic cascades regulating melanization

Authors: Osta Mike A.[1], Saab Sally[1], Nakhleh Johnny[1] and El Moussawi Layla[1], [1]Department of Biology, Faculty of Arts and Sciences, American University of Beirut, Lebanon

Abstract: In Insects, key humoral immune responses such as antimicrobial peptide synthesis by the Toll pathway, melanization and complement-mediated attack are regulated by serine protease cascades composed mainly of clip-domain serine proteases (cSP) and their non-catalytic homologs (cSPHs). These cascades have been mostly studied in the context of melanization, an immune effector response that is triggered locally in response to cuticle injury or systemically following microbial invasion of the hemocoel. Despite being non-catalytic, cSPHs were shown initially to play critical roles in the insect melanization response by mediating the proper activation cleavage of PPO. Studies in the malaria vector A. gambiae revealed novel functions of cSPHs that extend beyond PPO activation to the regulation of complement activity. The substantial number of cSPHs and cSPs involved in melanization suggest that the protease cascades regulating this response are governed by a staggering complexity of interactions, especially that both cSPHs and cSPs form expanded gene families. Here, we provide an integrated view of mosquito cSPHs, their hierarchical organization and their critical role in controlling the proteolytic activation of cSPs. In fact, biochemical and genetic studies in our lab suggest that cSPHs are likely to interact with cSPs at different levels within the protease network that regulates melanization. Our data provide novel insights into the regulation of CLIP protease cascades in the mosquito hemolymph, which should help decipher the dynamic interactions between the cSP and cSPH components of these cascades.

Effects of Euscelidius variegatus Iflavirus 1 on fitness parameters and transmission ability of the phytoplasma vector E. variegatus

Authors: Ottati Sara[2], Rossi Marika[1], Galetto Luciana, Bodino Nicola, Rossi Marika[2], Ottati Sara[2] and Abbà Simona[2], [1]CNR Institute for Sustainable Plant Protection, Turin, Italy, [2]Institute for Sustainable Plant Protection, National Research Council of Italy (IPSP-CNR), Italy

Abstract: Virus-based biocontrol technologies have been discussed for decades as sustainable alternatives to synthetic pesticides in crop protection. New virus-based tools to control pests and plant diseases became a reality since the advent of NGS applied to viral metagenomic analyses of insect populations. In this perspective, we aimed at identifying potential biocontrol agents from the virosphere of phytoplasma vectors. Euscelidius variegatus Kirschbaum (Hemiptera Cicadellidae) is a polivoltine and polyphagous leafhopper and an efficient vector of phytoplasmas of agricultural importance (i.e. Flavescence dorée of grapevine). The transcriptomic analysis of an E. variegatus laboratory population reared in Italy (Torino, EvaTO) led to the identification of a new insect virus species ascribed to the Iflavirus genus. The +ssRNA virus was named E. variegatus virus 1 (EVV1). EVV1 infection appeared to be asymptomatic and had a 100% prevalence across EvaTO population. On the contrary, an E. variegatus laboratory population from France (Bordeaux, EvaBX) was found to be virus-free and used as a negative control. EvaBX individuals microinjected with EVV1 derived from EvaTO population (EvaVI) were able to vertically transmit the virus to offspring. In EvaTO rearing, the virus was present mainly in ovaries, but also in testes, hemolymph, Malpighian tubules and alimentary canal. It was also detected in the honeydew of infected individuals and on the surface of plants exposed to infected insects, but horizontal transmission appeared to occur only occasionally. We hypothesized that viral particles can penetrate the cuticle and replicate in the insect body only with a low efficiency. To evaluate the effects of EVV1 on newly infected insects, a rearing of EvaVI individuals was established. Longevity and fecundity of EvaVI insects were compared to those of EvaTO and EvaBX populations and related to viral loads. Preliminary results on EvaTO population showed that the virus was constantly detected both in phytoplasma-exposed and non-exposed vectors, but, interestingly, the virus load was significantly lower in FD-exposed insects. Phytoplasma acquisition and transmission efficiency of the three populations, reared under laboratory conditions, are under evaluation. New insights in EVV1-phytoplasma interaction might provide the unprecedented opportunity to promote the use of insect viruses as biocontrol agents against phytoplasma vectors. Moreover, the construction of infectious clones for virus-induced gene silencing (VIGS) could be used to manipulate the expression of the insect genes potentially involved in phytoplasma acquisition/transmission.

In vitro interactions between immunodominant membrane protein Imp of Flavescence dorée phytoplasma and protein extracts of its leafhopper vectors

Authors: Ottati Sara[3], Rossi Marika[2], Galetto Luciana, Bucci Luca, Marzachì Cristina, Manfredi Marcello[1] and Abbà Simona[3], [1]Center for Translational Research on Autoimmune & Allergic Diseases - CAAD Università degli studi del Piemonte Orientale, Novara, Italy, [2]CNR Institute for Sustainable Plant Protection, Turin, Italy, [3]Institute for Sustainable Plant Protection, National Research Council of Italy (IPSP-CNR), Italy

Abstract: Phytoplasmas are phloem-limited plant pathogenic bacteria that cause diseases in hundreds of plant species, producing severe economic losses to crops worldwide. Phytoplasmas are transmitted by Hemipteran insect species, belonging to the suborder Auchenorrhyncha (Fulgoromorpha and Cicadomorpha) and the family Psyllidae. Once acquired by an insect, phytoplasmas must cross its midgut membrane, spread in the hemolymph, colonize the salivary glands and enter the saliva in order to be transmitted to another plant. Since phytoplasmas are wall-less bacteria, membrane proteins are possibly involved with the internalization process in the host cell. In the present study, the involvement of immunodominant membrane protein (Imp) of Flavescence dorée phytoplasma (FDp) in the interaction with vector proteins was investigated. FDp is a grapevine quarantine pest and represents a major threat to the viticulture of several European regions. Scaphoideus titanus is the main natural vector of FDp to grapevine, whereas Euscelidius variegatus is commonly used as laboratory vector. In a previous work, we demonstrated that the external domain of FDp Imp selectively interacts with proteins from vector species rather than those from non-vectors. Nevertheless, the identity of the insect vector proteins interacting with FDp Imp is still unknown. Imp C-terminus domains of both FDp strains, covering the whole portion of the protein predicted to be exposed outside the bacterial cell, were synthetized together with His-tag, using an optimized E. coli expression system. Similar patterns of interacting insect proteins were obtained from both vector species, following pull-down procedure based on agarose beads conjugated with Nickel and saturated with His-tagged FDp Imp proteins. The insect proteins interacting with FDp Imp were trypsin-digested and analysed by mass spectrometry and the bioinformatic analyses are ongoing. Peptide identification was based upon the appropriate protein datasets, according to the NGS transcriptomes produced by our lab for both S. titanus and E. variegatus. Five E. variegatus proteins interacting with Imp were further characterized by measuring expression of their corresponding transcripts in different insect tissues and in healthy vs infected insects. The five genes were silenced to evaluate the effects on phytoplasma acquisition. The specific silencing of two of them, namely legumain and natterin-4-like, resulted in a significant reduction of phytoplasma multiplication in insects upon pathogen acquisition compared to control insects. As control of phytoplasma diseases is based on insecticides against vectors, this work is an initial step to elucidate key stages of FDp transmission specificity and vector infection mechanisms, which might be targeted to disrupt the epidemiological cycle, providing tools to integrate chemical treatments for more sustainable pest control.

Estimation of insect's flight parameters with entomological radar and radiosonde data

Authors: Otuka Akira[1] and Sanada-Morimura Sachiyo[2], [1]Institute of Agricultural Machinery, National Agriculture and Food Research Organization, Japan, [2]Kyushu Okinawa Agricultural Research Center, National Agriculture and Food Research Organization, Japan

Abstract: A variety of migratory insect pests arrive in Japan. To develop an overseas migration prediction model for pest management, we need to know flight parameters characterizing their migration process. To estimate the parameters, a x-band vertical looking radar (VLR) to monitor insects flying at altitudes in night was used. The study location was in an agricultural plain of 20×60 km surrounded by mountains in western Japan where rice and soybean are cultivated in summer. Daily radiosonde data observed at 2100 h local time over Fukuoka Meteorological Station 30 km northeast of the site were also used. Flight parameters were investigated for night events in September 2018 when many targets were recorded. Major targets in three nights were suggested to be mostly moths based on shape parameters of a2 and a4. Plots of target speed versus flight height indicated cluster of radar targets, and three patterns were found: (1) a lower speed side of the cluster perfectly followed radiosonde's wind speed profile line on 14 Sep, (2) the cluster was located 1-3 m/sec and more above the wind speed profile line on 25 Sep, and (3) the wind speed profile line ran through the cluster. To explain these patters, flight direction and orientation were examined. Targets' flight direction and orientation in the three cases corresponded to downwind direction at the cluster's height (NE, SW and SW on 14, 25, and 27 Sep, respectively: radiosonde data). However, variation of the orientation from the downwind direction was different: variation on 25 Sep, about ±25º, in case 2 was smaller than those on 14 and 27 Sep, ±35º in case 1 and 3, respectively. The results suggested that heading was toward downwind direction and that common orientation contributed to flight speed in case 2. Relationship between top height of the cluster in late September and the radiosonde's temperature profile suggested that temperature ceiling beyond which moths don't fly up is located around at a height of 14 ºC (case 2, 3). Since temperature at radar detection range 1461 m on 14 Sep was 18.2ºC in southwestern warmer winds, which is more than the threshold, many targets were observed up to the level and the temperature ceiling should be located over the radar range. Radiosonde data suggest a possible temperature ceiling is around 2200 m. Because the relationship between flight speed and wind speed as well as the temperature ceiling affect predicted migration paths, the approach to these important flight parameters with VLR and radiosonde nearby is important. The same estimation in different seasons and years is necessary for a further study.

Indoor resting behaviors of the dengue vector Aedes aegypti (L.) in northeastern Thailand

Authors: Overgaard Hans J[3], Seangarwut Chadapond[1], Muenworn1 Vithee[1] and Hanboonsong Yupa[2], [1]Department of Entomology, Faculty of Agriculture, Khon Kaen University, Thailand, [2]Division of Entomology and Plant Pathology, Faculty of Agriculture, Khon Kaen University, Thailand, [3]Norwegian University of Life Sciences, Norway

Abstract: Aedes aegypti (L.) is a vector of several arboviruses, for example the dengue virus (DENV), which causes dengue fever and more severe forms such as hemorrhagic fever. As there is no cure, nor an effective vaccine for dengue, vector control is currently the only effective method of prevention. Vector control generally consists of elimination of breeding habitats and space spraying (fogging) for adult control. Both larval source reduction and fogging have proven ineffective to reduce dengue outbreaks. Targeted indoor residual spraying (TIRS) against adult mosquitoes has been proposed as an effective preventive measure. Effective TIRS depends on knowledge of adult mosquito resting behaviors. The objectives of this study were to determine Ae. aegypti indoor mosquito resting patterns in different rooms at different heights and to assess mosquito DENV infection status. The study was conducted in 120 houses in two rural sites in Mahasarakham province and 120 houses in two urban sites in Khon Kaen province during May to August 2019. A mechanical aspirator was used to collect resting mosquitoes on the walls at low (0-0.75 m), middle (0.75-1.5 m) and upper (>1.5 m) levels in the bedroom, bathroom, living room and kitchen in each house. Collections were done for 10 minutes at each level in the morning (08:00-12:00 hours) and in the afternoon (13:00-17:00 hours). Mosquitoes were pooled and DENV infection in pools was confirmed by real-time RT-PCR (qPCR). Although other mosquito species were collected, here only the results of Ae. aegypti are reported. A total of 1361 Ae. aegypti was collected and 751 (45%) females and 610 (55%) males were recorded. More than double the number of Ae. aegypti was collected in the rural sites (n=946, 70%) versus the urban sites (n=415; 30%). Ae. aegypti mosquitoes rested in bedrooms (n=550; 40%), bathrooms (n=447; 33%), living rooms (n=292; 22%), and in kitchens (n=72; 5%). Most mosquitoes rested at the middle height (n=1008; 74%) and at the lower height (n=310; 23%). Only 43 (3%) specimens were collected at the upper levels of the wall. There was no significant difference between number of mosquitoes collected in the morning compared to the afternoon (p>0.05). DENV was detect in one mosquito pool from a rural area in Mahasarakham province. Further statistical analyses are ongoing. Knowledge of indoor resting behavior of adult Ae. aegypti is important because it can be used to choose the most appropriate and effective vector control method, for example selectively targeting the adult resting population using TIRS. It is recommended that governmental vector control authorities assess TIRS as a strategy for dengue vector control and focus on walls at heights lower than 1.5 m in all rooms in both urban and rural areas.

Aedes mosquito infestation and their dengue virus infection in households in Northeastern Thailand

Authors: Overgaard Hans J[8], Fustec Benedicte[7], Phanitchat Thipruethai[1], Pientong Chamsai[2], Phanthanawiboon Supranee[5], Thaewnongiew Kesorn[9], J. Bangs Michael[10], Alexander Neal[6], Nonyong Patcharaporn[3], Aromseree Sirinart[4] and Ekalaksananan Tipaya[4], [1]Department of Medical Entomology, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand, [2]Department of Microbiology, Faculty of Medicine, Khon Kaen University, Thailand, Norway, [3]Khon Kaen University, Khon Kaen, Thailand, [4]Khon Kaen University, Khon Kaen, Thailand; HPV & EBV and Carcinogenesis Research Group, Khon Kaen University, Khon Kaen, Thailand, [5]Khon Kaen University, Khon Kaen, Thailand; HPV & EBV and Carcinogenesis Research Group, Khon Kaen University, Khon Kaen, Thailand, Norway, [6]London School of Hygiene and Tropical Medicine, London, United Kingdom, [7]Maladies Infectieuses et Vecteurs: Ecologie, Genetique, Evolution et Controle, Institut de Recheche pour le Developpement, Montpellier University, France, [8]Norwegian University of Life Sciences, Norway, [9]Office of Diseases Prevention and Control, Region 7, Khon Kaen, Thailand, [10]Public Health & Malaria Control, International SOS, Mimika, Papua, Indonesia

Abstract: Aedes mosquitoes are vectors of several arboviruses that cause important human diseases, including dengue, zika, and chikungunya. There is no cure or effective vaccines against the diseases. Disease prevention is done by vector control. Entomological surveillance is a fundamental tool in monitoring and controlling vector borne diseases. Thailand, rapid Aedes larval surveys are the official method to estimate the house, container and breteau index. Pupal and adult surveys can provide more information and improve vector control, but they aren't officially implemented because they are challenging to carry out. The objective of this study was to determine mosquito infestation in households in northeastern Thailand, an area of endemic dengue, and to detect dengue virus (DENV) infection in adult collected Aedes mosquitoes.

The study was carried out in KhonKaen, Mahasarakham, RoiEt and Kalasin provinces in northeastern Thailand. Entomological collections were undertaken at consenting subject's household, and 4 neighboring houses, recruited from a prospective hospital-based case-control study. Mosquito larvae and pupae were collected from all positive containers. Adult mosquitoes were collected using a prokopack aspirator. Mosquitoes were identified to species. Here only species belonging to Aedes genus are reported. Adult mosquitoes were stored individually in in -80°C and processed for DENV detection and serotyping using RT-PCR. Adult mosquitoes were separated into head/thorax and abdomen. DENV detection were performed on pooled specimens using abdomen with a pool size of 1-10. Positive pools were confirmed by individual mosquito head/thorax.

A total of 1,493 households were included, of which 380 were subject's households and 1,113 were neighboring households. A total of 1,973 immature and 3,129 adult Aedes mosquitoes were collected. The majority, 97.4%, was Ae. aegypti and 2.6% was Ae. albopictus. The proportion of DENV adult positive pools were 38.7% (72/186). All four serotypes were detected from individual mosquito. The most frequent was DENV-3 with 38.0% (63/166), followed by positive with more than one serotype (26.5%; 44/166), DENV-2 (23.5%; 39/166), DENV-1 (7.8%; 13/166) and DENV-4 (4.2%; 7/166). KhonKaen had the highest percentage of DENV positive mosquitoes of the four provinces.

All four dengue virus serotypes are co-circulating in the study area at high levels indicating a high risk of dengue transmission. Understanding the distribution of the different dengue serotypes within a region is useful for planning control strategies. A combination of entomological surveillance and xenosurveillance of DENV presented transmission intensities in the mosquito-human cycle that could be a better indicator for dengue transmission and important for developing and improving effective vector control programs. Moreover, xenosurveillance will be a capable method to alert arbovirus and other pathogens circulating including new emerging diseases in future.

Seasonal variations in immunological and entomological indices to estimate dengue vector infestation, a longitudinal study in Northeastern Thailand.

Authors: Overgaard Hans J[7], Fustec Benedicte[5], Phanitchat Thipruethai[1], Pientong Chamsai[2], Thaewnongiew Kesorn[8], J. Bangs Michael[9], Alexander Neal[4], Aromseree Sirinart[3] and Corbel Vincent[6], [1]Department of Medical Entomology, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand, [2]Department of Microbiology, Faculty of Medicine, Khon Kaen University, Thailand, Norway, [3]Khon Kaen University, Khon Kaen, Thailand; HPV & EBV and Carcinogenesis Research Group, Khon Kaen University, Khon Kaen, Thailand, [4]London School of Hygiene and Tropical Medicine, London, United Kingdom, [5]Maladies Infectieuses et Vecteurs: Ecologie, Genetique, Evolution et Controle, Institut de Recheche pour le Developpement, Montpellier University, France, [6]Maladies Infectieuses et Vecteurs: Ecologie, Genetique, Evolution et Controle, Institut de Recherche pour le Developpement, Universite Montpellier, [7]Norwegian University of Life Sciences, Norway, [8]Office of Diseases Prevention and Control, Region 7, Khon Kaen, Thailand, [9]Public Health & Malaria Control, International SOS, Mimika, Papua, Indonesia

Abstract: The dramatic increase of arboviral disease incidence together with the global climate changes foresaw that human populations might be more and more confronted to vector-borne diseases.

Vector density is related to abiotic factors such as rainfall and temperature, and their seasonal changes may impact on the entomological indices and disease transmission surveillance. Due to their facility of implementation, house and container indices remains standard for dengue vector surveillance. However, immature-based indices may fail to assess vector density and dengue transmission risk in some contexts. Assessing dengue vector density by targeting adult mosquitoes can be difficult to implement and time-consuming. Immune response the Aedes Nterm-34kDa salivary peptide might represent a good marker of dengue vector exposure. The relation between the serological biomarker and the Aedes density and their seasonal variations need to be better described to help the vector-borne disease surveillance systems. Our study aims to assess the correlation between immunological and entomological indices. Then, data were analyzed together with the climatic factors to address the seasonal variation changes in Aedes density and to address the seasonal variations in immune response to a salivary biomarker of vector exposure.

Our study was carried out from September 2017 to September 2019 in Khon Kaen and Roi Et city. In each city, 18 clusters of ten houses were included. At each visit, blood sample were collected on filter paper from the same two individuals per house. Adult Aedes were collected using battery-driven mechanical aspirators during 15 minutes both indoors and outdoors, pupae and larvae were collected and containers were recorded at each visit. Three sentinel houses per cluster in each city were visited every month. In addition, all houses were visited every four months. Daily climatic data were collected at the subdistrict level for temperature, and humidity, except rainfall which was recorded at the city level.

At the submission time, only a portion of the total dataset was analyzed. The immune response to Aedes saliva was measured monthly on a total of 90 and 77 individuals from Khon Kaen and Roi Et cities respectively. Aedes collections were monthly perfomed in 80 houses in Khon Kaen city and 55 houses in Roi Et city. Every four months all of the 180 houses in each city were inspected for Aedes and a total of 251 and 248 participants were enrolled in Khon Kaen and Roi Et districts respectively. During the study period, 2217 and 1188 female Aedes were collected in Khon Kaen and Roi Et provinces respectively. Preliminary results suggest that entomological indices were higher during the rainy season in both provinces. We expect the immune response to the salivary biomarker to be correlated with entomological indices and their seasonal variations. The use of a serological marker to assess the Aedes exposure and might ease dengue vector surveillance.

Can insights into the metabolic costs of digestion in biocontrol insects help practitioners with post-release efficacy predictions?

Authors: Owen Candice[2], Bosua Henrieka[1] and S. Terblanche John[1], [1]Department of Conservation Ecology and Entomology, Stellenbosch University, South Africa, [2]Department of Zoology and Entomology, Rhodes University, Centre for Biological Control, Department of Zoology and Entomology, Rhodes University, South Africa

Abstract: Thermal physiology investigations that predict post-release establishment and control success have recently been gaining popularity in the field of weed biological control (biocontrol). These experiments generally involve classical methods that look at the agent's developmental or behavioural reactions to temperature. Most of the physiological processes within an insect's body, however, can be linked to the functionality of their metabolism or energetic costs of diverse processes. Consequently, metabolic physiological responses can help understanding of research organisms, but it is an area that has not yet been fully integrated into weed biocontrol programmes. This study aimed to determine the metabolic responses, costs of digestion (specific dynamic action [SDA]) and energy budgets in a widely-established biocontrol agent of water hyacinth in South Africa, Neochetina eichhorniae, over a range of temperatures. Respiratory rates were tracked over time throughout digestion of a host plant meal in order to determine how much energy was required to complete digestion, and how these costs change in different environmental conditions. Digestion can arguably be considered one of the most important aspects of a biocontrol agent's efficacy, as it determines feeding frequency and damage extent. Results have indicated that energy and digestion costs, including rates thereof, in N. eichhorniae differ greatly depending on the environmental temperature. We illustrate how these differences could have important knock-on effects on the efficacy of the agents in field sites with differing thermal regimes, potentially explaining the lack of establishment and adequate control in some. Furthermore, we advocate for the use of respirometry as a novel way to predict post-release efficacy.

A novel mode of action of the ectoparasiticide fluralaner on insect GABA receptors

Authors: Ozoe Yoshihisa, Faculty of Life and Environmental Science Shimane University Matsue, Japan

Abstract: Fluralaner is an isoxazoline ectoparasiticide used for tick and flea protection for dogs. In 2010, we reported for the first time that fluralaner (A1443) is a noncompetitive antagonist that inhibits agonist response in ?-aminobutyric acid receptors (GABARs) more potently than that in inhibitory glutamate receptors (GluClRs). Subsequently, we showed that the low sensitivity of GluClRs to fluralaner is attributable to a Leu conserved in transmembrane region (TM) 3. Recently, we sought to identify amino acid residues that contribute to the high sensitivity of insect GABARs to fluralaner. Housefly (Musca domestica) GABARs with amino acid substitutions in TM1–TM3 of the RDL subunit were expressed in Xenopus oocytes and examined for the effects of the substitutions on the sensitivity to fluralaner. The Q271L substitution in TM1 led to a significant reduction in the sensitivity to fluralaner. Whereas the I274A and I274F substitutions in TM1 did not change fluralaner sensitivity, the I274C substitution significantly enhanced the sensitivity to fluralaner. The L278C substitution at a position one a-helical turn below Ile274 resulted in a reduction in fluralaner sensitivity. Substitutions of Gly333 in TM3 caused substantial reductions in the sensitivity to fluralaner. Our data indicate that four amino acid residues (Gln271, Ile274, Leu278, and Gly333), which are in the outer half of the transmembrane subunit interface, are deeply involved in the antagonism of GABARs by fluralaner.

How to use species distrubution models for endangered species conservation? A case study of Boros schneideri

Authors: Ozols Janis[2], Aunins Ainars[3] and Kalninš Martinš[1], [1]Daugavpils University · Institute of Life Sciences and Technology, Department of Biosystematics, Latvia, [2]The Entomological Society of Latvia, [3]University of Latvia, Faculty of Biology, Latvia

Abstract: Boros schneideri is an endangered saproxylic beetle species in Europe, which is included in The Habitats Directive ANNEX II species list. In Latvia micro-reserves for species protection can be established.
B. schneideri has been found in Latvia for the first time in 2003 (Vilks 2003). Since then scientists from Lithuania, Latvia and Poland have described local factors affecting this species on micro-habitat level, such as light intensity, area and thickness of the remaining bark upon pine snags, presence of Ascomycota fungi mycelium on a trunk, trunk's circumference, tree species preference. Other important ecological factors are age of the forest stand, the presence of dead wood in different stages of decomposition, and the number of snags per forest stand and forest stand type.
This study aimed to identify landscape ecological factors affecting the occurrence of B. schneideri and to make the species' distribution models. To evaluate affecting landscape ecological factors, data of species' findings was obtained from Nature Conservation Agency of Latvia (DAP) and Latvia's State Forests (LVM) and data of forest stands – from State Forest Service (VMD). Together 353 findings were analyzed. Using ArcGIS program, we randomly selected ten times more absence points (3530) in forest covered areas. Around each point we made a square buffer with edge sizes 100x100m.
Species distribution model is affected by such factors as forest type, dominant tree species composition, forest age structure, fragmentation, distance from the forest edge and distance from the sea .
These models allow to determine the most important territories for needs of species conservation in Latvia. We believe these models allow to determine the most important territories in the whole range of distribution of B. schneideri with minor changes. Furthermore, it is possible to use these models for other endangered saproxylic beetle species such as Nothorhina punctata, Chalcophora mariana, Tragosoma depsarium, Ergates faber and others that live in pine forests.

Hard to catch: Experimental tests of escape mimicry in Adelpha butterflies

Authors: Paez Vargas Erika[3], Valkonen Janne[5], Mappes Johanna[5], Willmott Keith[4], Elias Marianne[2] and Matos Maraví Pável[1], [1]Biology Centre CAS, Czech Republic, [2]Institut de Systématique, Evolution, Biodiversité (UMR 7205) Muséum national d'Histoire naturelle, France, [3]Institut of Systematics, Biodiversity and Evolution , National History Museum Paris, France, [4]McGuire Center for Lepidoptera & Biodiversity Florida Museum of Natural History, United States, [5]University of Jyväskylä, Finland

Abstract: Preys that advertise predators about their difficulty of capture using conspicuous signals, and convergence of these warning signals among different hard-to-catch prey species, known as escape mimicry, seems to be more common in nature than supposed. Many authors have suggested that escape mimicry could evolved similarly to classical Batesian and Müllerian mimicry in chemically-defended species. As most research has focused on aposematism and mimicry related to chemical defenses prey, little is known about the mechanisms underlying escape mimicry evolution, such as predators' avoidance learning and generalization. We carried out the first experimental investigation of escape mimicry that uses bearing naturally occurring color patterns, those of the butterflies belonging to the neotropical genus Adelpha, which is potentially involved in escape mimicry. We tested bird capabilities to learn to avoid wing color patterns associated to an efficient escape mechanism. We subsequently tested whether birds generalized their avoidance learning to different, never experienced wing color patterns. Additionally, we compared avoidance learning and generalization of escaping preys to classical aposematism and müllerian mimicry (i.e. related to chemical defense). We evidenced that bird predators learned to avoid evasive preys and generalize this avoidance to their potential mimics. Finnally, we observed that avoidance learning on evasive prey was faster compared to that on distasteful preys, and generalization was asymmetric depending on the model that birds learned to avoid on the previous phase.
We conclude that an efficient escape mechanism is also a profitability feature that can be signaled to predators, and that appears more effective than the level of distastefulness tested in terms of predator's learning and generalization.

Value of Biological Control in Urban Eucalyptus Forests

Authors: Paine Timothy, University of California, Riverside, United States

Abstract: Biological control programs in California have targeted members of invasive borer, defoliator, and sucking guilds of herbivores feeding on eucalypts. Herbivore species in each guild were subject to biological control. Estimates of the total number of eucalypt street trees in California ranged from a high of 476,527 trees to a low of 190,666 trees. The estimated mean value of an individual eucalypt was $5,978. Thus, the total value of eucalypt street trees protected by biological control in California ranged from $1,139,801,348 to $2,848,678.406 at a cost of $3,949,251.

Tri-trophic interactions among the eucalyptus weevil Gonipterus platensis (Coleoptera, Curculionidae), its egg parasitoid Anaphes nitens and Eucalyptus globulus

Authors: Paiva Maria Rosa[2], Mendes Davide[4], Mateus Eduardo[2], Pereira Manuela[4], Gomes da Silva Marco[3], Branco Sofia[1] and Schütz Stefan[5], [1]CENSE – Center for Environmental and Sustainability Research, NOVA School of Science and Technology, NOVA University of Lisbon, Caparica, Portugal, [2]CENSE, DCEA, FCT NOVA, Universidade Nova de Lisboa, Caparica, Portugal, [3]LAQV–REQUIMTE, DQ, FCT NOVA, Universidade Nova de Lisboa, Caparica, Portugal, [4]2Chemistry Department, LAQV/ REQUIMTE, NOVA School of Science and Technology, NOVA University of Lisbon, Caparica, Portugal, [5]Department of Forest Zoology and Forest Conservation, Buesgen-Institute Göttingen University, Göttingen, Germany

Abstract: The eucalyptus weevil Gonipterus platensis (Coleoptera, Curculionidae) is a defoliator that has spread worldwide, causing economic damage to plantations of most Eucalyptus species. Biological control using the specific egg parasitoid Anaphes nitens (Hymenoptera, Mymaridae) often achieves satisfactory results, yet fails to control the weevil in colder regions. The work developed aimed at decoding the chemical ecology of this tri-trophic interaction. Different gas chromatography-mass spectrometry/ electroantennography/ olfactometry systems were used to detect, identify and test the biological activity of the organic volatile compounds (VOCs) emitted by Eucalyptus globulus, G. platensis and A. nitens. Results showed that Eucalyptus plants emitted 51volatiles that elicited antennal responses from G. platensis, 33 of which were identified with standards. In olfactometer tests it was established that three of these compounds, camphene, (+)-α-pinene and 2-phenylethanol attracted virgin females. Regarding the VOCs emitted by adult insects, three compounds were male specific, namely verbenene, cis-verbenol and trans-verbenol, while eight others were emitted by both sexes. Bioassays with A. nitens showed that parasitoid females were attracted to several compounds emitted by E. globulus, which were identified, as well as to G. platensis egg capsules and to female feces. The identification of several pheromone candidates of G. platensis was achieved and the host finding behaviour of A. nitens female wasps decoded. These breakthroughs allow for the design of new biotechnological monitoring and control strategies of the eucalyptus weevil, based on the use of VOCs, to manipulate the populations of the phytophagous insect and of its most efficient parasitoid. Use of data-driven models to predict to risk of invasion of pre-emergent pest species

Authors: Pallipparambil Godshen[2], Suiter Karl[1], [1]North Carolina State University, United States, [2]NSF Center for Integrated Pest Management, North Carolina State University, Raleigh, NC, United States

Abstract: A major pathway for the introduction of exotic invasive pests that impact the agriculture and natural resources of a region is through international trade of agricultural commodities and planting materials. Therefore, it is important to predict the likelihood that a pest may enter, establish and impact a new area. This knowledge allows to allocate the right amount of resources to identify and stop these pests before they reach or establish within our borders. In this session, we will discuss a framework of data-driven models to forecast the entry, establishment, and impact of pre-emergent pest species. Models used for this non-native pest forecast includes Self-Organizing Maps (SOM), a neural network algorithm using unsupervised competitive learning. We also examine the use of pest monitoring systems and the path forward in this new era of big data.

Hot, sour, and spicy: tolerance of bee parasites to high temperature, low pH, and pollen phytochemicals

Authors: Palmer-Young Evan[4], Raffel Thomas R [2], Schwarz Ryan[1], Chen Yanping [3] and Evans Jay[3], [1]Fort Lewis College, [2]Oakland University, [3]USDA-ARS, [4]USDA-ARS, United States

Abstract: Heat, acidity, and antimicrobial phytochemicals are three factors that can limit parasitic infection. The colony-level endothermy, acidic guts, and pollen-based diets of social bees provide unique opportunities to study how temperature, acidity, and dietary phytochemicals shape insect-parasite associations. We compared temperature, pH, and phytochemical tolerance between three trypanosomatid gut parasites from social bees and a related trypanosomatid from poikilothermic mosquitoes, which have alkaline guts and pollen-free diets.

Relative to mosquito parasites, bee parasites had higher heat tolerance that reflected body temperatures of hosts. Heat tolerance of the honey bee parasite Crithidia mellificae was exceptional for its genus, implicating honey bee endothermy as a plausible filter of parasite establishment. Whereas both honey bee parasites tolerated the acidic pH's found in bee intestines, mosquito parasites tolerated the alkaline conditions found in mosquito midguts. Bee parasites exhibited greater tolerance of chrysin—a flavonoid found in nectar, pollen, and plant resin-derived propolis. In contrast, mosquito parasites were more tolerant of cinnamic acid—a product of lignin decomposition present in woody debris-rich larval habitats.

Collectively, these results suggest that temperature, gut pH, and ingested phytochemicals could influence the distribution of trypanosomatids in insects and resistance to infection in pollinators.

Oral delivery of dsHvlwr is a feasible method for management of the pest Henosepilachna vigintioctopunctata (Coleoptera: Coccinellidae)

Authors: Pan Huipeng, Department of Entomology, South China Agricultural University, China

Abstract: RNA interference (RNAi) techniques have emerged as powerful tools for the development of novel insect pest management strategies, such as for Henosepilachna vigintioctopunctata (Coleoptera: Coccinellidae) that is a major pest of Solanaceae crops in Asia. Our results showed the lesswright (lwr) gene of H. vigintioctopunctata (Hvlwr) had an ORF of 480 bp and encoded a 160-amino acid protein. Levels of Hvlwr expression were greater in fat body than in other tissue types. Silencing of Hvlwr led to greater H. vigintioctopunctata mortality rates and appeared to be time- and partially dose-dependent, likely as a result of the number of hemocytes that increased with dsRNA concentration, but decreased with time. Bacterially expressed dsHvlwr that was applied to detached plant leaves caused 88, 66, and 36% mortality in 1st instars, 3rd instars, and adults after 10, 10, and 14 days, respectively; when applied to living plants, bacterially expressed dsHvlwr led to greater mortality in 1st and 3rd instars, with no effect on adults. Bacterially expressed dsHvlwr led to improved plant protection against H. vigintioctopunctata, indicating the potential for use of Hvlwr as an RNAi target gene for the control of this pest species.

Mutations in the coat protein of a begomovirus result in altered transmission by different species of whitefly vectors: a way of virus evolution?

Authors: Pan Li-Long[2], Chi Yao[1], Liu Shu-Sheng[1], Liu Chao[1] and Fan Yun-Yun[1], [1]Zhejiang University, China

Abstract: For many crop pathogens including viruses, high genetic variation provides them with potential to adapt to and prevail in a changing environment. Understanding genetic variation in viruses and their significance are a key to elaborating virus epidemiology and evolution. For the genetic variation of plant viruses, while its impact on virus-host interactions has been documented, how it affects virus-insect vector interactions remains elusive. Here we report the impact of mutations in the coat protein of squash leaf curl China virus (SLCCNV), a begomovirus, on the interaction between the virus and its whitefly vectors. We characterized mutations in the coat protein of SLCCNV and found several residues exhibited much higher mutation rates than the others. We assayed the impact of mutation on infectivity using agro-inoculation and found these mutations marginally affect virus infectivity. We further analyzed their functions using virus acquisition and transmission trials and found some of mutations resulted in altered transmission of SLCCNV by different species of the whitefly Bemisia tabaci complex. We then identified the key amino acid residue(s) involved and found that a single-residue mutation in the coat protein of SLCCNV was sufficient to significantly alter the whitefly transmission characteristics of SLCCNV. We examined the competition between different genotypes of SLCCNV in plant infection and whitefly transmission, and found that while mutations in the coat protein did not alter the fitness of SLCCNV in plants, they rendered the virus more competitive in transmission by certain species of whiteflies. Our findings indicate that mutations in the coat protein may play a key role in both the adaptation of begomoviruses to the changing vector populations and the evolution of begomoviruses.

Management of Colorado potato beetle in invasive frontier areas

Authors: Pan Xubin[2], Wang Cong[1], [1]Chinese Academy of Inspection and Quarantine, China, [2]Institute of Plant Quarantine, Chinese Academy of Inspection and Quarantine, China

Abstract: Colorado potato beetle (CPB) is one of the most devastating invasive insects and it is native to North America. It feeds on several wild species of the genus Solamum, such as S. elaeagnifolium and S. rostratum Dunal, and is one of the major pests of potato and eggplant. Beginning in the early 19th century, CPB has rapidly spread across North America, Europe, and Central Asia. CPB was first reported to invade Xinjiang of China in 1993 and it was effectively controlled in Mori County. Since 2013, CPB has also been found in Jilin and Heilongjiang in Northeast China, and it likely migrated to these provinces from Russia. Thus, China has become the frontier for the global CPB spread, and risk management and monitoring systems for this pest are urgently needed. Here, we summarize pest management methods that are used in areas at the frontier of the CPB invasion, and put forward rameworks for further preventing and controlling of the spread of CPB. The management methods for CPB can also serve as an example for the control of invasive species mitigation in frontier areas.

Quality, quantity, or both? Agri-environmental measures and extensification mainly foster grassland pollinator species richness but less not overall insect biomass

Authors: Panassiti Bernd[1], Wolfrum Sebastian, Birnbeck Sabine, Burmeister Johannes, Freibauer Annette, Morinière Jérôme and Walter Roswitha, [1]Bavarian State Research Center for Agriculture (LfL), Germany

Abstract: A key target of agri-environmental schemes (AES) is increasing biodiversity. However, if and how insect biomass and diversity benefit from grassland AES is, not well known. Using Malaise trap samples from 72 grasslands, we investigated the effect of 1) on-site AES management (three levels: control, farm-wide, site-specific), 2) an index of land extensification (LEI), 3) plant species richness on insect biomass and species richness of all insects, Coleoptera, Diptera, Hymenoptera, Lepidoptera, Hemiptera and three pollinator groups (Syrphidae, Apiformes, Papilionoidea) derived by metabarcoding methods. Bayesian mixed models clearly indicated that site-specific AES and a high LEI positively influenced the species richness of pollinators. An increasing LEI additionally increased the number of all insects, Hemiptera and Hymenoptera species while especially Apiformes and Papilionoidea benefited from a high plant diversity. Moreover, we found an interaction of site-specific AES and the amount of AES in the surrounding landscape explaining differences in insect biomass and species richness of all insects, Coleoptera, Diptera, Hymenoptera and Lepidoptera. When the amount of AES in the surrounding landscape was low a high LEI was especially beneficial e.g., for Lepidoptera. We conclude that many grassland insects (especially pollinators) benefit from site-specific AES and extensive management.

From high-throughout hiccups to real biology for comparative insect genomics

Authors: Panfilio Kristen, School of Life Sciences, University of Warwick, United Kingdom

Abstract: The proliferation of new genome resources across the breadth of the insect phylogeny opens many new possibilities for comparative investigation of genome evolution and the genomic basis of key biological traits for insect development, physiology, and environmental interactions. Rapid improvements in long-read sequencing technologies and hybrid computational approaches are increasingly generating high quality genome assemblies, even from single individuals of small-bodied species. Yet, recent and new publications that go beyond resource documentation often still present biological findings from older, short-read-only technologies and fragmented assemblies. How can these datasets with different levels of quality, from different NGS eras, be reconciled and integrated? Second, it is all too easy to get lost in extended computational pipelines, with many steps at which data are filtered (excluded) and assumptions are made. How can we navigate our way through the pipelines to valid organismal insights? Here, I will discuss some notable lessons learned as an experimental geneticist who has thoroughly enjoyed a decade-long crash course on collaborating with computational biologists to get the most out of insect genomes. I owe particular thanks to the many excellent colleagues from the 1KITE, i5K, and Ag100Pest sequencing initiatives.

Analyzing evolutionary conservation of developmentally dynamic genes in the milkweed bug

Authors: Panfilio Kristen, School of Life Sciences, University of Warwick, United Kingdom

Abstract: Midway through embryogenesis, hemimetabolous insects undergo katatrepsis, a major tissue reorganization event wherein the extraembryonic tissues contract and reposition the embryo within the egg. Katatrepsis is energetically demanding and sensitive to perturbation, yet it is essential for the embryo to complete development. Gaining a greater understanding of the genetic basis of katatrepsis will clarify the nature of a defining embryological trait that has been recognized since the 19th century. Equally, understanding the genetic elements for katatrepsis that are broadly conserved or lineage-specific could contribute to the identification of new targets for molecular pest control strategies.

The milkweed bug Oncopeltus fasciatus is a representative of the species-rich Hemiptera and offers a highly tractable lab model for developmental genetics research, supported by a recent, high-quality genome project. Here, we will present our work to date on analyzing the molecular control of katatrepsis. In preparation for RNA-sequencing after RNA interference (RNA-seq and RNAi) experiments, we have generated high-quality, staged transcriptomes that span mid-embryogenesis stages, including katatrepsis. The use of multiple, sequential stages in our analysis – integrating staging by age and by morphology – is a powerful strategy to identify differentially expressed (DE) genes with changing expression (up- or downregulation) specifically during katatrepsis.

Furthermore, a key outcome of this dataset is the opportunity to analyze DE genes in terms of evolutionary age. Ongoing analyses thus involve assessing the taxonomic distribution of their orthologues through hierarchical, orthology clustering across the insects. The growing wealth of sequenced genomes within the Hemiptera also allows nuanced appraisal of whether lineage-specific genes are common to this order or restricted to the Heteroptera or Pentatomomorpha.

Ultimately, the goal is to determine (1) which genes have dynamic expression required for katatrepsis and (2) the extent to which these genes are evolutionarily old and broadly conserved or represent recent, lineage-specific innovations.

Advances on electropenetrography (EPG) studies with Neotropical pentatomids: waveforms and histology analyses

Authors: Panizzi Antônio Ricardo[1], Lucini Tiago[1], [1]Embrapa National Wheat Research Center, Brazil

Abstract: On the electropenetrography (EPG) technique, a sucking insect and its host plant make part of an electrical circuit where an electric current flow through the system. As the insect inserts its stylets into the electrified plant tissue the circuit closes; this makes the current flows through the insect-plant interface causing changes in the voltage of the system according to the stylet activity (e.g., stylet penetration, salivation, ingestion). The signals obtained are captured and recorded in graphical form (waveforms). By so doing, it is possible to determine the feeding site exploited by the bug (e.g., parenchyma tissue, vascular vessels, seed endosperm), the time spend by the bug on each feeding site, and the activities carried out such as salivation and ingestion. Correlations between each waveform with a specific feeding site are achieved mostly via histological studies. In the past 50 years, several species of sucking insects, mostly aphids and leafhoppers, had their feeding behavior determined using the EPG technique. However, the study of the feeding behavior of stink bugs (Pentatomidae) using the EPG is much more recent. Therefore, in this lecture we will discuss the advances on the use of the EPG technique to reveal the feeding process of Neotropical stink bugs, and the potential use of EPG as a tool to explore other research lines with these bugs.

Stink bug pests bioecology in the neotropics: host-plant interactions and implications for their management

Authors: Panizzi Antônio Ricardo[1] and Lucini Tiago[1], [1]Embrapa National Wheat Research Center, Brazil

Abstract: Stink bugs (pentatomids) are polyphagous feeding on several species of plants, cultivated and non-cultivated. They feed by introducing the stylets (2 maxillae + 2 mandibles) into the plants to obtain nutrients and water. Feeding strategies include the salivary sheath, the cell rupture, and the osmotic pump feeding. Plants explored can be divided into hosts and associated plants. On host plants, bugs feed, nymphs complete development, and produced adults that continue breeding. On associated plants, however, bugs may feed, use them as shelter, lay eggs on, but nymphs do not complete development, and any resulting adults do not breed. Nymph and adult biology is variable on those plants, and the nymph to adult food-switch may have a variable impact to adult biology. Although polyphagous stink bugs show some degree of preferences for determined plant taxa, and less-preferred plants, often overseen, may show an important role in their bioecology. Considering any integrated pest management (IPM) programs, the multiple interactions of stink bugs with their host or associated plants should be taken into consideration. This is important because the information on host-plant interactions certainly helps to develop holistic tactics that will mitigate the deleterious effects of stink bugs on cultivated plants.

The underestimated role of pentatomid parasitoids in the neotropics

Authors: Panizzi Antônio Ricardo[1], Zerbino María S.[2], [1]Embrapa National Wheat Research Center, Brazil, [2]INIA, Uruguay

Abstract: Stink bugs are pests of economic importance of extensive crops (commodities) in the Neotropics, particularly in Southern South America. They are abundant, have a broad geographical distribution, and cause severe damage. Main species include the Neotropical brown-stink bug, Euschistus heros (F.), the red-banded stink bug, Piezodorus guildinii (Westwood), the Southern green stink bug, Nezara viridula (L.), the green-belly stink bugs, Dichelops furcatus (F.), and D. melacanthus (Dallas), and the brown-winged stink bug, Edessa meditabunda (F.). The management of these pest species on crops is complex because they can cause economic damage in low numbers, and it is difficult to control by the commonly used insecticides. Therefore, biological control appears as the most important tactic to be implemented in stink bug management programs. Among the many natural enemies present on the various agroecosystems, egg parasitoids (Hymenoptera) and parasitoids of adult stink bugs (Diptera and Hymenoptera) are the most promising groups to be exploited as biological control agents of pest species. In the Neotropics about 30 species of egg parasitoids of stink bugs and more than 12 species of tachinid flies have been recorded. Efforts should be concentrated on conservation biological control. This biocontrol effort should be integrated with other tactics, such as the use of trap crops and semiochemicals. Landscape planning providing parasitoids with food, hibernation, and refuge sites favors their permanence, and cultivation spatially and temporally planned should be developed. Considering the biodiversity of the Neotropics, there is a tremendous potential to increase the use of biocontrol agents to mitigate pests.

Overwintering of Piezodorus guildinii (Heteroptera, Pentatomidae) populations at Southern latitudes of South America

Authors: Panizzi Antônio Ricardo[1], Zerbino María S.[2], Altier Nora[3] and Miguel Lucía[4], [1]Embrapa National Wheat Research Center, Brazil, [2]INIA, Uruguay, [3]Instituto Nacional de Investigación Agropecuaria. INIA, Uruguay, [4]Ministerio de Ganadería Agricultura y Pesca, Dirección General de Servicios Agrícolas (MGAP-DGSA), Uruguay

Abstract: Piezodorus guildinii (Westwood) is a soybean pest that causes significant economic losses in the Americas. The variability of overwintering (diapause) traits was evaluated in populations of the Southwest (SW) (33°55'-34°17' S, 57°13'-57°46' W) during 2 years-period (2011-2013) and of the Northwest (NW) (32º01'-33º02' S, 57º50' -57º24' W) during 1 year-period (2014-2015) regions of Uruguay. Samples were taken from different plant species (cultivated legumes, wild shrubs and trees), and from overwintering sites (leaf litter and bark). Alfalfa, Medicago sativa L. was the main host, with a collection period of 10-11 months in the SW and 12 months in the NW. Cluster analysis for each sex was carried out to group the months according to the similarity in diapause traits of populations (body size, body lipid content, immature reproductive organs, and clear type of pronotum band and connexivum in females). Female diapause in the SW was longer (beginning of autumn to end of winter) than in the NW (mid-autumn to mid- winter). Male diapause was longer (mid-autumn to mid-winter) in SW1 (1st year) than in SW2 (2nd year) and NW (late-autumn to mid-winter). Male diapause was shorter than female diapause in both regions. Differences were associated with maximum temperature at daylight hours = 12.1, being necessary maximum temperatures below 23.8 °C for females and 19.2 °C for males to initiate diapause. Earlier resumption of seasonal development in spring and later termination of activity in autumn may generate greater number of P. guildinii generations per year in the NW than in SW regions.

Natural genetic variation for life history traits: opportunities and constraints for insect breeding

Authors: Pannebakker Bart[5], Verhulst Eveline[4], Zwaan Bas[5], Ferguson Kim[1], Groenen Martien[3], Bijma Piter[3] and Xia Shuwen[2], [5]Wageningen University, Netherlands, [4]Wageningen University & Research, Netherlands, [1]Wageningen University & Research, Canada, [3]Wageningen University & Research, Netherlands, [2]Wageningen University & Research, China

Abstract: The Arthropod phylum contains many species that can be used in human society, such as for biocontrol of agricultural pests and for exploiting organic waste streams in circular agriculture and economies. Many of these applications involve mass rearing of insects and it is fair to say that thus far not much attention has been given to both exploiting and maintaining genetic variation for traits that matter for the performance of the focal species. Moreover, the "desired traits" are often life-history traits that have co-evolved and have been shaped in the natural habitat. In this talk I will argue that taking lessons from life-history theory and quantitative genetics has the potential to strongly benefit the rapidly growing field of insect farming. Incorporating such evolutionary genetic knowledge will result in better designed breeding programmes and, importantly, realistic expectations on their outcomes.

Next-generation biological control: the need for integrating genetics

Authors: Pannebakker Bart, Wageningen University, Netherlands

Abstract: Secure and sustainable food production in terms of quantity and quality is a major challenge facing human societies. However, food security is continuously threatened by current and invasive pest species. In addition, regulations for the use of pesticides are getting stricter to ensure food safety and protect ecosystem health. Biocontrol of agricultural pests by using natural enemies has great potential to deal with these two demands. Biocontrol of novel exotic pests, however, often involves importing non-native natural enemies. Such practices are being restricted due to the Nagoya Access and Benefit Sharing regulations. The dependence on imported natural enemies can be reduced by optimizing existing and native biocontrol agents. A powerful way of optimizing biocontrol agents is the use of genetic knowledge. This not only entails classical selective breeding, but ranges from applying basic population genetic principles, to monitoring genetic variation during rearing and post-release, determining the genetic basis of traits, to advanced methods such as genomic selection. In this talk, I will outline the use of genetic tools and knowledge to improve the efficiency of biocontrol and present several cases of the wide range of application of genetics to improve biocontrol efficacy.

Overwintered Drosophila suzukii are the main source for infestations of the first fruit crops of the season

Authors: Pannebakker Bart[5], Panel Aurore[1], van der Sluis Bart[3], Wertheim Bregje[2], Helsen herman[3], Zeeman Laura[4] and van Elk Peter[3], [1]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [2]University of Groningen, Netherlands, [3]Wageningen University & Research, Field Crops, Netherlands, [4]Wageningen University & Research, Laboratory of Entomology, Netherlands, [5]Wageningen University, Netherlands

Abstract: The mechanisms allowing the widespread invasive pest Drosophila suzukii to survive from early spring until the availability of the first fruit crops are still unclear. Seasonal biology and population dynamics of D. suzukii were investigated in order to better understand the contribution of the early spring hosts to the infestation of the first fruit crops of the season. We identified hosts available to D. suzukii in early spring and assessed their suitability for the pest oviposition and reproductive success under field and laboratory conditions. The natural infestation rate of one of these hosts, Aucuba japonica, was assessed over springtime and the morphology of the flies that emerged from infested A. japonica fruits was characterized under field conditions. Then, these findings were correlated with long-term monitoring data on seasonal reproductive biology and morphology of the pest, using a cumulative degree-days (DD) analysis. Field sampling revealed that overwintered D. suzukii females were physiologically able to lay eggs at 87 DD which coincided with the detection of the first infested early spring hosts. The latter were continuously and increasingly infested by D. suzukii eggs in nature from early spring until the end of May, in particular Aucuba japonica. Individuals emerged from most of these hosts were characterized by a poor fitness and a rather low success of emergence. In the field, only few summer morphs emerged from naturally infested A. japonica fruits around the end of May-beginning of June. However, field monitoring in orchards revealed that D. suzukii individuals consisted solely of winter morphs until mid-June. These observations indicate that overwintered D. suzukii females are the predominant source for the infestations in the first available fruit crops of the season. We discuss these findings in the context of possible pest control strategies.

Horizontal transmission of Metarhizium sp. conidia in Popillia japonica adults.

Authors: Paoli Francesco[1], Marianelli Leonardo[1], Barzanti Gian Paolo[1], Roversi Pio Federico[1], Benvenuti Claudia[1], Giacometto Emanuela[2], Bosio Giovanni[3] and Torrini Giulia[1], [1]CREA - Council for Agricultural Research and Economics – Research Centre for Plant Protection and Certification (CREA-DC), Italy, [2]Regione Piemonte - Settore Fitosanitario e servizi tecnico-scientifici, Italy, [3]Settore Fitosanitario, Regione Piemonte, Torino, Italy

Abstract: Microbiological control of pest populations has greatly developed due to the increasingly high restrictions applied to the use of chemical insecticides.

As regards fungal Biological Control Agents (BCAs), the transmission of infecting conidia from one individual to another is very important since it causes the spreading of infections within the pest population and the induction of epizootics (Lacey et al., 1994b; Hesket et al., 2010).

Two different Metarhizium-based commercial products available in Italy were used as source of inoculum in our experiments and horizontal transmission during mating between infected and uninfected Popillia japonica (Pj) adults was studied according to the following scheme: infected male x uninfected female (MixF), uninfected male x infected female (MxFi), infected male x infected female (MixFi), and uninfected male x uninfected female (MxF) as a control (Quesada-Moraga et al., 2008).

Horizontal transmission potential was also assessed in one-against-twenty experiments. Ten infected male and ten infected female Pj adults were individually brought in contact with twenty (ten males and ten females) uninfected Pj adults each.

Experiments showed 100% mortality by 19 days after treatment with the first product, while mortality associated with the second one was 30-65%.

The ability to transport and spread conidia in both male and female Pj adults was also analyzed and no difference between sexes was observed.

In one-against-twenty experiments final mortality achieved by a single infected male and a single infected female was 67% and 72% respectively.

Our tests confirmed that the inoculum can be transmitted from one infected adult to a healthy one during copulation, thus supporting the idea of an auto-dissemination of the fungus within the pest population that can induce epizootics.

Phylogeography of the invasive scarab beetle Popillia japonica

Authors: Paoli Francesco[2], Marianelli Leonardo[2], Carapelli Antonio[3], Roversi Pio Federico[2], Strangi Agostino[2], Kimoto Troy[1], Leo Chiara[3], Brunetti Claudia[3], Cucini Claudio[3], Nardi Francesco[3], Cutino Ilaria[2], Iovinella Immacolata[2] and Shimizu Ken[4], [1]Canadian Food Inspection Agency, [2]CREA - Council for Agricultural Research and Economics – Research Centre for Plant Protection and Certification (CREA-DC), Italy, [3]Department of Life Sciences, University of Siena, Italy, [4]Laboratory of Agro-Environment, Warm Region Horticulture Institiute, Chiba Prefectural Agriculture and Forestry Research Cente

Abstract: Popillia japonica Newman (Coleoptera: Scarabaeidae) is a scarab beetle native to Japan that in the last century invaded North America, the Azores and, more recently, Italy and Switzerland. It is a notorious agricultural pest that has been added to the 2019 EU priority pest list. Economic damage is due to larvae feeding on plant roots, and adults feeding on leaves, flowers and fruits. In order to limit the further spread of this pest urges to reconstruct its worldwide range expansion. The aim of the present contribution was to analyze the P. japonica population structure and phylogeography, with a special focus on its spatial movements.

The present work is based on sequence data from two different mitochondrial loci and nine microsatellite loci from P. japonica samples covering its global distribution.

Basing on mitochondrial data, the North American population of P. japonica appears to include two different maternal lineages, one grossly localized in the Great Lakes region and the other displaying a larger distribution for the rest of North America. The two lineages display very limited genetic variability, possibly due to a strong founder effect. Out of the 13 haplotypes found in North America, only 3 were identified in Japan, two of which being the most frequent overall in North America and having spread and differentiated to produce a series of ancillary haplotypes. It is therefore possible to hypothesize that these haplotypes characterized the original introduction, with others satellite being generated by casual mutation during the colonization process. These two most frequent North American haplotypes were identified only in a limited geographical region of Japan, in the center of Honshu island between the Ibaraki, Tochigi, and Gunma Prefectures. As such, this geographical region can be considered as the most likely origin of the invasive specimens associated with the first North American outbreak of P. japonica.

The Italian outbreak is characterized by the same haplotypes of the Azorean population, nevertheless their haplotypic frequencies are totally different. On the contrary, Italian and Swiss individuals share one and the same mitochondrial haplotype, suggesting a common origin from the Italian outbreak.

Microsatellite data suggest an old differentiation between Southern and Central Japan, with this latter region contributing to the invasion in the US. Popillia japonica in North America is subdivided in two different populations: the first one is mainly localized on the north-east coast and the second in the south-east coast of the continent. The more recent invasions in Italy and the Azores appear to be related to the US but displaying a marked genetically differentiation; Italian outbreak seems to be closer to north-eastern population while Azorean beetles were closer to south-eastern one.

Agroferstation and beekeeping: the LIFE VAIA project

Authors: Paolo Fontana[1] and Valeria Malagnini[1], [1]Edmund Mach Foundation

Abstract: Storms, floods, fires: the occurrence of extreme climatic events, with the dramatic repercussions they have on our territories, is the testimony of climate change in recent decades. The VAIA storm that hit North East Italy in 2018 caused extensive damage to mountain areas and their delicate ecosystems. Extreme weather events quickly create open spaces where there were forests. Agroforestry is a solution that can provide for the exploitation of the new habitat, both by introducing temporary crops and through the implementation of beekeeping. In fact, in these environments we can observe the rapid and abundant appearance of a nectarous and polleniferous flora.

A little known insect order: general information, collection, breeding and study of Italian and Mediterranean Embioptera

Authors: Paolo Fontana[1], Filippo Maria Buzzetti[2] and Stancher Gionata[2], [1]Edmund Mach Foundation, [2]Fondazione Museo Civico di Rovereto

Abstract: The Embioptera or web spinners, are perhaps the least studied and therefore least known insect order in Italy. In order to stimulate and facilitate new studies on these unique insects, general information on their biology, collection, breeding and study techniques and current knowledge on their presence in Italy and Europe are presented. A key to identify genera and an extensive bibliography are also provided.

A mobile phone application to survey and monitor the wild colonies of Apis mellifera

Authors: Paolo Fontana[1], Daniele Andreis[1] and Valeria Malagnini[1], [1]Edmund Mach Foundation

Abstract: Although Apis mellifera have been reared by humans for millennia, it remains a wild animal) as reported by ancient authors and modern beekeepers and researchers. Until a few decades ago, wild colonies of A. mellifera were largely common. However, since the early 1980s there has been a rapid and underestimated rarefaction of the “wild” colonies due to a parasite, the fearsome Varroa destructor mite. The effect of the Varroa mite on unmanaged colonies was so strong that today in Europe most of the survived honey bees live in hives managed by beekeepers. Indeed, for many years it has even been thought that in Europe wild honey bees were disappeared. Rather surprisingly, there are no scientific studies on this phenomenon and the only available information deals with the number and distribution of honey bees colonies owned by beekeepers. In recent years, reports and interest in wild honey bee colonies have increased significantly and today we can say that even in many areas of Europe these colonies are still there. The app BeeWild intends to survey and monitor these wild colonies through a typical citizen science action.

Fruit fly invasion a global phenomenon with huge agricultural and trading implications

Authors: Papadopoulos Nikos T. [3], Terblanche John S.[1] and De Meyer Marc[2], [1]Dept of Conservation Ecology and Entomology, Stellenbosch University, South Africa, [2]Royal Museum for Central Africa, Belgium, [3]University of Thessaly, Thessaly, Volos, Greece

Abstract: Fruit flies (Diptera: Tephritidae) comprise a major group of pests including several invasive species, such as the Mediterranean fruit fly, the oriental fruit fly and the peach fruit fly that threaten sustainable fruit and vegetable production worldwide. Because of the extremely high economic relevance invasion events have documented since the beginning of the last century. Intense government-mandated eradication campaigns are implemented after the documentation of an invasion event of a fruit fly of economic importance that almost always declared as successful. New invasion events following an eradication campaign often trigger debates regarding the success of the operation. The risks of arrival, establishment and range expansion of invasive fruit flies are expected to escalate because of global climate change, increased trade and human mobility. Establishment of an invasive fruit fly in a new area, besides having a huge direct impact on fruit and/or vegetable production, increases insecticide use and dramatically affects trading of fresh commodities and impose quarantine regulations. Incursion of invasive fruit flies in Australia, north America and Europe is estimated to result in losses of billions of Euros because of direct and indirect damage. And a single eradication campaign costs several million Euros. The current paper covers several aspects of the fruit fly invasion biology, including (a) historical perspectives, (b) the enormous impact on local, national and regional economies, (c) interception and detection efforts, (d) management of invasion event including eradication campaigns, and (d) predictive ecological and climatic modelling. The need for revisiting existing policies is also highlighted.

DNA barcoding and phylogeny of Afrotropical Rhiniidae (Diptera: Calyptratae) and placement of the enigmatic Prosthetosomatinae

Authors: Pape Thomas[5], Jensen Arn Rytter[2], Martinez-Sanchez Anabel[1], Thomas-Cabianca Arianna[1], Buenaventura Eliana[4], Cerretti Pierfilippo[3] and Rojo Santos[1], [1]Departamento de Ciencias Ambientales y Recursos Naturales. Universidad de Alicante, Alicante, Spain, [2]Department of Biology and Biotechnology "Charles Darwin", Sapienza University of Rome, Rome, Italy Natural History Museum of Denmark, University of Copenhagen, , Denmark, [3]Dipartimento di Biologia e Biotecnologie 'Charles Darwin', Sapienza Università di Roma, Rome, Italy, [4]Museum für Naturkunde, Leibniz Institute for Evolution and Biodiversity Science, Berlin, Germany, [5]Natural History Museum of Denmark, University of Copenhagen, Denmark

Abstract: The family Rhiniidae, represented by almost 400 species, is distributed in the Australasian, Palearctic, Oriental and Afrotropical region, with around 150 of the species occurring in the Afrotropical region. The biology of the Rhiniidae is poorly known and the phylogeny is not well understood. Adult flies are often seen visiting flowers and potentially play an important role as pollinators. In the Afrotropics at least six Rhiniidae genera are associated with termites, and some larvae apparently develop in termite nests as parasitoids, predators or scavengers, but in general the knowledge about this association is scarce. Identification of Rhiniidae species is challenging and relies heavily on male terminalia, which makes identifications of females difficult. Immature stages are largely unknown, with larvae only described for five species. Accurate identification of Rhiniidae species is important when exploring their biology and phylogeny, but also to aid in conservation and pollination studies. By building a reference library of DNA barcodes from voucher specimens, this study aims at linking conspecific males and females, and exploring the phylogenetic relationships within the Rhiniidae. COI barcodes were obtained for more than 60 species covering 14 of 16 genera recorded from the Afrotropical Region. Species limits and phylogeny was explored by reconstructing neighbor-joining, maximum likelihood and Bayesian inference phylogenetic trees and calculating genetic distances. COI barcodes enabled us to link females with their conspecific male morphotype and, combined with a sample of larvae from South Africa, to place the enigmatic Prosthetosomatinae in the family Rhiniidae.

Molecular armament: a first attempt at solving Polleniidae and Rhinophoridae phylogeny using molecular data

Authors: Pape Thomas[5], Gisondi Silvia[2], O. Stireman III John[1], Cerretti Pierfilippo[4] and Nihei Silvio[3], [1]Department of Biological Sciences, Wright State University, Dayton, OH, United States, [2]Department of Biology and Biotechnology 'Charles Darwin', 'Sapienza' University of Rome, Italy and Natural History Museum of Denmark, University of Copenhagen, [3]Department of Zoology, Institute of Biosciences, University of São Paulo, Brazil, [4]Dipartimento di Biologia e Biotecnologie 'Charles Darwin', Sapienza Università di Roma, Rome, Italy, [5]Natural History Museum of Denmark, University of Copenhagen, Denmark

Abstract: Recent attempts at resolving oestroid phylogeny employing limited taxon sampling have converged in retrieving monophyly for most families and subfamilies, and the deeper relationships among these are now stabilising. In this context, we reconstructed phylogenetic relationships within the parasitoid fly families Polleniidae (cluster flies) and Rhinophoridae (woodlouse flies) using two nuclear protein-coding loci (CAD and MCS, 3872 bp) with a broad and representative selection of the two target clades comprising 11 species of cluster flies and 62 species of woodlouse flies, as well as a selection of taxa representing the main oestroid lineages (Tachinidae, Sarcophagidae, Oestridae, Calliphoridae, etc.). We analyzed the dataset using Maximum Likelihood and Bayesian Inference.

As expected, analysis with these loci provide good resolution and strong support for distal nodes, though several basal nodes are weakly supported, as highlighted in previous literature. Polleniidae and Rhinophoridae are retrieved as monophyletic groups with strong support.

Cluster flies are divided in two lineages: a Pollenia clade and a Morinia + Melanodexia clade, with Morinia reconstructed as paraphyletic. Despite including only five species of Pollenia, monophyly of this genus is well supported and the only included Australian taxon takes up a position as sister to the remaining Pollenia species. The two included species of Morinia (i.e., an undescribed species from South Africa and the type species M. doronici) form a grade from which the North American endemic Melanodexia arose. The sister group relationship of Polleniidae and Tachinidae is confirmed with high support.

Our analyses confirm the division of woodlouse flies into two groups, which is supported by larval morphology: the Stevenia-group and the Phyto-group. The sister group to Rhinophoridae remains unclear, with two different hypotheses based on the analytical method used. All genera within Rhinophoridae emerge as monophyletic except for Rhinomorinia. Species assigned to Rhinomorinia are split into two clades corresponding to biogeographical distributions: the Palaearctic R. sarcophagina clusters as sister to Oplisa, whereas the Afrotropical species form a monophyletic group sister to all the remaining taxa of the Stevenia-group. This result leads to the resurrection of the genus group name Oxytachina for the Afrotropical clade.

The present phylogenetic reconstruction is the first molecular-based phylogenetic backbone for Polleniidae and Rhinophoridae at a world scale.

Redefinition of blowflies from a phylogenomic perspective

Authors: Pape Thomas[1], Yan Liping[2], Zhang Dong[2], [1]Natural History Museum of Denmark, University of Copenhagen, Denmark, [2]School of Ecology and Nature Conservation, Beijing Forestry University, China

Abstract: Blowflies (Diptera: Calyptratae, Calliphoridae) have been recognized since earliest times by humans as metallic-coloured, carrion-breeding flies. However, they exhibit a rich diversity morphologically and biologically, and the monophyly and general classification of this group have been debated for decades, making them the main challenge in tracing the phylogeny and evolutionary history of oestroid calyptrates. Following a modified 1KITE pipeline with a dipteran ortholog reference library of 3,755 genes, we conducted the most comprehensive analysis using transcriptomic data covering 11 out of 13 (formerly) recognized calliphorid subfamilies. The raising to family rank of Mesembrinellidae and Polleniidae was confirmed in our study. The remaining calliphorids sensu lato (including Rhinophoridae) emerge as monophyletic, while the carrion-breeding blowflies originated twice independently (Chrysomyinae and Calliphorinae + Luciliinae). Accordingly, a re-classification of calliphorids sensu lato is proposed based on the robust backbone phylogeny recovered in this study. The evolutionary history of oestroid breeding habits is also traced to understand the origin of these flies.

Females adjust maternal hormone concentration in eggs according to male condition in a burying beetle

Authors: Paquet Matthieu[2], Parenteau Charline[1], Angelier Frédéric[1], Richardson Jon[3], Ford Lucy[3], Smiseth Per[3] and Ratz Tom[3], [1]Centre d'Etudes Biologiques de Chizé, Centre National de la Recherche Scientifique- La Rochelle Université, France, [2]Department of Ecology, Swedish University of Agricultural Sciences, ,Uppsala, Sweden Institute of Evolutionary Biology, University of Edinburgh, [3]Institute of Evolutionary Biology, University of Edinburgh, United Kingdom

Abstract: In vertebrates and more specifically birds, there is good evidence that females adjust their allocation of hormones in response to prenatal environmental conditions, such as food availability or male phenotype, with profound consequences on life history traits. In insects, there is evidence that females deposit juvenile hormones (JH) and ecdysteroids (ESH) in their eggs, hormones that play a key role in regulating offspring growth and metamorphosis. However, it is unclear whether females adjust their hormonal deposition in eggs in response to prenatal environmental conditions. Here we address this gap by conducting an experiment on the burying beetle Nicrophorus vespilloides, in which we manipulated the presence of the male parent and the size of the carcass used for breeding at the time of laying. We also tested for effects of the condition (i.e., body mass) of the parents. We then recorded subsequent effects on JH and ESH concentrations in the eggs. We found no evidence for an effect of these prenatal environmental conditions (male presence and carcass size) on hormonal concentration in the eggs. However, we found that females reduced their deposition of JH when mated with heavier males. This finding is consistent with negative differential allocation of maternal hormones in response to variation in the mass of the male parent. We encourage further work to investigate the role of maternally derived hormones in insect eggs.

Cotton Insect Management in the Semi-Arid Region: Pest Management and Production Profitability.

Authors: Parajulee Megha, Texas A&M University, United States

Abstract: Cotton is a major agricultural crop in the Texas High Plains (THP), producing over 6.4 million metric ton of cotton per year. This represents an average of 30% of U.S. cotton and approximately 4% of world cotton. THP is a semi-arid region in south-central United States with characteristic low rainfall, with production agriculture supported by limited irrigation or solely rain-fed. As a result, the cropping system in this region is largely low-input and the producer decision-making in economically profitable input use is a challenge. Low cotton market price, increased nitrogen fertilizer price, and reduced water availability have forced farmers to move toward reorganizing available input resources to sustain their production enterprise, particularly arthropod pest management. The western flower thrips, Frankliniella occidentalis, is the most dominant thrips species affecting seedling cotton in THP, which is the most economic pest of cotton in this region. Cotton fleahoppers, Pseudatomoscelis seriatus, and western tarnished plant bugs, Lygus hesperus, are two important plant bug pests of cotton that feed on reproductive structures of cotton. Cotton fleahoppers are early season pests while Lygus bugs are mid- to late season pests in THP. Cotton squares up to pinhead size are most susceptible to fleahopper damage, and yield loss is most likely from feeding during the first three weeks of fruiting, whereas Lygus bugs mostly feed on developing bolls. A comprehensive field study was conducted to characterize the host-plant sequence and movement of these insect pests from non-cotton habitats to cotton. While grassy weeds and terminating wheat are responsible for thrips colonization in seedling cotton, cotton fleahopper and Lygus utilize several weed hosts during non-cotton season and move to cotton when non-cotton habitats are no longer a suitable host. Extensive field studies have established management thresholds for all three insect pests, whereas their impact on cotton production risks have been evaluated with various combinations of single versus multiple-species infestations under three deficit-water (near-zero, intermediate, and high) production scenarios. These studies are crucial because a significant component of IPM lies in adoption of new tactics by growers to improve profitability and production sustainability. However, producer decisions are complicated by uncertainty of production risks posed by the interaction of biotic (pests) and abiotic (water) factors. Because these three insect pests of cotton occur sequentially in Texas High Plains cotton, we experimentally discerned the population dynamics and damage potential of each insect species infesting the crop in isolation or in combination (sequentially), all under different water-deficit production scenarios. This allowed us to develop specific crop production models under various production settings which would help producers to optimize input resources for profitable cotton production.

Neem oil (Azadirachta indica) fabricated silver nano-particles as an eco-friendly tool for the control of Helicoverpa armigera – A case study

Authors: Parajulee Megha[2], Murugan K.[1], [1]Bharathiar University, India, [2]Texas A&M University, United States

Abstract: Helicoverpa armigera is a polypghagous insect pest that infests many crop plants. Indian neem (Azadirachta indica) tree is a versatile plant which possesses enormous insect control properties. Nanoencapsulations and nanoemulsions are the potential nanotechnology tools that can be used in managing biological systems, including insect pest control. In this study, neem oil nanoencapsulate silver nanoparticles (AgNPs) and neem nanoemulsions were tested against larval and pupal populations of the cotton bollworm, Helicoverpa armigera, and lethal concentrations (LC50 and LC90) were established. The silver encapsulated insecticidal nanomaterials performed as reducing and stabilizing agents. Results obtained from UV, XRD, FTIR, DLS, ZETA, SEM, TEM and EDX analyses showed quantitative and morphological characters of the synthesized nanoencapsulated silver nanoparticles. Neem essential oil, nanoemulsions and encapsulated silver nanoparticles showed significant larvicidal and pupicidal toxicity against the Helicoverpa armigera. Sub-lethal doses of nanoencapsulated silver nanoparticles and neem oil nanoemulsion treatment significantly affected the longevity and fecundity and also reduced egg hatchability. Treated insects displayed reduced food consumption as well as lower growth and nutritional indices such as efficiency of ingested and digested food materials (ECI and ECD) and concomitant reduction in the digestive enzyme activity (a-amylase, lipase and proteases, serine, cystein and aspartic proteinases). In addition, the insects egested lesser number of faecal pellets and time taken to pass out first faecal pellets were also diminished in the experimental insects. The results revealed that encapsulated AgNPs of nanoemulsified droplet concentrations (ppm level) might have affected the digestive physiology of insects. Overall, encapsulated AgNPs and nano-emulsions from plant essential oil have shown demonstrated potential for the development of safer alternative insecticidal formulations for the control of H. armigera.

Will an exotic, competitive egg parasitoid displace a native larval parasitoid?

Authors: Paranhos Beatriz[2], Nava Dori[3], Alexandre Sá Luiz[1], Manoukis Nicholas[6], Morelli Renata[5] and Poncio Sonia[4], [1]Embrapa Environment, Jaguariúna, SP, Brazil, [2]Embrapa Semiarid Agriculture, Petrolina, Brazil, [3]Embrapa Temperate Agriculture, Pelotas, RS, Brazil, [4]Federal Institute Farroupilha, Frederico Westphalen, RS, Brazil, [5]ProInsecta P&D, Piracicaba, SP, Brazil, [6]USDA-ARS Daniel K. Inouye US Pacific Basin Agricultural Research Center, Hilo, HI, United States

Abstract: Fopius arisanus Soman (Hymenoptera: Braconidae) is a generalist tephritid egg parasitoid from the Indo-Pacific region introduced to Brazil in 2012 to control the exotic fruit fly pest Bactrocera carambolae Drew & Hancock (Diptera: Tephritidae) in the northern region. Doryctobracon areolatus Szépligeti (Hymenoptera: Braconidae) is a native generalist parasitoid of second instar larval fruit flies from Central and South America. Because both species of fruit fly parasitoids share some genera of fruit fly hosts, we evaluated if the commercial release of F. arisanus could cause adverse effects (e.g., competitive displacement) on the native parasitoid. Host preference and competitive ability were compared using as hosts the native Anastrepha fraterculus Wiedemann (Diptera: Tephritidae) and the exotic Ceratitis capitata Wiedemann (Diptera: Tephritidae) fruit fly species. To evaluate host preference, choice and no-choice experiments were conducted with lines of F. arisanus reared from each of the hosts. Laboratory studies showed that F. arisanus accepted only 2-3% of the native hosts compared to 34-41% of the exotic hosts under no choice conditions, with similar results when given a choice of native and exotic hosts. The field cage choice study showed similar results when F. arisanus was reared on the exotic host, but when reared on the native host, F. arisanus parasitized more of the native host than when reared on the exotic host. However, both lines of the parasitoid preferred the exotic host. To evaluate competitive ability, experiments with both species together and separate were conducted in the laboratory and in field cages. Both experiments showed that F. arisanus had no measurable detrimental effect on the native parasitoid in either the native or exotic host. Indeed, the native parasitoid was consistently the superior competitor in native host even though it parasitized larvae while F. arisanus is an egg parasitoid. These results indicated that F. arisanus interacted minimally with the native parasitoid on the native host, and while it interacted with the native parasitoid on the exotic host, it did not detrimentally affect it. Thus, F. arisanus is unlikely to cause adverse effects on the native parasitoid, D. areolatus in Brazil.

Sacbrood virus suppression in Apis cerana by virus-derived dsRNA produced from Bacillus thuringiensis toxic to Galleria mellonella

Authors: Park Min Gu[1], Choi Jae Young[1], Park Dong Hwan[1], Wang Minghui[1], Kim Hyun Ji[1], Je Yeon Ho[1], [1]Department of Agricultural Biotechnology, College of Agriculture & Life Science, Seoul National University, Republic of Korea, South Korea

Abstract: Honeybees play an important role in the global economy by assisting in the pollination of food crops and by producing honey, and other hive products. The health of honey bees is inevitably threatened by a range of pathogens including bacteria, fungi, microsporidian parasites, and viruses. The Asian honey bee, Apis cerana is a native honey bee species in Korea, and has been noted for its strong resistance to Varroa destructor, however, it shows weakness to Sacbrood virus and Galleria mellonella. Recently, RNA interference (RNAi) has been suggested as a promising strategy for suppression of honey bee viruses. Also, Bacillus thuringiensis (Bt) has been widely applied for the control of lepidopteran pests such as G. mellonella, the greater wax moth. In this study, it was intended to develop dsRNA production platform using Bt. For this, the pBTdsVP1 vector which transcribes sense and anti-sense SBV vp1 gene under the control of Cyt1Aa sporulation-dependent promoter with STAB-SD sequence was constructed. This vector was introduced into Bt strain NT0423 expressing Cry1-types toxins. SBV replication was suppressed in the worker A. cerana ingested dsRNA produced from the Bt transformant. Crystal proteins from the Bt transformant showed high level of insecticidal activity against 4th instar larvae of G. mellonella. These results demonstrated that Bt-based dsRNA producing system could be exploited for the control of both SBV and G. mellonella simultaneously.

Transcriptome analysis of fat body from Japanese pine sawyer beetle, Monochamus alternatus, infected with the entomopathogenic fungus Beauveria bassiana ERL836

Authors: Park Yulim[1], Kim Jae Su[1], Im Yeram[1], Jeon Insoo[1], Jeong Yujin[1] and Song Gahyeon[1], [1]Jeonbuk National University, South Korea

Abstract: In forest, Japanese pine sawyer beetle, Monochamus alternatus, is a vector of pine wilt nematode causing pine wilt disease (PWD). Management of M. alternatus has been relied on chemical insecticides that cause environmental pollution and insect resistance. In this study, entomopathogenic fungi, the biological control agents were used to control M. alternatus, and the response of fat body from M. alternatus to the fungus was investigated. The virulence test was conducted using a spraying method with a conidial suspension at 1×10^7 conidia/ml. As a result, the mortality of M. alternatus was higher than 70% in seven isolates, including Beauveria bassiana ERL836. ERL836 showed the highest level of mycosis on insect body and the highest conidial thermostability. We investigated the response of fat body from ERL836-infected M. alternatus using RNA-seq. RNA samples were obtained from fat body of M. alternatus in 2 and 4 days after ERL836 treatment. On day 2 and 4, genes involved in muscle contraction were upregulated, however, genes involved in defense response were downregulated. Additionally, genes involved in ion-channel activity were downregulated on day 4. In conclusion, according to transcriptome analysis, it seems that genes related to defense and ion-channel activity are downregulated by ERL836 infection.

Dosage compensation in sexual and asexual stick insects

Authors: Parker Darren[2], Schwander Tanja[1], Jaron Kamil[2], Robinson-Rechavi Marc[2], Galtier Nicolas[3] and Tran Van Patrick[2], [1]Department of Ecology and Evolution, University of Lausanne, Switzerland, [2]University of Lausanne, Switzerland, [3]University of Montpellier, France

Abstract: In species with differentiated sex chromosomes, genes on the X (or Z) will be present in different copy numbers in males and females. This creates a problem since for many genes expression is proportional to their copy number. To alleviate this problem, organisms have evolved several methods of dosage compensation to equalise expression between the sexes. Most model species show ‘complete dosage compensation’ whereby all genes on the sex chromosomes are up- or down- regulated dependent on which sex they are present in. However, recent studies using non-model species have shown that the extent of dosage compensation is in fact very variable.

The explanatory factors that influence the amount of dosage compensation are largely unknown. One proposed factor is the amount of differentiation between the sex chromosomes, with greater dosage compensation evolving as genes on the sex chromosomes diverge. X0 systems represent an extreme point in this continuum, since all genes on the X chromosome will be single copy in males; however the extent of dosage compensation in X0 systems has been largely unexplored. Here we examine dosage compensation across five X0 species of stick insect in the genus Timema. Using this approach we are able to i) quantify the extent of dosage compensation in each species, and ii) identify possible turnover and migration of dosage compensated genes from the X to autosomes.

Complementary to this approach, we also investigate the fate of dosage compensation in three asexual Timema species. In asexual species selection for dosage compensation has stopped, and thus we predict that asexual species will have evolved a reduced capacity for dosage compensation. Here we quantify this reduction and determine if this reduction is equal across the X chromosome or more pronounced among certain classes of genes.

Social cognition and behavioral integration in a model ant-myrmecophile partnership

Authors: Parker Joseph[1], Wagner Julian[2] and Naragon Thomas[2], [1]California Institute of Technology, Parker Lab, United States, [2]California Institute of Technology, United States

Abstract: Myrmecophilous lifestyles are often highly host-specific, and rely on chemical and tactile cues exchanged between host and symbiont that promote their behavioral interaction. The identities of these cues are for the most part unknown, and how they act as releasers for interspecies social behaviors is poorly understood. In this talk, I describe a model host-myrmecophile relationship that can be reconstituted in the laboratory and studied in high throughput. This system has enabled us to use machine learning to quantify behavioral interactions between the myrmecophile and other objects or organisms that partially or fully recapitulate the host ant phenotype. By gaining experimental control over myrmecophile behavior, we have been able to address the nature and function of ant body-derived cues that are perceived by the myrmecophile and underlie host recognition. We demonstrate a minimal set of cues that are necessary and sufficient to release stereotyped social behaviors that enable the myrmecophile to achieve integration inside the colony. Although in nature the myrmecophile is stringently associated with a single ant species, the ant body cues that trigger its symbiotic behaviors are not host-ant specific. We show how the myrmecophile shows no preference for its host ant in a choice assay, its fidelity towards its host being readily broken in the laboratory. The extreme host specificity of many myrmecophilous relationships may be enforced by colony cues other than those directly associated with the ant body, loosening constraints on social cognition and enabling the myrmecophile to perceive a broad range of ants as potential hosts. This behavioral strategy may be adaptive in allowing the myrmecophile to integrate into colonies in the face of variation in chemical and tactile cues associated with the ant body.

Cell type evolution of a rove beetle chemical defence system revealed by single-cell biology

Authors: Parker Joseph[2], Brueckner Adrian[1], [1]California Institute of Technology Division of Biology and Biological Engineering, Pasadena, CA, United States, [2]California Institute of Technology, Parker Lab, United States

Abstract: Multicellular exocrine glands, where cells work collectively to synthesize bioactive secretions, provide a paradigm to study the evolution of novel cell types and biosynthetic pathways. We exploit a new unique model system – the defensive gland of the rove beetle Dalotia coriaria. This rove beetle has a large defensive gland at the dorsal abdomen tip consisting at least two cell types, which produce a cocktail of three different benzoquinones (D1 cells), or the hydrocarbon solvent undecane and two esters (D2 cells). To shed light on how these cell types evolved and whether they arose from pre-existing cell types, we perform bulk and single-cell comparative transcriptomic analyses (10x droplet-based sequencing and SMARTseq) of the beetles' gland segment and compare it to other non-gland bearing segments. In total, over 3000 genes are differentially expressed in the gland cells and can be assigned to different cell types. We use these data and harness the power of newly developed bioinformatic tools to assign transcriptional building blocks and reconstruct the molecular architecture of the glandular complex from pre-existing tissue. Additionally, stable-isotope experiments help to trace potential precursors and interfere the biosynthetic pathways on both molecular and biochemical level. Overall, we show how state-of-the-art single cell biology can be utilized to evolutionarily dissect the assembly of novel gland cell types with unprecedented molecular and transcriptional resolution.

Rove Beetle Genomes Provide Insight into Defensive Gland Evolution

Authors: Parker Joseph[2], Brueckner Adrian[1], Kitchen Sheila[3], Miller David[3], Wagner Julian[3], Naragon Thomas[3] and Kishi Yuriko[3], [1]California Institute of Technology Division of Biology and Biological Engineering, Pasadena, CA, United States, [2]California Institute of Technology, Parker Lab, United States, [3]California Institute of Technology, United States

Abstract: Rove beetles (Staphylinidae) comprise the largest family in Metazoa with nearly 64,000 species. The vast radiation of rove beetles can be attributed in part to their shortened elytra that enhanced abdomen flexibility, thereby allowing occupation of diverse and novel habitats. A second key innovation was the evolution of a defensive tergal gland in the largest subfamily Aleocharinae. The gland can discharge volatiles through abdomen flexing to deter predators. The development of the abdominal gland has been proposed as a primary preadaptation for social insect symbiosis. Many lineages have convergently evolved into highly social, symbiotic organisms through repeated changes in morphology, glandular chemistry and behavior to assimilate into the complex societies of ants and termites. In this study we investigate the evolutionary "ground state" of aleocharine beetles through genomic, transcriptomic and chemical profiling. We present the near chromosome-level genome assembly of Dalotia coriaria, a new genetic model system, and draft genome assemblies of 12 other species. Genomic scans for conservation of genes, gene families and genomic architecture in tergal gland development were assessed within the higher Aleocharinae and the convergently-derived defensive glands of Tribolium castaneum. Genes previously characterized to be specific to the gland tissue and volatile production in T. castaneum were compared with differential expression of control and gland tissue, targeted RNA interference and quantification of gland volatiles with GC/MS in D. coriaria. We highlight common molecular processes underlying the evolution of the defensive gland in beetles and those specific to the aleocharines that were key to their diversification.

Myrmecophile assemblages as models for testing hypotheses in community ecology

Authors: Parmentier Thomas, Ghent University, Belgium

Abstract: Ant colonies house a hidden diversity of symbiotic arthropods. Gradually, we gained a profound understanding of how these so-called myrmecophiles interact with their ant host. They possess a range of chemical, morphological and behavioural tactics to be able to live in the hostile ant nest environment. Interestingly, myrmecophiles do not only interact with their ant host, but also strongly interact with other co-habiting myrmecophiles by predation and competition. In fact, myrmecophiles are often part of heterogeneous communities spanning different trophic levels. In this talk, I will lay out how these neat microcosm communities can be used as model systems to address general hypotheses on spatial ecology, ecological succession, community stability and the drivers of food chain length.

Nutrient value and safety of black soldier fly larvae fed on organic waste streams for use in animal feed

Authors: Parry Nina[1] and Weldon Chris[1], [1]University of Pretoria, South Africa

Abstract: Fly larvae can be used to effectively reduce and valorise organic waste streams and produce value-added products such as a protein supplement for monogastric animal feed and lipids for biodiesel. The black soldier fly, Hermetia illucens L. (Diptera: Stratiomyidae), is commonly used in bioconversion due to its versatility and efficiency in reducing various types of organic waste, including fruit and vegetable waste and animal manure. The type of organic waste that larvae feed on can affect their nutritional composition and the presence of pathological microbes and heavy metals. This study investigated the nutritional composition of larvae that fed on three different types of organic waste. Freshly hatched neonates (90 mg), collected within three hours of hatching, were placed on 12 kg of pre-consumer waste, post-consumer waste or chicken manure and collected 15 days after egg hatch. The larvae were held at 28 ± 0.5°C and this was repeated for fifteen different batches of each waste type. Proximate analyses (crude protein, crude lipid content, ash and fibre), fatty acid analyses, amino acid analyses, microbiological tests and heavy metal tests were performed on larvae and on each waste batch. Nutritional composition, microbiological load and heavy metal presence of the larvae were related to the waste type that they fed on. The nutritional composition, performance and efficacy of waste reduction and bioconversion of the larvae on each waste type was compared. The nutritional composition of the larvae fed on different waste types was compared to the ideal nutrient composition of traditional protein sources for animal feed. Results to be discussed.

Assessment of the repellent effect of essential oils and volatile compounds against apple sawfly (Hoplocampa testudinea) in organic orchards

Authors: Parveaud Claude-Eric[1], Tasin Marco[2] and Jacquot Maxime[1], [1]Research Group for organic Farming, France, [2]Swedish University of Agricultural Sciences, Sweden

Abstract: The European apple sawfly Hoplocampa testudinea (Klug) (Hymenoptera: Tenthredinidae) is a pest in apple orchards in Europe and in North America. In organic production, methods to control this pest have a low efficacy, and damages can reach up to 80%. However, since this pest causes damage during the blooming period, the use of insecticides is not recommended to preserve beneficial insects. Thus, disruption of host-plant finding before oviposition by using volatiles compounds is a sustainable way to control it. Inspired by the publication from De Almeida et al. (2017) who demonstrated a significant repellent effect of yarrow flower strips (Achillea millefolium L.) and sprayed yarrow essential oils, we assessed the repellent effect of essential oils and volatile compounds in organic orchards during two years. In 2018, the experiments were conducted in three organic apple orchards to test separately the repellent effects of the three essential oils (Achillea millefolium, Artemisia dracunculus and Cananga odorata) on apple sawflies, predators and pollinators. Taragon (A. dracunculus) and C. odorata essentials oils were selected because they respectively contain beta-ocimene and alpha-farnesene. Essential oils were diffused with 2 mL drilled vials put on white sticky traps. Captures were compared with the control treatment, i.e. traps without essential oil diffusion. A gradient of pest pressure was observed in the three experimental plots: from 10 to 155 apple sawflies were counted per trap in 15 days. No significant repellent or attractant effect of the three essentials oils on apple sawflies and pollinators was observed. In 2019, the experiments were conducted in two organic apple orchards to test separately the repellent effects of Achillea millefolium essential oil and a 50:50 blend of beta-ocimene and alpha-farnesene. Dispensers consisted of 1mL of a base matrix paste (SPLAT paste, ISCA Technologies) used to hold and release semiochemicals. Each 1 mL droplet was put in a plastic cup which was easy to hang on trellis wire. Apple sawfly damages were assessed at two dates. No significant repellent effects were observed. The discrepancy between literature and the present results may be explained by the quantity of repellent used. De Almeida et al. (2017) sprayed daily a solution at 4% of essential oil: apple sawflies were certainly exposed at a higher concentration of organic compound than in our experiments with passive diffusion only. The dynamics of diffusion of volatile compounds over time could also be involved.

Oviposition-related cues affect plant responses against herbivores, and life history traits

Authors: Pashalidou Foteini, INRA Versailles-Grignon, France

Abstract: Plants can detect cues associated with the risk of future herbivory and modify defense phenotypes accordingly. However, our understanding of these early warning cues and associated plant responses is limited, both with respect to the range of cues to which plants respond and the nature of the responses. We assessed plant responses to different early warning cues, egg deposition and volatile emissions from neighbors infested with herbivore eggs, and measured changes in both defense and fitness-related traits. We show that exposure to oviposition–early warning cues promotes stronger defense responses to subsequent herbivory in Brassica species. Furthermore, exposure to these volatile cues induced earlier flowering and increased seed production in Brassica nigra, suggesting a strategy of reproductive escape. Our results thus document novel cues for plant responses, and show that plants respond to the threat of herbivore attack through changes in both defense and life-history traits to preserve fitness.

The crucial role of the circulatory system in maintaining the biomechanical properties of insect wings

Authors: Pass Guenther, Department of Integrative Zoology University of Vienna, Austria

Abstract: As every entomologist knows from experience, insect wings quickly stiffen and become brittle when they dry out. This is clearly due to a physical process, as it can easily be reversed by high humidity or prolonged immersion in water. The strong dependence of the flexibility and toughness of the insect wing cuticle on its hydration status inevitably involves also the problem of constantly replacing the loss of water caused by evaporation. Despite the importance of this topic for the biomechanics of the insect flight apparatus, only marginal notes on the water balance of the wings can be found in the literature. Studies on the ultrastructure of the wing cuticle support the hypothesis that the wing membrane, which consists almost exclusively of epicuticle, requires little hydration. On the other hand, the cuticle of the wing veins needs continuous hydration since it also contains layers of chitin-protein complexes and resilin. The necessary water is obviously supplied by the hemolymph which flows continuously through the veinal network of the wing. The influence of the hemolymph mass and the circulating flow in the veins on the aerodynamic properties of insect wings also requires further investigation.

Local adaptations or genetic diversity: which is more beneficial in a biocontrol agent population?

Authors: Paterson Iain, Rhodes University, South Africa

Abstract: Significant efforts are invested into ensuring that classical biological control agents are suitably adapted to the target pest population and the climatic conditions to where they are intended for introduction. The most effective biological control agents are assumed to be those that have a close evolutionary association with the target pest population and those that were collected in climatically similar areas to the introduced range. An alternative strategy to ensure that biological control agents are suitably adapted to the introduced range is to release a genetically diverse agent population that can adapt to the target pest population and climatic conditions of the introduced range over time. This could be achieved by collecting agent populations from a wide variety of target pest populations across a wide variety of climatic zones in the native distribution. Releasing the best adapted biocontrol agent and releasing a genetically diverse agent population on which evolution can act are mutually exclusive, so one of these approaches must be selected for each new biological control agent. Specific examples of weed biological control agents from South Africa, as well as an analysis of how genetic bottlenecks and founder population size effect success of the agents released in the country, indicated that neither of these approaches can be seen as a general rule. The relative importance of genetic diversity and local adaptation is dependent on the nuances of each individual biological control programme.

With or without increased competitive advantage in Pereskia aculeata, susceptibility to a biological control agent, Catorhintha schffneri, remains genotype specific

Authors: Paterson Iain[1], Egbon Ikponmwosa N.[3], Hill Martin[2] and Compton Stephen[4], [1]Rhodes University, South Africa, [2]South Africa, [3]University of Benin, Nigeria, [4]University of Leeds, United Kingdom

Abstract: Native species transported without their natural enemies to new habitats could invest more in fitness, as opposed to defence, which explains their invasiveness according to ‘Evolution of Increased Competitive Ability’ (EICA). We tested here native and invasive genotypes of Pereskia aculeata Miller as models to test for EICA and explore how ‘enemy release’ influenced the invasion success of the introduced populations. Plant growth parameters (height and shoot length) of fifteen genotypes, and the susceptibility of ten genotypes to a specialist herbivore, Catorhintha schaffneri Brailovsky & Garcia, were compared in common garden experiments. Introduced genotypes grew significantly taller than native-range genotypes. Furthermore, invasive genotypes were more susceptible to herbivory than the native genotypes, though the observed differences were not completely explained by ranges as EICA had predicted; nonetheless, the observed data partially support its predictions, because invasive genotypes generally and significantly grew taller more quickly and were more susceptible to damage from a specialist herbivore, C. schaffneri, than some native genotypes. Higher susceptibility to herbivore damage by the invasive genotypes suggests that C. schaffneri may be more damaging in South Africa where it is introduced as a biological control agent than it is in the native range.

Measuring success of aquatic weed biological control in Africa

Authors: Paterson Iain[2], Martin Grant[1], Coetzee Julie[1], Hill Martin[3] and Motitsoe Samuel[1], [1]Centre for Biological Control, Department of Zoology and Entomology, Rhodes University, Makhanda, South Africa, [2]Rhodes University, South Africa, [3]South Africa

Abstract: The economic, social and environmental impacts of invasive aquatic weeds have largely been quantified in Africa, where, uniquely, biological control is the primary method of control in many parts of the continent. However, post-release evaluations are still neglected, with the exception of South Africa, where the effect of releasing host-specific natural enemies has been quantified at different scales, including cellular, individual plant, population and landscape scales. In most cases, biological control has successfully reduced the invasion according to these metrics. While the reduction in the invasion is assumed to alleviate the negative impacts, this is not measured, and ecosystems are unlikely to revert to pre-invasion conditions after control has been implemented, in the absence of active restoration efforts. Studies that directly measure the economic, social and environmental benefits generated by aquatic ecosystems before, during and after biological control, will improve how success is quantified. The first studies of this kind, which have investigated the environmental benefits of biological control on aquatic ecosystems in South Africa, recommend that biological control programmes must be followed by active restoration practices. Further investigations into trophic structure and function will provide holistic aquatic weed management strategies for ecosystem recovery and restoration of invaded aquatic ecosystems in southern Africa and globally.

The Hymenoptera collections of the Finnish Museum of Natural History

Authors: Paukkunen Juho, Finnish Museum of Natural History, Finland

Abstract: The entomological collections of the Finnish Museum of Natural History (LUOMUS) contain about 9 million preserved insect specimens. The most abundantly represented groups are Lepidoptera, Coleoptera and Hymenoptera, followed by Diptera and the smaller orders. The Hymenoptera collections comprise approximately 1,5 million specimens of which 1 million belong to the Eastern Fennoscandian collection and 500 000 to the World collection. Most specimens in the Eastern Fennoscandian collection are from Finland, but also much material from the Russian part of Fennoscandia is included. The World collection contains specimens from all over the world, while the majority are from Europe and other parts of the Palaearctic region. Particularly well represented regions include Macaronesia, southern Europe and Russia. The collections have accumulated during two hundred years, mainly starting from the 1840s. The four most abundant superfamilies are Ichneumonoidea, Apoidea, Tenthredinoidea, Chalcidoidea and Formicoidea. Of the approximately 3500 Hymenoptera type specimens about 1000 are name-bearing types of several authors such as Wolter Hellén, Eitel Lindqvist and William Nylander. Approximately 15% of all the Hymenoptera specimens have been digitized by 2022, the majority of which are Finnish aculeates. The collections have been growing steadily by thousands of specimens every year during the past decade.

Population Genomics of the Antarctic midge (Belgica antarctica)

Authors: Pavinato Vitor[2], Edgington Hilary[1] and Michel Andrew[2], [1]The College of Wooster, [2]The Ohio State University, United States

Abstract: Phylogenetics show that Antarctica's terrestrial arthropods persisted throughout the repeated glaciation events of the Pleistocene. As ancient glacial-interglacial cycles are similar to current and future environmental changes, these arthropods are ideal systems to study the evolutionary responses to climate changes. The Western Antarctic Peninsula (WAP), which is home to the Antarctic midge (Belgica antarctica), had experienced a dramatic climate change. This species is an ideal candidate to study how ancient glacial-interglacial cycles have shaped genetic diversity, persistence and adaptation. Preliminary study showed two distinct evolutionary signals co-exist in the genetic makeup of Antarctic midge: 1) a signal of deep phylogeographic divergence among islands populations, and 2) signals of recent and frequent dispersion of individuals to nearby islands. This apparent paradox might indicate the role of local selection against migrants thereby maintaining locally adapted genotypes. Population genetics offers the framework to quantify the relative role of local adaptation and neutral processes in determining the species genetic diversity. We are going to show how methods for demography inference (neutral processes as admixture, population size changes, etc) can help us identify the last glacial-interglacial events that left recognizable signals in the species genome.

Population genomics and epigenomics reveal differential adaptations for biotype evolution

Authors: Pavinato Vitor[3], Shahid Saima[2], Wenger Jacob[1], Slotkin R. Keith[2] and Michel Andrew[3], [1]California State University, [2]Donald Danforth Plant Science Center, [3]The Ohio State University, United States

Abstract: Agroecosystems force intense selection pressures on biodiversity. For some species, these pressures present significant barriers to population stability and persistence, evidenced by low species and genetic diversity. As some species perish, others flourish in these constantly changing landscapes. Rapid insect pest evolution in agroecosystems negatively impacts crop production, as the failure of control causes severe economic losses. Evidence of the role of beneficial mutations in the evolution of pest resistance has been accumulated for several pest systems. However, little is known about the role of epigenetic modifications which could facilitate pest adaptation. We investigated the adaptation to host-plant resistance (HPR) in the soybean aphid, Aphis glycines. This aphid has adapted to soybean with natural resistance, but the mechanism of this virulence is unknown. We combined population genomics, transcriptomics, and a comparison of differentially methylated regions to identify genomic areas associated with virulence. Our combined data sets suggest an interplay between mechanisms associated with the evolution of virulence.

First Inventory of Coleoptera Fauna Associated to Mangroves Ecosystems from the Dominican Republic

Authors: Payano Mercado Ernesto De Jesús[1] and Bastardo Ruth H.[1], [1]Instituto de Investigaciones Botánicas y Zoológicas Prof. Rafael M. Moscoso

Abstract: This is the first faunistic inventory of mangroves ecosystems carried out in the Dominican Republic. The studied mangroves are from four species. The areas from Pedernales, a province at the southwestern region of the country, were selected as the locations to conduct the study, in which samples were taken during the dry season and the season with the highest humidity. The landscape is dominated by herbaceous plants, inaccessible lagoons, swamps, and a coastline overwhelmed by Sargassum. Different sampling techniques were utilized in terrestrial and aquatic habitats as part of a project that had as its main objective collecting invertebrates from a wide variety. Sweep nets, beating sheets, aquatic nets, bowl traps, and UV light tramps were used to capture the coleoptera. Preliminary data shows the presence of thirty families of and fifty more Coleoptera species. On the other hand, the result data is still not sufficient to reach a conclusion regarding which season possesses the most abundance and diversity of coleoptera. Moreover, the poor taxonomic information available about this entomofauna, make the identification of the aforementioned species more complex. Consequently, we recommend further research and studies in this region ensuring the inclusion of specialist from the abovementioned taxonomic groups.

Biocontrol Predators-in-first (PIF) strategies in greenhouse crops

Authors: Pekas Apostolos[3], Wackers Felix[2], Pijnakker Juliette[4], Vangansbeke Dominiek[3], Duarte Marcus[3] and Moerkens Rob[1], [1]Biobest, [2]Biobest Group NV, Belgium, [3]Biobest, Belgium, [4]Biobest, Netherlands

Abstract: The expiration of registration of broad spectrum and persistent pesticides and the availability of new more selective ones have allowed for the emergence of new IPM tactics in greenhouse crops. Nowadays, growers tend to prefer Inoculative Biological Control (IBC) or Conservation Biological Control (CBC), rather than repeated releases of natural enemies of greenhouse pests. Tools like modification of the crop environment or adaptation practices are developed to enhance early establishment and population growth of biocontrol agents on the plants before pest invasion or outbreaks. Examples of effective IBC/CBC techniques, as used by growers, are discussed.

Soluble proteins of chemical communication across arthropods

Authors: Pelosi Paolo[2], Amigues Beatrice[1], Cambillau Christian[1], Zhu Jiao[2] and Knoll Wolfgang[2], [1]AFMB, CNRS, Marseille, France, [2]Austrian Institute of Technology, Tulln, Austria

Abstract: Since the discovery of odorant-binding proteins (OBPs) about four decades ago, a very large number of reports have been published on soluble proteins of chemical communication. However, nearly all the work has been focused on insects and very few studies have addressed other arthropods. Recently, at least two classes of soluble proteins, putative carriers for semiochemicals, have been identified and characterised in spiders, ticks and mites. Niemann-Pick type C2 (NPC2) proteins have been well characterised in vertebrates, where a single sequence is expressed in each species with a common function of carrier for cholesterol and fatty acids. In arthropods, instead, NPC2 proteins have undergone extensive duplication and differentiation, probably under environmental pressure, with a dozen or more members in each species, suggesting a role in chemical communication. In fact, these proteins, so far reported in Hexapoda, Crustacea and Chelicerata, are expressed in chemosensory organs and may represent the main class of soluble proteins of chemical communication in non-insect arthropods.

Another family of soluble binding proteins, named OBP-like for their sequence similarity to insect OBPs, has been found only in Chelicerata and Myriapoda, with only 4-6 members in each species. Despite their significant, although poor, similarity with insect OBPs, these proteins present a completely different structure. The six cysteines are paired in a pattern unlike the interlocked fashion observed in insect OBPs and this likely contributes to the peculiar folding of these proteins. Unlike their insect counterparts, in these proteins the N-terminus and the C-terminus are close and point in the same direction, brought together by a disulphide bridge between the first and the last cysteines.

We have focused our recent work on two species of ticks, the specialised honeybee parasite Varroa destructor and the generalist plant pest Tetranychus urticae. We have expressed and characterised representative members of NPC2 and OBP-like proteins with the aim of investigating the involvement of these soluble binding proteins in chemical communication or in other unrelated functions.

Harnessing endosymbionts for management of vectors and vector-borne agricultural pathogens

Authors: Pelz-Stelinski Kirsten[1], Neupane Surendre[1] and Bonilla Sylvia[1], [1]University of Florida, United States

Abstract: Insect pests represent a significant problem for agriculture as a result of economic losses resulting from direct plant damage and indirect losses resulting from the transmission of plant pathogens during feeding. Globalization has increased the prevalence of many pathogens during recent years, while increasing concerns associated with pesticide use have limited the efficacy of insect pest management programs. Citrus greening disease is one of the most destructive diseases of citrus worldwide. The putative causal agent, Candidatus Liberibacter asiaticus (Las), is transmitted by the Asian citrus psyllid, Diaphorina citri Kuwayama (Hemiptera: Liviidae). The goal of this project was to develop a novel, biological control-based tool for decreasing pathogen transmission by harnessing native D. citri microbial flora to reduce pathogen transmission. Here, we describe the development of a D. citri-derived Wolbachia culture and the establishment of a paratransgenesis system using genetically-modified Wolbachia to introduce a phenotype-altering transgene into D. citri. Development of this biological control-based strategy may have a significant impact on the epidemiology of vector-borne agricultural pathogens as a novel tool to disrupt pathogen transmission.

Extending the knowledge of the African savannah parasitic wasp fauna: the Braconidae and Ichneumonidae from the Quiçama National Park

Authors: Penteado-Dias Angélica[4], José Almeida[3], Pontes Aristófanes[2], Timoteo Ferreira[1], Ferreira João[1], de Fátima Silva Maria[2] and Pedro Tatiana[5], [1]Federal University of São Carlos, Angola, [2]Institute of the Biodiversity and Conservation Areas, Angola, [3]Methodist University of Angola, Angola, [4]Taxonomic Collection of the Department of Ecology and Evolutionary Biology (DCBU), Department of Ecology and Evolutionary Biology (DEBE), Federal University of , Brazil, [5]University Agostinho Neto, Angola

Abstract: The currently designated Quiçama National Park, 9 o 55'2 " south latitude and 13 o 52'37" west longitude, 70 km south of Luanda, is located in Quiçama municipality, Luanda province, Angola. It has a total area of 960,000 hectares of Savannah vegetation and its average temperature ranges from 27o to 28oC during the rainy season and from 23o to 24oC in the dry season. The Park is bordered by the Kwanza River (the largest in the country), the Long River and bathed by the Atlantic Ocean, with a humidity between 80% and 87% and its average annual rainfall varies between 400 mm, on the coast and 1000 mm, more to the interior . From January to April 2019, with monthly Malaise trap collections in the dry and wet savannah area of Quiçama Park we studied the Braconidae (954 specimens, 15 subfamilies) and Ichneumonidae (212 specimens, 8 subfamilies). Among the Braconidae are Cardiochilinae (316 specimens, 5 genera) and Agathidinae (229 specimens, 3 genera); among the Ichneumonidae, Campopleginae (104 specimens, 6 genera) and Cremastinae (57 specimens, 4 genera) were the most common in the samples. Our results are new species or first occurrences for Angola and even for the Afrotropical region.

Evidence of ATP-binding cassette transporter (family C4) gene is involved in eCry3.1Ab resistance mechanism in western corn rootworm

Authors: Pereira Adriano[1], Hibbard Bruce[2], Shelby Kent[2], Gregory Michelle[2] and Coudron Thomas[2], [1]University of Missouri, United States, [2]USDA/ARS, United States

Abstract: Western corn rootworm (WCR), Diabrotica virgifera virgifera LeConte, has proved to evolve resistance to any control tactics in the field. In this study, we investigated the resistance mechanisms in WCR-resistant strain to the Bacillus thuringiensis (Bt) protein eCry3.1Ab by using double stranded(ds) RNA to knockdown WCR midgut genes potentially involved in resistance mechanisms. The genes ABC-transporter, Aminopeptidase-N, Cadherin, and Cathepsin-B, were found to be differentially upregulated in eCry3.1Ab-resistant WCR larvae. Initially, we compared the expression of those four genes with Green Fluorescent Protein (GFP) in WCR-resistant and susceptible strains by exposing neonate larvae to 1µg of dsRNA/cm2 of artificial diet for three days to perform RT-qPCR. The results showed that all those four genes were significantly knocked down in both WCR strains. Finally, WCR-resistant and susceptible larvae were exposed to eCry3.1Ab and dsRNA mixed together in 10-day diet overlay toxicity assays. We report the first case of partial restoration of WCR resistant larvae to susceptibility to eCry3.1Ab protein after feeding on eCry3.1Ab and ABCC4 transporter dsRNA mixed together. We also report that mortality observed in WCR larvae is the opposite of what was shown in lepidopteran in which susceptible insects became less susceptible to Bt protein after ABC transporter knockdown. ABC transporter is known to be involved in Bt resistance in several lepidopteran and in at least one coleopteran insect pes. Therefore, our results show evidence that ABC transporter may be involved in WCR resistance to Bt protein eCry3.1Ab

Insect Pathogens and their Control in Insect Rearing Facilities

Authors: Pereira Roberto, University of Florida, United States

Abstract: General discussion will be presented on the principal entomopathogens that may occur in large scale production of insects. The characteristics of the different pathogen groups, and the signs that may be useful in their detection, will be discussed in relation to preventive measures to be used in production systems. Decontamination and other corrective actions to control entomopathogens and contaminants in insect colonies will be discussed in relation to different production systems and the final use of insects in production..

New insights on corn borer resistance to Bt maize in Europe

Authors: Pérez Farinós Gema[1] and Ortego Félix[1], [1]Margarita Salas Center for Biological Research (Spanish National Research Council), Madrid, Spain

Abstract: Maize varieties derived from event MON810 expressing Cry1Ab toxin (Bt maize) are currently the only genetically modified plants approved for cultivation in the EU. Ninety-five percent of them are found in Spain, representing approximately 30% of the maize grown in the country. Bt maize effectively controls the maize pests Sesamia nonagrioides (Mediterranean corn borer) and Ostrinia nubilalis (European corn borer). Despite the widespread trend towards the development of resistance of target pests to Bt crops (Tabashnik & Carrière, 2019), both species remain susceptible to MON810 maize, with no cases of practical resistance detected in the field after 24 years of Bt maize cultivation (Bt176 between 1998 and 2005, and MON810 since 2003) (Farinós et al., 2018; Thieme et al., 2018).

Insect resistance management in Spain is based in the high-dose/refuge (HDR) strategy and in the implementation of monitoring programs, to assess the potential development of resistance of both target pests to Bt maize. Since 2016 monitoring is focused on the Ebro Valley (northeast Spain). This is Europe's only hotspot, where target pests have been exposed to Cry1Ab maize continuously since 1998 and the adoption rate of Bt maize is normally above 60%. A resistance evolution model for S. nonagrioides, developed considering biological, ecological and agronomical variables known to affect resistance development, showed that low initial adoption rates of Bt maize, as well as high compliance with the use of refuges by farmers (around 90% in the last 12 years), appear to have been key to prevent resistance (Castañera et al., 2016). Despite this, an allele of resistance was found in a S. nonagrioides field population in 2016 using the F2 technique (Camargo et al., 2018). The resistance evolution model was updated with this new information and it showed that resistance did not seem to be evolving faster than predicted, although the frequency of resistance was triple the value recommended for an effective implementation of the HDR strategy, so vigilance must be maintained.

The sustainability of Bt maize cultivation in the EU faces several challenges, the most important being the uncertainties of EU policy for GM crops and the reduced set of tools available for resistance management, since pyramided Bt maize varieties cannot be used. Thus, it is essential the strict compliance of refuges, as well as continuing the monitoring of resistance evolution in the Ebro Valley.

Performance of the Mediterranean corn borer Sesamia nonagrioides (Lepidoptera: Noctuidae) on cultivated and wild host plants: implications for Bt maize resistance management in Spain.

Authors: Pérez Farinós Gema[1], Martín Camargo Ana[1], Arias-Martín María[1] and Castañera Pedro[1], [1]Margarita Salas Center for Biological Research (Spanish National Research Council), Madrid, Spain

Abstract: The Mediterranean corn borer Sesamia nonagrioides (Lefèbvre) is an important maize pest restricted to the Mediterranean area that is effectively controlled by maize varieties derived from the event MON 810 that express the Cry1Ab toxin (Bt maize). The continued cultivation of Bt maize in Spain exerts high selection pressure on the target pests, which could lead to the development of resistance to this crop. Provision of refuges of non-Bt plants to prevent the development of resistance is an essential point in the high-dose/refuge (HDR) strategy. In this work we analyze whether two cultivated plants (rice and sorghum) and four wild plants (johnsongrass, cattail, common reed and giant reed), reported as hosts of S. nonagrioides, are suitable for larval development and oviposition of this pest compared to maize. The results provide information on the possibility that these plants can be used as unstructured refuges for Bt maize, and therefore on their role in delaying resistance development to this crop.

We carried out different types of bioassays to assess: i) the larval performance of S. nonagrioides on all seven hosts, and ii) the larval feeding preference and the oviposition preference between the three cultivated hosts, maize, rice and sorghum. Females of S. nonagrioides laid eggs on all seven plants. However, bioassays conducted with plant pieces or whole plants showed that the larval cycle could only be completed in the three cultivated plants and in johnsongrass. Females showed a strong preference for ovipositing on maize plants in comparison with sorghum or rice. Although neonates chose to feed on sorghum rather than maize in two-choice bioassays, both larvae and adults had a better performance when larvae fed with maize throughout their larval stage.

Our results suggest that none of the alternative hosts of S. nonagrioides tested here should be used as an unstructured natural refuge for Bt maize in Spain, nor be considered within the HDR strategy in this species, as some of the necessary requirements to effectively delay resistance development would not be met.

Nectar-inhabiting bacteria affect attraction and fitness of egg parasitoids

Authors: Peri Ezio[1], Colazza Stefano[1], Cusumano Antonino[1], [1]University of Palermo, Italy

Abstract: Floral nectar is ubiquitously colonized by a variety of microbial organisms among which yeasts and bacteria are the most common. Microorganisms inhabiting floral nectar can alter several nectar traits, including nectar odor by producing microbial volatile organic compounds (mVOCs). Evidence showing that mVOCs can affect the foraging behavior of insect pollinators is increasing in the literature, whereas the role of mVOCs in altering the foraging behavior of third-trophic level organisms such as insect parasitoids is largely overlooked. Parasitoids are frequent visitors of flowers and are well known to feed on nectar. In this study we isolated bacteria inhabiting floral nectar of buckwheat, Fagopyrum esculentum, to test the hypothesis that nectar bacteria affect the foraging behavior of the egg parasitoid Trissolcus basalis via changes in odors of nectar. In behavioral assays, we found that T. basalis wasps were attracted towards nectar fermented by 4 out of the 14 bacterial strains isolated, which belong to Staphylococcus epidermidis, Terrabacillus saccharophilus (both Firmicutes), Pantoea sp. (Proteobacteria) and Curtobacterium sp. (Actinobacteria). Results of chemical investigations revealed significant differences in the volatile blend composition of nectars fermented by the bacterial strains. Our results indicate that nectar-inhabiting bacteria play an important role in the interactions between flowering plants and foraging parasitoids. These results are also relevant from an applied perspective as flowering resources, such as buckwheat, are largely used in agriculture to promote conservation biological control of insect pests.

Phylogenomic reconstruction of the Polideini (Tachinidae: Tachininae) through the lens of Ultraconserved Elements

Authors: Perilla López Juan Manuel[1], Buenaventura Eliana[3] and O. Stireman III John[2], [1]United States, [2]Department of Biological Sciences, Wright State University, Dayton, OH, United States, [3]Museum für Naturkunde, Leibniz Institute for Evolution and Biodiversity Science, Berlin, Germany

Abstract: The Polideini are a primarily New World tribe of the Tachininae with about 160 described species. They display strikingly diverse external morphological variation, a wide geographic distribution, and a broad array of host associations. The tribe, as currently understood, was defined by O'Hara in 2002, and its monophyly is well supported by morphological and molecular analysis using four nuclear loci. However, the true diversity of the tribe in the Neotropical region is still unknown. Limits of Neotropical genera are poorly defined and numerous genera and species remain undescribed. The Polideini provide an ideal case study to assess the ability of Ultraconserved Elements (UCEs) to resolve relationships in a rapidly diversifying and taxonomically confusing clade of insects. Using a recently developed UCE probe set designed to target families of the Oestroidea, we performed target enrichment and multiplexed sequencing of 77 representatives of the Polideini and outgroups, capturing an average of 630 loci per taxon. Using a maximum likelihood analysis, the Polideini were reconstructed as monophyletic, supporting previous morphological and molecular locus-limited analyses. Reconstructed relationships within major clades are robustly supported, however relationships between them are characterized by very short internode intervals suggesting a recent an explosive radiation of the Polideini. Nearctic Polideine were resolved as several clades well nested within Neotropical lineages suggesting a Neotropical origin of the tribe, with multiple colonization events of temperate regions. In addition, our results suggest that large-bodied spiny Polideine lineages have convergently evolved several times within the tribe. Our UCE-based phylogeny provides a foundation for understanding the evolutionary relationships within this morphologically diverse tribe, sets the stage to define limits of morphologically distinct and disjunct genera, and highlights the widespread morphological homoplasy throughout the Tachinidae.

Benefits of insect conservation measures in agricultural areas

Authors: Peris-Felipo Francisco Javier[2], Schade Michael[1], Gugger Rudolf and Swart Gina[3], [1]Syngenta, [2]Syngenta Crop Protection, [3]Syngenta Crop Protection Basel, Switzerland

Abstract: Land-use changes in the 1950–1970's notably impacted modern intensive agricultural practices, resulting in a substitution of heterogeneous agricultural landscapes by homogeneous ones. Land consolidation led to the elimination of edges and other ecologically valuable structural elements that provided floral resources and nesting sites.

Habitat loss triggered critical changes in the insect communities. Within beneficial insects, pollinators, mainly wild bees, have been severely affected and suffered the highest decline, reaching up to 50%. Reviews carried out demonstrate that habitat loss, invasive species, parasites and diseases, non-sustainable use of pesticides, and climate change explain the reduction of insect abundance and diversity.

Here we present LIVINGRO™, a collaboration between Syngenta and nine universities. This agro-ecological program aims to build substantial and comprehensive scientific data from real-world field trials. The data will serve to test our hypothesis that the use of modern agricultural technology and best agricultural practices, together with ecological compensatory measures, can sustainably improve biodiversity and soil health in agricultural landscapes.

LIVINGRO™ examines the performance of crops and natural ecosystems across different geographies, and on a variety of perennial and rotational crops. The researchers will look at all orders of insects, whether they are living above ground or in the soil.

Differential influence of temperature on the toxicity of three insecticides between Cydia pomonella (L.) and two natural enemies: consequences of global warming on biological control in orchards

Authors: Perrin Marie[3], Moiroux Joffrey[2], Siegwart Myriam[5], Borowiec Nicolas[6], Thaon Marcel[6], Dib Hazem[1], Melloul Emile[3] and Delattre Thomas[4], [1]Avignon University, [2]Avignon University, France, [3]Avignon University, France, [4]INRAE Avignon, [5]INRAE Avignon, France, [6]INRAE Sophia-Anitpolis

Abstract: Insecticide toxicity may strongly vary with temperature and interspecific differences have been commonly reported for this relationship. A differential influence of temperature on insecticides toxicity between pests and their natural enemies may have important consequences on biological control in a warming world. This study aimed to investigate cross effects between temperature and three insecticides on the mortality of a major pest in orchards, Cydia pomonella, and two natural enemies in southern France, the predatory earwig Forficula auricularia and the introduced parasitoid Mastrus ridens. We observed a decreased efficiency of emamectin and spinosad at high temperature to control the codling moth while temperature did not influence chlorantraniliprole efficacy. Increasing temperatures however increased the toxicity of all insecticides on M. ridens, and of emamectin on F. auricularia. Such study provides insight to make recommendations for the use of these insecticides in combination with the use of natural enemies to control pests in a warming world. An alternating use of emamectin during early spring, when its toxicity is the lowest on F. auricularia, with chlorantraniliprole during summer could for example limit the risks of resistance appearance in codling moth populations while reducing insecticides impact on populations of natural enemies.

Post-fire trends of pollinators in the Aegean Archipelago, a biodiversity hotspot

Authors: Petanidou Theodora, University of the Aegean

Abstract: Fire is among the most important disturbances in Mediterranean ecosystems, and frequent enough to be considered as an integral characteristic of this Region and of other Mediterranean-type regions of the world. The increasing inflammability within these systems, as a result of climate change, will boost both the frequency and the severity of fires. In this talk I will present the results of a series of systematic studies carried out in three areas of Greece (two Aegean islands and a mainland) on the effects of wildfires on pollinator diversity, principally bees, considering fire history, fire severity, and post-fire recovery both in the short- and the long-term. The results show that fire history does not affect richness and abundance of bees, but it does shape their community structure, vis-à-vis functional traits (nesting habit, polylecty, body size). Regarding the effect of fire severity, major insect guilds (bees, sawflies, wasps) respond to fire severity at relatively small spatial scales (250-300 m) and in conformity with the Intermediate Disturbance Hypothesis; flies and beetles respond to larger spatial scales, their response being of decreasing type. The entire set of conclusions stemming out from these results constitute a valuable basis for forest management targeting to pollinator conservation.

The project LIFE 4 POLLINATORS: Educating about pollinators in the Mediterranean Region

Authors: Petanidou Theodora[1], Chroni Athanasia, Tsamparli Fereniki, Tzannetou Maria and Galloni Marta[2], [1]Department of Geography, University of the Aegean, Greece, [2]University of Bologna, Italy

Abstract: Despite consisting a major bee hotspot and world center of bee speciation, the bees and pollinators of the Mediterranean are poorly studied. What is particularly missing in all Mediterranean countries, however, is public awareness on the role of wild pollinators, as most of the existing awareness-raising initiatives there focus exclusively on honeybees. The EU LIFE 4 POLLINATORS project aims to safeguard the pollinators of the Mediterranean by focusing on public awareness of different stakeholders and the public in four Mediterranean countries making use of citizen science through developing a series of outreach tools. Here we will present some of the tools already in use by the project in Greece, particularly in the Aegean, such as mini bioblitzes, bee-hotels, and most importantly, a 3-D Mediterranean flower–pollinator garden. The garden consist of 13 different plant species models bearing flowers of different floral architecture, i.e. of diverse pollination syndromes, together with their pollinators; all pieces are 5x the natural size and constructed from recycled material, mainly paper. The garden gives immense possibilities for education on plant–pollinator relationships and for inspiration to animators and children to make stories out of natural history.

Transcriptome-based phylogenomics in Hymenoptera – achievements and problems

Authors: Peters Ralph S., Zoologisches Forschungsmuseum Alexander Koenig, Germany

Abstract: Analyses of transcriptome sequence data have been established in the last ten years to decipher phylogenetic relationships between taxa, and have also been applied to the insect order Hymenoptera and some of its subgroups (e.g., Chalcidoidea, Vespidae, Apoidea). Data sets usually span thousands of genes and millions of amino acid or nucleotide positions.

In several cases, analyses have helped to resolve relationships that had so far been unknown or controversial. In other cases, we still see unresolved relationships and significant conflict within data sets, incongruence between phylogenomic results and evidence from other data sources or we still face large gaps in the Hymenoptera tree due to coarse taxon sampling.

Analyses pipelines have many steps implemented that deal with data quality management, contamination issues, detection and avoidance of conflicting signal or confounding effects; steps are widely automized in order to be able to process very large data sets. However, while most analyses allow inferring well-supported and plausible trees, transcriptome-based datasets fail to resolve some of the hymenopteran relationships.

I will present the status quo of transcriptome-based phylogenies in Hymenoptera and summarize the achievements and problems; I will focus on the measures we take to target and solve those problems and will outline possible reasons why some of the problems still persist.

Sensitivity and specificity of two LAMP eDNA assays for Buprestid forest pests

Authors: Peterson Donnie[3], Kyle Kathleen[2], Pecori Francesco[1], Santini Alberto[1], Luchi Nicola[1] and Cleary Michelle[3], [1]Institute for Sustainable Plant Protection - National Research Council (IPSP-CNR, [2]Rutgers University, [3]Swedish University of Agricultural Sciences

Abstract: The early detection of forest pests using genetic tools is relatively new in forestry. qPCR assays have been used for forest pests, but they can take hours to receive results. LAMP eDNA assays are a rapid tool with results in 30 minutes. Buprestid pests are an emerging forest invader across the world and the early detection of these pests is vital to prevent their establishment. In our study, we designed and modified two LAMP eDNA assays for two Buprestids, both are major pests that if they are not detected early, they could spread further or establish in other European forests. We conducted specificity and sensitivity testing for a current LAMP design for the detection of one Agrilus. We then designed a new LAMP assay for the detection of another species. We found that both assays only amplified DNA of for the targeted species when tested against 12 other European Agrilus and another 12 non-Agrilus. We found both assays were highly specific for detection. The sensitivity of the assays was high, with a limit of detection of 20 femtograms/ul. The results of this study provide a promising tool that is specific and sensitive to the target organisms.

LIFE 4 Oak Forests: Structure and composition enhancement and its monitoring in 5 Natura2000 oak forest habitat types in Hungary and Italy (LIFE16NAT/IT/000245)

Authors: Petroncini Serena[2], Aszalós Réka [1], Frank Tamás [1] and Fidlóczky József[3], [1]Centre for Ecological Research, [2]Ente di gestione per i Parchi e la Biodiversità Romagna, Italy, [3]FENCON Ltd

Abstract: The biodiversity of oak forests is declining because of intensive commercial use. With the nature conservation interventions our goal is to promote the regeneration of the forests and to restore the diversity of forest structure, native tree species composition and micro habitats. As a results, the protected forest mammals, birds, insects, plants, and fungi will be preserved and their populations will increase.

Unlocking the potential of insect biomonitoring surveys using DNA-metabarcoding: Examples from two nationwide monitoring schemes in the UK

Authors: Petsopoulos Dimitrios[2], Evans Darren[1], Lunt Dave, Kitson James, Collins Larissa, Bell James, Boonham Neil and Morales-Hojas Ramiro, [2]Newcastle University, United Kingdom, [1]Newcastle University

Abstract: Insect monitoring schemes have enormous potential for understanding biodiversity declines, but to date have largely been underutilised. We evaluate the use of DNA-metabarcoding of samples from two insect monitoring schemes in the UK and compare them with conventional methods of identification. First, using archived aerial suction samples from the Rothamsted Insect Survey (RIS, collected between 2003-2018), we show that it is possible to successfully metabarcode stored samples over a 20 year period. Congruence with taxonomic identifications varied. Second, we used FERA yellow water-pan trap (YWT, 70 agricultural sites across the UK) and metabarcoded the ‘by-catch’ of non-target insects that would otherwise be discarded. We then examined changes in the seasonal patterns of insect biodiversity. Our results highlight how DNA-metabarcoding can add value to already established bio-monitoring schemes by: i) providing a way to non-destructively analyze archived samples, and therefore unlock their ‘hidden’ potential, and ii) increasing the breadth of taxa being monitored in traditional surveys by including hitherto overlooked by-catch species. We discuss the emerging trends of how species-interactions can be derived using these methods, ultimately leading to the construction and analysis of highly-resolved ecological networks that can then be used to better understand and mitigate insect declines.

Daily and seasonal temperature fluctuation in hollow urban trees – implications for saproxylic beetle conservation

Authors: Peuhu Elina[1], Hölttä Teemu[1] and Mattsson Teppo[1], [1]University of Helsinki, Department of forest sciences, Finland

Abstract: Hollow trees are a key habitat for biodiversity in many environments. A vast number of species live in or utilize trees during their lives. Certain species are specialized to tree cavities and are endangered. Ancient hollow trees have declined in great numbers due to land-use, forestry and agricultural changes, and the trees are still continuously declining. Previously, species assemblages living in hollow trees have been studied worldwide but some issues have been given less attention. For example, the effect of microclimate within hollow trees on saproxylic species existence is yet to be discovered. We measured hollow cavity temperatures in ten lindens (Tilia x vulgaris) in two city parks in Helsinki, Finland. We placed one temperature logger (iButton©) in each tree on the inner wall of the cavity just above the wood mould layer and one at a depth of 15 cm within the wood mould. Ambient temperature was measured with five loggers each attached to the bark of linden trees in the parks. Temperature was measured in 60-min intervals from May 14th 2009 to October 6th 2010 with an accuracy of 0.5 C. The most rapid daily temperature fluctuation was detected with ambient temperatures. Cavity temperatures followed ambient temperatures closely. Wood mould temperatures on the other hand reached their daily maximum during nighttime (around 22:00 in summer) and minimum close to midday. A similar trend in the delay for reaching maximum and minimum temperature was seen with seasonal changes. Average temperature in wood mould seems to be related to cavity size and the height of the opening from ground level. In the future, the relation between microclimate in tree cavities and saproxylic insect occurrences should be studied further to understand the environmental preferences of species assemblages in hollow trees and thus the most important trees for biodiversity.

Citizen Science and the Introduction of Spotted Lanternfly into Virginia, USA

Authors: Pfeiffer Douglas[1], Day Eric[1] and Dellinger Theresa[1], [1]Department of Entomology Virginia Tech Blacksburg VA, United States

Abstract: Spotted lanternfly is a fulgorid hopper, closely associated with tree-of-heaven, but with a wide host range, notably grapes. This species was introduced into Pennsylvania in 2014, and it has expanded its range each year since. This was the first infestation outside of Asia. It is now established in parts of Virginia, Maryland, Delaware, New Jersey and West Virginia. Spotted lanternfly was first detected in Virginia in January 2018. This insect feeds on a broad range of species; winegrapes are a commercial crop at high risk. Because of the dispersed nature of host plants, difficulty in detecting in low densities, and high risk of economic impact, we instituted a Citizen Science approach with three main approaches: surveillance using brown sticky band traps, an online reporting portal, and an online training to meet quarantine requirements. Citizens were trained in use of traps and identification of spotted lanternfly. Subsequent visits to northern Virginia were made to follow up on proper use, and evaluation of catch. Advantages and disadvantages of current assessment tools will be discussed. For paper sticky traps, disadvantages included lack of sensitivity and selectivity. The online reporting portal was made available through various outlets. The goal was to provide specialists with knowledge of incipient infestations in the state. In spring of 2019, the state of Virginia established a quarantine for the infestation zone. This could have posed a problem for fruit growers and other shippers. On online training course was established to allow members of the public to obtain certification to inspect shipments, incorporating citizens not only in collection of data, but on meeting the resulting regulatory needs.

Pesticide usage and handling practices in the malaria endemic region of north-western Tanzania: Implications to the control of malaria vectors (Anopheles gambiae s.l)

Authors: Philbert Anitha[2], Lyantagaye Sylvester[1], [1]Department of Molecular Biology and Biotechnology University of Dar es Salaam, Tanzania, [2]University of Dar es Salaam, Tanzania

Abstract: Pesticides remain the mainstay for the control of agricultural pests and disease vectors. However, their indiscriminate use in agriculture ought to be the source of resistance among disease vectors against public health insecticides. We investigated the practices of farmers with regard to pesticide handling and usage and their impact on susceptibility status of An. gambiae s.l. to insecticides.

Methods
Data collection involved administration of questionnaires and observation of the practices. The surveys were complemented by bioassay tests to assess the susceptibility of vectors to pyrethroids (permethrin-0.75%, cyfluthrin-0.15%, deltametrin-0.05% and lambdacyhalothrin-0.05%) and DDT using WHO test kits. Molecular analysis was performed to identify sibling species of An. gambiae s.l and to characterize the knockdown resistance (kdr) genes.

Results
Forty eight pesticides were used for control of crop and livestock pests, 50% of these were pyrethroids. Pesticide mixing (cocktails), overspray and disposal of left overs in the mosquito breeding habitats were common practices. Susceptibility test results confirmed high phenotypic resistance among An. gambiae populations, mortality rate up to 54% against permethrin. Anopheles arabiensis was the dominant species (86%) followed by An. gambiae s.s (6%), kdr genes were not detected in all of the specimens tested.

Conclusion
The study found out that there is a common use of pyrethroids in agriculture and public health. The study also reports high phenotypic resistance among An. gambiae s.l against most of the pyrethroids tested. These findings are important for introduction of combined integrated pest and vector management (IPVM) strategies.

Chemical cues used by natural enemies of the green peach aphid (Myzus persicae) (Hemiptera) to locate their prey in canola fields

Authors: Phillips Andrew, Murdoch University, Australia

Abstract: The green peach aphid (GPA, Myzus persicae) is a serious pest of canola. Control of GPA has traditionally been achieved using pesticides, however, GPA has shown considerable ability to develop resistance to insecticides. Therefore, alternative methods of control are needed, such as biological control. Historically, biological control has not been successful for aphids in broad-acre crops, such as canola. Therefore, my project aims to explore ways to optimise biological control in canola by investigating the chemicals that natural enemies of the GPA use to find their prey in canola fields. Firstly, six canola fields in Western Australia were sampled to determine which natural enemies were present. Secondly, the volatile profile of canola would be sampled using GC-MS. Finally, the behavioural and electrophysiological response of the natural enemies to canola volatiles would be determined using Y-tube olfactometers and electroantennography (EAG). Preliminary results indicate that the most common natural enemies in canola fields are the parasitoid wasps and hoverflies. Other natural enemies present include lacewings, ladybird beetles and spiders. EAG results indicate that 2-Heptanone, cis-3-hexen-1-ol and Hexenyl acetate elicit a strong response from both hoverflies and wasps.

Phosphine resistance in two species of grain beetles, Tribolium castaneum and Rhyzopertha dominica in North America: Geographic Variation in Resistance Phenotypes and Genotypes

Authors: Phillips Thomas, Kansas State University, United States

Abstract: The lesser grain borer, Rhyzopertha dominica (F) (Coleotpera: Bostrichidae) and the red flour beetle, Tribolium castaneum (Herbst) (Coleoptera: Tenebrionidae) are two of the most destructive stored-product insect pests worldwide. Phosphine gas, or hydrogen phosphide (PH3) is an effective and widely used fumigant pesticide for controlling stored grain insects world-wide. Most likely due to long-term selection pressure, sub-optimal fumigation concentration or/and fumigation failure, phosphine resistant populations of T. castaneum and R. dominica have been reported in many countries. Phosphine resistance (PH3) was investigated for 29 populations of R. dominica from 8 states of USA and 4 provinces of Canada and 35 populations of T. castaneum from 12 states of USA, four provinces of Canada and one population from Thailand using both FAO discriminating dose bioassay and molecular marker analysis. Our results showed that the distribution of PH3 resistance in both species was varied and it was not related to geographic coordinates. However, PH3 resistance was highly correlated with R allele frequencies in both species.

Can we identify them before they disappear? Machine learning to scale insect identification

Authors: Picard Christine[2], Badirli Sarkhan[1], Dundar Mehmet[1] and Mohler George[1], [1]Indiana University Purdue University Indianapolis, [2]IUPUI, United States

Abstract: With only an estimated 20% of insects currently described and known, and anthropogenic impacts continually threatening insects, our process for identifying insects is flawed. Current methods require expertise in taxonomic groups, and a significant input of resources in generating morphological characters that ultimately describe the new species. We have developed a new method that addresses the massive scale of the problem by bypassing human expertise through computer vision and machine learning approaches. In our proof-of-concept, we developed a novel machine learning algorithm that integrated DNA and insect images on a large number of insect species (>1000 across four orders) to not only classify known species with high accuracy (>97%) but delivering the highest accuracies (~81%) to date in classifying unknown species to their correct genus (species that contained neither image nor DNA data in the training dataset). Next steps include extracting morphological information from the images that humans are unlikely to perceive and generate a new way of doing insect identification. The proposed approach can pave the way for more sustainable and scalable monitoring of biodiversity and can become instrumental in offering objective measures of the impacts of recent changes our planet is going through.

Comparative Genomics of Insect Development for Feed and Food Applications

Authors: Picard Christine[2], Tarone Aaron[3], Andere Anne[1] and Rosche-Flores Hector[1], [1]Indiana University Purdue University Indianapolis, [2]IUPUI, United States, [3]Texas A&M University

Abstract: Development time is a classic quantitative trait that can be influenced by genetic and environmental factors and is associated with fitness. This study evaluated genetic components of development time variation through selection experiments on three different experimental populations established from distinct Texas locations. There is was ample standing genetic variation in the species, with most genetic variation segregating within, not among, experimental populations. The selection response was biased such that wild flies appear to be more similar to strains selected for fast development. Genome-wide patterns of selection revealed SNPs with significant shifts in allele frequencies, including in traditional genes associated with regulating growth in Drosophila melanogaster. The presentation will highlight these genomic regions and their homologous regions in commercially relevant insects.

Do floral traits mediate indirect interactions between co-flowering Sierra wildflowers?

Authors: Picklum Devon[1], Richards Lora[1], [1]University of Nevada at Reno, United States

Abstract: Pollinators provide reproductive services to flowering plants by carrying pollen between individuals while collecting nutritional resources in the form of nectar or pollen. In diverse flowering communities, pollinators may visit several different species concurrently, which has direct consequences for plant fitness. Heterospecific pollen transfer represents a cost in lost male gametes and may prevent subsequent pollination if stigmas become clogged with the wrong species of pollen. In this way, plant species that interact indirectly via shared pollinators may experience impaired pollination services. Alternatively, plants interacting indirectly may facilitate each other when pollination services are enhanced due to increased abundance of pollinators. In natural settings, these indirect interactions can be context dependent, and may be influenced by floral traits (eg. morphology, reward type, or floral displays). Here, we investigate the pollination of two flowering species with multi-trait floral similarity to disentangle the role that floral traits play in shaping indirect interactions. Dodecatheon alpinum (alt. Primula tetrandra, Alpine shooting star) and Pedicularis groenlandica (Elephant head lousewort) share similar color, a pollen reward, specific behavioral requirements (buzz pollination), habitat preference, and are both predominately visited by Bombus (bumblebee) species. We first describe bee foraging behavior and pollen deposition, showing that bees move between these species where they co-occur. Pollen placement data and stigma samples show that these species partition pollen on bees' bodies imperfectly, leading to occasional heterospecific pollen transfer. We then measure floral trait similarity using fine-scale reflectance measurements and visual models and floral volatile profiles using dynamic headspace sampling and GC-MS. Visual modeling indicates these two plant species overlap in color to a bumble bee's eyes but vary within their populations. Lastly, we characterize indirect interactions between naturally co-occurring populations of P. groenlandica and D. alpinum. In this field-based approach, we measure co-flowering density and abundance, and look for resulting patterns of con- and heterospecific pollen transfer between these species across close, plot level, and landscape level scales. Together these data connect sensory traits, bee preference, and plant reproductive ecology, setting the groundwork to further understand the evolution of floral traits.

First evidence of long-lasting association between viruses and the Black soldier fly, Hermetia illucens

Authors: Pienaar Robert[3], Herniou Elisabeth[4], Gilbert Clement[2], and Herrero Salvador[1], [1]BIOTECMED, University of Valencia, Spain, [2]EGCE, Paris Saclay University - CNRS - IRD, France, [3]IRBI, CNRS - Tours University, France, [4]IRBI, CNRS - Tours University, France

Abstract: In insect farming, viruses have caused negative economic impacts to long-established species like honeybees or crickets. More recent models used in the insect industry, such as black soldier flies (Hermetia illucens, BSF) may also face viral diseases, but lack of knowledge about any natural pathogens of BSF leaves the industry unaware of any potential threats from viruses. As traces of contemporary and past viral infections can be mined in transcriptomics and genomic datasets, we undertook a bioinformatic approach to explore publicly available BSF data. A novel pipeline for the discovery of endogenous viral elements (EVEs) uncovered several EVEs in 3 BSF genomes. Some EVE sequences were found in all three BSF genomes, indicating ancient integration in the BSF genome. In a second approach based on transcriptome analyses, we uncovered an exogenous virus that we refer to as Hermetia illucens Toti-like virus 1 (HiTV1) and that is related to some of the EVEs. Of note, a short sequence, that is highly similar to one EVE, is expressed in BSF. Altogether, the results suggest that HiTV1 is an exogenous virus producing an active infection, and that related viruses have long been associated with BSFs.

Developing novel mode of action insecticides and repellents for mosquito control from medicinal plants

Authors: Piermarini Peter M.[1], L. Rakotondraibe Harinantenaina[2] and Cheng Xiaolin[2], [1]Department of Entomology, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster, Ohio, United States, [2]Department of Medicinal Chemistry & Pharmacognosy, The Ohio State University, Columbus, Ohio, United States

Abstract: The emergence of resistance to pyrethroids and other conventional insecticides in mosquitoes is a global challenge that has prompted a need to discover novel mode of action insecticides. In response, we are exploiting the chemistry of cinnamodial (CDIAL), which is a natural drimane sesquiterpene enriched in endemic plants of Madagascar used in traditional medicines (Cinnamosma species). We previously demonstrated that CDIAL exhibited similar insecticidal potency against pyrethroid-susceptible and pyrethroid-resistant strains of Aedes aegypti. Moreover, CDIAL was a potent antifeedant and repellent against Ae. aegypti that modulated transient receptor potential ankyrin 1 (TRPA1) channels. Here we provide new insights into the chemical features of CDIAL that promote its insecticidal and antifeedant activities, as well as its molecular interactions with mosquito TRPA1 channels. Our results will be discussed in the context of developing novel mode of action insecticides and biorational repellents for controlling mosquito vectors.

Emerging biological control agents for bed bugs

Authors: Pietri Jose[2], Liang Dangsheng[1] and Potts Rashaun[2], [1]Apex Bait Technologies, Inc, United States, [2]University of South Dakota, United States

Abstract: Bed bugs have become widespread across the globe over the last several decades and pose significant health concerns for human populations. The development of resistance against commonly used chemical insecticides along with the spread of bed bugs to diverse environments has created an urgent need for new, effective, and flexible bed bug control tools. Microbial biological control agents have been used with success to combat a number of insect pests. However, despite its efficacy in other systems, this form of control has only explored against bed bugs to a limited degree. We previously determined that several species of environmental bacteria that are harmless to mammals are highly toxic when administered to bed bugs in the laboratory via an artificial blood-meal or through simulated wounding. This presentation will discuss up to date results of ongoing research to leverage knowledge of bacterial entomopathogen virulence, bed bug immune responses, and bed bug feeding behavior towards the development of effective biological control tools that are easily applicable under a broad range of settings.

In search of suitable predatory mites against the tomato russet mite Aculops lycopersici (Acari: Eriophyidae)

Authors: Pijnakker Juliette[3], Hürriyet Asli[1], Petit Clément[1], Vangansbeke Dominiek [1], Duarte Marcus [1], Moerkens Rob[1], Arijs Yves[4] and Wackers Felix[2], [1]Biobest, [2]Biobest Group NV, Belgium, [3]Biobest, Netherlands, [4]Private Company, Belgium

Abstract: The efficiency of nine predatory mite species (Phytoseiidae) in controlling the tomato russet mite Aculops lycopersici was evaluated on tomato plants in an experimental greenhouse. Neoseiulus californicus, Amblyseius andersoni and Neoseiulus fallacis showed the strongest pest reduction. Although these species had a low survival and the curative strategy did not totally eliminate the pest, plants remained healthy. These predatory mites could be used in a curative biological control strategy, but would be too expensive for growers due to the required repeated introductions, as the mites do not establish. Other predatory mites, like tydeoids, can survive on tomato and can reach high densities when pollen is supplied. High densities of the tydeoids Homeopronematus anconai and Pronematus ubiquitus were obtained in trials due to the weekly provision of Typha angustifolia pollen as alternative food. When the predatory mites were introduced and allowed to establish at an early plant stage, high tydeoid densities were reached. This preventative predator establishment proved successful in preventing the development of TRM. The predators did not sufficiently control eriophyid mites when they were introduced curatively. The potential of tydeoids for biological control of eriophyids as an alternative to chemical treatments is discussed.

Density-dependent polyphenism in sub-arctic populations of the winter moth Operophtera brumata: the thermal melanism hypothesis

Authors: Pincebourde Sylvain[4], Laksforsmo Vindstad Ole Petter[1], Uhd Jepsen Jane[3], Laparie Mathieu[2], Alsila Annika[3], Heinänen Emma[3], Gilles Yoccoz Nigel[7] and Anker Ims Rolf[1], [1]Department of Arctic and Marine Biology University of Tromsø (UiT) Tromsø, Norway, [2]INRAE, URZF, Orléans, France, [3]Norwegian Institute for Nature Research (NINA) Framcentre Tromsø, Norway, [4]Research Institut of Insect Biology, CNRS-University of Tours, France, [5]University of Tromsø - The Arctic University of Norway

Abstract: Density-dependent polyphenism of cuticle melanization is a widespread phenomenon in Lepidopteran larvae. In the sub-Arctic Fennoscandian birch forest, where the winter moth (Operophtera brumata) is expanding northward and exhibits 10-year cyclical outbreaks, crowding has been associated with the promotion of melanized spanworms. No such striking polyphenism has been reported at lower latitudes, possibly due to lower densities. However, dark pigmentation does not seem to prevail either in populations currently invading North America despite outbreak densities, which raises questions on the adaptive function of polyphenism in Fennoscandia. The evolutionary significance of melanism at high densities is not fully understood, but evidence is accumulating in a number of species that it can be associated with increased immunity, predator avoidance (camouflage, warning), or thermoregulation. In the winter moth, however, the camouflage and immunity hypotheses have been rejected, and melanization even appeared to increase vulnerability to enemies. We hypothesized that melanization might be an intra- and interspecific advantage over pale competitors during outbreaks if better absorption of solar radiation results in higher body temperature and earlier nymphosis (before total defoliation), especially at midnight sun latitudes. Such thermal melanism was tested by comparing metabolic rate and phenology among larval phenotypes. Metabolic rate was found to vary greatly but was 150% higher in melanized versus pale larvae under artificial light. The causal relationship with radiation absorption was further explored using respirometry with no light, and thermography. Preliminary results on the phenology of either phenotypes will be presented. Our findings suggest ecophysiological benefits of melanization that may offset its costs on resistance to enemies during outbreaks. Sliding selection regimes caused by cold summers and cyclic dynamics at the northern front likely contribute to maintaining phenotypic heterogeneity, a parameter largely neglected in attempts to predict expansions and invasions.

Effects of local microclimates on the phenology of the pine processionary moth, a forest pest invading urban areas

Authors: Pincebourde Sylvain[3], Poitou Laura[1], Laparie Mathieu[1], Backe Kristi[2], Robinet Christelle[1], Suppo Christelle[3] and Rousselet Jérôme[1], [1]INRA, URZF, Orléans, France,[2]North Carolina State University, Department of Entomology and Plant Pathology, United States, [3]Research Institut of Insect Biology, CNRS-University of Tours, France

Abstract: There is growing evidence that the phenology of many insects is impacted by climate change. Since temperature influences their development time, considering microclimates is crucial to deeply understand the variability in space and in time of insect phenology. The pine processionary moth (PPM), Thaumetopoea pityocampa, is a forest pest that has been invading urban areas due to the plantation of numerous ornamental pine trees. The PPM is expanding its distribution due to climate warming, but the phenological consequences are still unknown, yet time shifts and range shifts are most likely two interrelated responses to overcome climatic barriers. We conducted both field observation and field experimentation to explore phenology change compared to historical data and to determine the phenology variability across different microclimate conditions. We studied variability in a stand, between and across bioclimatic regions. Microclimate is suspected to vary in space due to different conditions at which pine trees are exposed (e.g., sun-exposed versus shaded trees, urban heat versus cool green areas), but it can also vary depending on microhabitat features such as the silk tent in which PPM larvae develop throughout winter, or the number of larvae in it. Temperature recorded in these tents can differ by up to 4°C from air temperature depending on the time of the day. Precisely estimating temperature inside tents and the factors of their variation is challenging, but the development of biophysical model based on these estimations will allow understanding larval development times and better predicting their phenology under climate change.

Living in the leaf microclimate: thermal ecology and biophysics of plant microcosms

Authors: Pincebourde Sylvain, Research Institut of Insect Biology, CNRS-University of Tours, France

Abstract: The surface of pant leaves hosts a huge diversity of interacting ectotherms. The ecophysiology of these tiny organisms, as well as the rate of biotic interactions, depends on the leaf surface temperature. Most of these organisms are tiny enough to be totally submerged within the leaf boundary layer, making them largely under the influence of the leaf functioning. The temperature of a leaf surface can deviate from air temperature sometimes quite strongly. In this presentation, I will detail the biophysical mechanisms determining the microclimate of arthropods living at the leaf surface. A comprehensive understanding of the leaf-air temperature deviations as well as the temperature heterogeneity at the within-leaf surface scale, is important to identify the extent to which ectotherms can exploit these thermal patterns to thermoregulate. Then, arthropod herbivore can fundamentally modify the functioning of the leaf when feeding on it; these changes have cascading effects on the leaf microclimate. These cascading effects can help explain the patterns of thermal adaptation among arthropod herbivores and predict the consequences of competitive interactions. From here, we can extrapolate on the role of the leaf microclimate in modulating prey-predator interactions at the leaf surface. Finally, the leaf microclimate can be placed in the context of climate change impacts: will the leaf surface provide ectotherms with a buffer of extreme heat or by contrast will it magnify the atmospheric changes? This knowledge of the leaf microclimate helps us determining the vulnerability of arthropods to warming.

Phenology of the pine processionary moth as an indicator of climate change

Authors: Pincebourde Sylvain[3], Poitou Laura[2], Laparie Mathieu[2], Robinet Christelle[1], Suppo Christelle[3] and Rousselet Jérôme[2], [1]INRA, URZF, Orléans, France, [2]INRA, URZF, Orléans, France, [3]Research Institut of Insect Biology, CNRS-University of Tours, France

Abstract: Insect development, reproduction and survival are closely linked to temperature. As a result, global warming could considerably impact the spatio-temporal dynamics of insects. However, it is often difficult to disentangle the effects of climate warming from the effects of other disturbances. The Pine processionary moth (PPM) is a major tree pest in Europe, which causes severe economic and public-health problems. It has become a model to understand the ecological impacts of climate change because its spatial distribution has expanded due to the increase of winter temperature which facilitated larval feeding and survival. Although the effect of climate change on the distribution of the PPM is clearly understood, potential phenological consequences are so far poorly documented. However, an increasing phenological variability is being reported, and atypical cycles up to 6-month early can now be observed in some areas. A better understanding of such phenological changes is crucial, not only for the better assessment of the effects of climate change, but also to optimize control methods and to limit urtication risks at unusual periods. We conducted field observations to compare current phenology with historical data and to determine the variability across different microclimate conditions. A phenological model was developed to predict future changes. While field observations were used to validate the model, its initial calibration was based on experimental data. First, the rate of development from egg to late instar larva was measured in controlled conditions at different temperatures. Second, the silk nest spun by larval colonies create a microhabitat that confers a thermal gain compared to ambient air. Correctly predicting PPM phenology therefore implied accounting for the microclimate the larvae are actually exposed to in the nests, which was estimated in semi-natural conditions.

Using the principles of ECOstacking to develop ecologically-based IPM approaches in apple agroecosystems in New England

Authors: Pinero Jaime[2], Regmi Prabina[1], Saadat Dorna[1], Leskey Tracy[4], Shapiro-Ilan David[3], [1]University of Massachusetts, [2]University of Massachusetts, Stockbridge School of Agriculture Amherst, MA, United States, [3]USDA ARS Southeastern Fruit and Tree Nut Research Laboratory, [4]USDA-ARS, Appalachian Fruit Research Station

Abstract: One ecological approach to pest management involves manipulating the habitat by means of planting non-crop plants. Non-crop plants can be trap crop plants that can pull the pests away from the cash crop, and insectary plants that can attract and boost natural enemy populations. In 2018, we initiated a long-term project aimed at developing a permanent, low-cost, trap cropping system for multiple apple pests by grafting selected perimeter-row trees with 6 apple cultivars that are attractive to key pests including plum curculio, Conotrachelus nenuphar (Coleoptera: Curculionidae), and apple maggot fly, Rhagoletis pomonella (Diptera: Tephritidae). This type of IPM approaches can be readily implemented to support ecologically-based pest management via ECOstacking in support of more sustainable crop production.

Detecting the Unexpected: Invasive Insect Surveillance using Non-Destructive DNA Metabarcoding

Authors: Piper Alexander M[2], Rodoni Brendan[1], Martoni Francesco[3], Valenzuela Isabel[3], Batovska Jana[1], Paul Cunningham John[1], Blacket Mark[3] and Cogan Noel[1], [1]Agriculture Victoria Research, AgriBio, Bundoora, Vic, Australia School of Applied Systems Biology, La Trobe University, Bundoora, Vic, Australia, [2]Agriculture Victoria Research, AgriBio, Bundoora, Vic, Australia School of Applied Systems Biology, La Trobe University, Bundoora, Vic, Australia, [3]Agriculture Victoria Research, AgriBio, Bundoora, Vic, Australia

Abstract: Trap based insect surveillance forms a key component of plant biosecurity and pest management programs, aiming to detect newly arrived exotic taxa as well as track the population levels of established or endemic pests. However even when targeted lures are used, surveillance traps generally capture many more native species than the target pests and the extensive specimen sorting required prior to identification forms a major diagnostic bottleneck. DNA Metabarcoding has recently emerged as a high-throughput sequencing based method for conducting simultaneous, multi-species identification of complex mixed communities. By analysing bulk DNA extracts rather than single specimens metabarcoding circumvents the ‘needle in a haystack’ problem of previous identification methods and allows a dramatic scale up of both the quantity of traps that can be processed concurrently, and the number of species that can be actively monitored for.

Despite the wealth of information provided by metabarcoding assays, integrating novel multi-species diagnostics into previously highly targeted surveillance programs presents unique technical and regulatory challenges. Of particular concern is ensuring accurate species-level detections in the face of complex laboratory and bioinformatic pipelines, and how the incidental detection of invasive species that were outside the scope of the initial assay validation should be responded to. In order to address these issues, we have developed a non-destructive DNA metabarcoding assay that provides sensitive and rapid detection of high-priority pest insects for Australia, while maintaining the integrity of morphological specimens for later confirmation. We anticipate that adoption of non-destructive DNA extraction techniques will bridge the gap between new genomic methods and traditional entomological techniques and may bootstrap the acceptance of metabarcoding based diagnostics within international regulatory frameworks.

Odorant Receptors in the Housefly, Musca domestica

Authors: Pitts Jason[1] and Boyi John[1], [1]Baylor University, United States

Abstract: The common housefly, Musca domestica L, is a major worldwide pest and a potential mechanical vector for a number of human and animal pathogens, especially those that cause enteric diseases. As in all insects, houseflies utilize a highly-developed olfactory system to locate resources in the environment via host-emitted kairomones. Odorant receptors are molecular receptors that respond to volatile odors and comprise a large gene family in the housefly (MdomOrs). In this study, we compare MdomOrs with those of other Diptera, highlighting receptor evolution. We have characterized MdomOr expression profiles in adult antennae using RNA sequencing. While most MdomOrs show similar abundance levels in both sexes, a subset of conserved receptors appear to be differentially expressed. These receptors are closely related to a receptor in Drosophila melanogaster that mediates behavioral responses to a male-produced pheromone. In M. domestica, (Z)-9-tricosene is produced by females and induces courtship in males. We propose that these conserved MdomOrs are candidate pheromone receptors that are activated by components of housefly cuticular hydrocarbon pheromone blends. This study will help illuminate the functional roles of chemoreceptors in the chemical ecology of houseflies and advance efforts in their control.

Managed solitary bee advances for crop pollination

Authors: Pitts-Singer Theresa, USDA Agricultural Research Service Pollinating Insects Research Unit Logan, Utah, United States

Abstract: The enhancement of propagation and management protocols of Osmia lignaria and Megachile rotundata has assured the use of these pollinators for orchard and alfalfa seed crops, respectively. Open field, large field cage, and laboratory studies were conducted to track and assess female bees, their behavior, and their reproduction. Understanding visually- and chemically-mediated behavior of these bees has helped to increase the retention of bees within targeted crops, including the invention of a bee attractant for O. lignaria. Assessment of the number of bees released in fields and the number of females retained at bee shelters has informed stocking densities and pollination efficacy. Evaluation of the effect of an insect growth regulator (employed to control a seed predator) on M. rotundata reproduction provided the first evidence of its ovicidal activity that can great reduce sustainability of commercial populations. Certain fungicides used in orchards were applied to ground cover and showed disrupted nesting behavior for both M. rotundata and O. lignaria. Phenologies of O. lignaria from disparate geographical regions of the United States were shown to differ due to variations in larval and pupal develop times at natural and at common field temperatures. Affects of photoperiod and nutrition were examined for M. rotundata and showed the aversion of prepupal diapause when mothers were exposed to a relatively long photoperiod and when larvae fed on relatively small provisions, leading to theories on maternal control of offspring diapause fate. All results have important implications for successful and economically feasible commercial bee management.

Ecdysone is essential for cell differentiation in the ovary of the cockroach Blattella germanica.

Authors: Piulachs Maria-Dolors[2], Rumbo Mireia[1] and Pagone Viviana[1], [1]Institute of Evolutionary Biology, [2]Institute of Evolutionary Biology (CSIC- Univ. Pompeu Fabra). Barcelona, Spain

Abstract: The role of ecdysone in oogenesis has been deeply studied in holometabolous insects with meroistic ovaries, especially in Drosophila melanogaster, while in panoistic ovaries, the most ancestral ovary type, is still poorly understood. Using the hemimetabolous species Blattella germanica (German cockroach) as a model, which has panoistic ovaries, we have depleted the expression of the Ecdysone receptor (EcR) with RNAi, in order to characterize the role of ecdysone in ovaries of sixth instar nymphs, thus providing knowledge about the evolutionary changes or conservation of the ecdysone role in insect oogenesis. In sixth instar nymphs of B. germanica females, dsEcR treatment arrests the synthesis of ecdysone in the prothoracic gland, helping us to demonstrate that ecdysone is essential for the regulation of the germinal stem cells differentiation, as well as for the correct distribution of cells in the germaria of this cockroach species.

The Blattella germanica piRNAs key regulators of materno-zygotic transition.

Authors: Piulachs Maria-Dolors[3], Bau Josep[1] and Montañés Jose Carlos[2], [1]Department of Biosciences, University of Vic–CentralUniversity of Catalonia, , [2]Hospital del Mar Medical Research Institute (IMIM), Barcelona, Spain, [3]Institute of Evolutionary Biology (CSIC- Univ. Pompeu Fabra). Barcelona, Spain

Abstract: During insect oogenesis, a series of genes must be transcribed and translated on-site in the ovarian follicle at the right time to guarantee embryo development. In the last years, the sncRNAs have appeared as candidates to regulate mRNA expression and their importance in regulating the transition materno-zygotic was begin studied in insect species.

Between the small non-coding RNAs there are the piRNAs that have a length comprised between 26 and 31 nt, which is longer than that of miRNAs and siRNAs (21 to 25 nt). The piRNAs are involved in the control of transposable elements (TEs), as part of an evolutionarily conserved mechanism that protects the genome, preserving the fertility of the individual by ensuring the development of gametes. However, the role of piRNAs as regulators of mRNA expression is emerging, which opens a new avenue for functional studies.

Using small RNA libraries from cockroach Blattella germanica we identified the piRNAs expressed in adult ovaries during the first gonadotropic cycle and we have analyzed those piRNAs stored in eggs and those expressed just after the zygote formation. The analysis of this set of piRNAs is giving us information on how the oocyte keeps some mRNAs blocked waiting until zygote formation.

Influence of tilling on invertebrate food webs and their dynamics in wheat fields

Authors: Plantegenest Manuel[1], Ortiz-Martinez Sebastian[2], [1]Agrocampus Ouest - UMR IGEPP - Rennes, France, [2]Institut National de Recherche en Agronomie - UMR IGEPP - Rennes, France

Abstract: The transition towards a more sustainable agriculture has become one of the main issues of our society. Developing new agricultural practices promoting ecosystem services that biodiversity provides, rather than using chemical inputs, is one of the considered solutions to increase agricultural sustainability.

Conservation agriculture is one of these promising agroecological farming systems, which notably proposes to limit soil disturbance and to foster the maintaining of a permanent vegetal cover in order to promote ecosystems services. We conducted a study to figure out how soil management in wheat field affect the biodiversity of species of direct agricultural interest (weeds, pests, beneficial arthropods), as well as the ecosystem services of regulation provided. We used molecular tools to assess precisely the diet of carabid beetles, and to unravel all trophic interactions, including all potential prey for carabids beetles. Thus, ecological trophic networks observed in conventional versus conservation wheat fields were constructed from the sequencing data's of predator gut contents.
We explored how soil management practices influence the structure of the trophic network. These ecological networks also give interesting insight in the seasonality and the compromise that can exist between ecosystems services.

Combining models of agricultural landscapes and soil-dwelling pest population dynamics to design novel management strategies against wireworms

Authors: Plantegenest Manuel[1], Plantegenest Manuel[5], Boussard Hugues[2], Sergent Mike[3], Bourhis Yoann[6] and Mammeri Youcef[4], [1]Agrocampus Ouest - UMR IGEPP - Rennes, France, [2]BAGAP, INRA, Agrocampus Ouest, 35042 Rennes, France, [3]French National Institute for Agricultural Research, France, [4]LAMFA, Université de Picardie Jules Verne, CNRS UMR 7352, Amiens, France, [5]L'Institut Agro, UMR IGEPP, [6]Rothamsted Research, Department of Biointeraction and Crop Protection, United Kingdom

Abstract: Elaterid pest species exploit both cultivated and uncultivated areas in the agricultural mosaic. Understanding their movement from sources that sustain important populations, i.e. uncultivated areas, to vulnerable crops is central in the development of pest management strategies. Considering movement ecology and landscape ecology is then critical to design pest-resilient agroecosystems, particularly in the context of a dramatic reduction of the use of pesticides. The main objective of our study was to simulate the colonisation dynamics of click beetles and their larvae in agricultural landscapes, and discuss the implications for crop protection against wireworms.
First, we built a spatially-explicit and mechanistic model describing the pest population dynamics in both aerial and soil compartments along its life cycle. Larval and adult mortality, larval maturation, oviposition, and adult movements (in terms of diffusion and advection) were the main processes considered. Model parameterisation derives from a comprehensive review of the literature regarding the wireworm biology and ecology. Secondly, we modelled agricultural mosaics at two spatial scales: (i) the local level (i.e. a focal field and its adjacent land uses) comprising grasslands and arable crops, and (ii) the landscape level (about 2 km^2) using CAPFarm, a multi-year cover allocation simulator generating landscapes (here considering three land uses: arable crops, temporary and permanent grasslands) under agronomic constraints. In both cases, habitat quality was characterised in terms of carrying capacity. Combining these two framework components, we investigated how the spatial arrangement and dynamics of crops influence pest density distribution.
At the local level, model outputs show qualitative agreement with field observations. We outline how the balance between diffusion and advection can drive the population spillover on both sides of the transitions between land uses. We also demonstrate that spatiotemporal connectivity between grasslands affect the pest infestation levels within crops. At the landscape level, we studied correlations between metrics characterising the landscapes and levels of wireworm infestation to draw some interesting avenues to design beneficial spatiotemporal organisation of agricultural landscapes. Providing new insights into the role of grasslands in pest infestation in a dynamic agricultural mosaic, our findings bring an original contribution to the prospect of innovative landscape-scale strategies for pest management.

Providing the board and the lodging- How conservation agriculture can deal with its pests? Wireworms as case study

Authors: Plantegenest Manuel[1] and Sergent Mike[2], [1]Agrocampus Ouest - UMR IGEPP - Rennes, France, [2]French National Institute for Agricultural Research, France

Abstract: The sustainability of low-input and environment-friendly crop productions involve an overview of the services and dis-services that the agro-ecosystem could provide. Conservation Agriculture (CA), which combine the no-disturbance of soil, its permanent cover and crop diversification, has been introduced worldwide as a low-input system and is notably known to enhance soil physical properties such as erodibility, carbon storage or root penetration. This system, by not disturbing the ground, provides favourable conditions (i.e. "the lodging") for soil dwelling organisms including pests.

Wireworms, the larvae of click beetles (Coleoptera: Elateridae, Agriotes) are among the most notorious soil dwelling pests since long in Europe. Because of wireworms upsurge since 15 years, understanding their ecology and the factors influencing their pest potential have become a key issue in crop protection. Their life history traits lasting several years and taking place largely in soil, tillage may impact several parts of their life cycles. During the oviposition period in spring, females lay their eggs in the top soil layer as far as possible in a buffered environment such as litter or grass because of their own sensitivity to temperature fluctuation and eggs sensitivity to desiccation. After hatching, larvae are exposed to soil tillage, in particular to ploughing making them vulnerable to the predation or desiccation

In line with previous studies that put forward the hypothesis that reducing tillage will lead to a physically hospitable habitat to wireworms, the outcomes of our investigations in experimental platform or agricultural plots confirmed that reducing tillage rise wireworm populations. Previous studies also demonstrated the preference of click beetles for grass compared to bare soil and also the sensitivity of female to soil temperature variations. The outcomes of our monitoring showed that females lay their eggs in bare soil anyway and confirmed the population reduction under arable crops is due to the repeated disturbance of the soil.

Nevertheless, reducing tillage without combining it with soil permanent cover and crop diversification in association or sequence (i.e. rotations) only represents an incomplete implementation of CA. And both of these practices may, on one side, impact populations of ground and soil dwelling arthropods. For example, including cover crop such as Brassicaceae or buckwheat could reduce wireworms populations. On the other side, providing the "board" by covering soil with mulch or companion plant had been proven to lure wireworms away from the main crop and the mitigate their harmfullness.

Mutualism between the invasive mealybug Delottococcus aberiae and the mediterranean ant Lasius grandis in citrus crops

Authors: Plata Ángel[1], Gómez María A.[1], Beitia Francisco[1] and Tena Alejandro[1], [1]Valencian Institute for Agricultural Research (IVIA), Spain

Abstract: The exotic mealybug Delottococcus aberiae has become a key pest of citrus in Spain. D. aberiae excretes copious amounts of honeydew that can be exploited by ants. The aim of this work was to study the interactions between mediterranean ants and the invasive mealybug species. For this, we first sampled 16 citrus orchards in spring, summer and autumn of 2020 and 2021. The Mediterranean ant Lasius grandis represented 95% of the ant complex that attended the invasive mealybug. Ant attendance and absolute ant attendance (number of ants per colony) by L. grandis were positively correlated with the mealybug colony size. Finally, orchards with higher density of D. aberiae were associated with higher density of L. grandis. To further evaluate the benefit obtained by the mealybug from L. grandis attendance, we perform an ant-exclusion experiment in two additional orchards during two consecutive years. Ant-excluded trees reported lower D. aberiae density and damage, as well as a higher density of generalist predators. Overall, our results describe the mutualistic relationship between the Mediterranean ant L. grandis and the invasive mealybug D. aberiae and demonstrate that ant exclusion from citrus canopies can reduce D. aberiae damage up to 50% in Mediterranean citrus.

Testing the ‘Pay-back’ hypothesis in the field: Can bumblebee pollination ‘rescue’ seed production in cucumber mosaic virus-infected tomato plants?

Authors: Platoni Anna[1], Murphy Alex[2], Glover Beverley[2], Clover Gerard[3], Waghorn ian[3] and Carr John[2], [1]Department of Plant Sciences, University of Cambridge, Royal Horticultural Society, RHS Garden Wisley, Woking, United Kingdom, [2]Department of Plant Sciences, University of Cambridge, United Kingdom, [3]Royal Horticultural Society, RHS Garden Wisley, Woking, United Kingdom

Abstract: The interactions between plants and associated insects are complex and often mediated by volatiles. Infection by viruses alters plant volatile signatures and consequently affects how insects interact with plants. In lab experiments cucumber mosaic virus (CMV) was shown to cause plants to emit volatile chemicals that attract bumblebees (Bombus terrestris) (Groen et al. 2016). Bumblebees are important tomato pollinators but do not transmit CMV. For wild plants under natural conditions, helping host reproduction by encouraging bee visitation, pollination and increased host reproduction might represent a ‘payback’ by the virus to susceptible hosts (Groen et al. 2016). Experiments in the summer of 2018 and 2019 tested this hypothesis for the first time under field conditions by comparing pollination rates and resulting seed set of CMV-infected and mock-inoculated tomato plants. In the field mock-inoculated plants produced similar numbers of seeds whether or not pollinators were excluded but CMV-infected plants produced a greater number of seeds when pollinators were allowed access to flowers. This is additional evidence supporting the idea that the virus is ‘paying back’ its susceptible host by attracting pollinators and aiding seed production. An additional aim of this work at Royal Horticultural Society is to further understand the interactions between plants, insects, and plant viruses in order to inform and benefit both amateur gardeners and the horticultural industry. Groen SC et al. PLoS Pathogens 12(8):e1005790

Problems and pitfalls of long-read sequencing in insect genomics

Authors: Podsiadlowski Lars[1], Moraes Simeão[2], Misof Bernhard[1] and Philip Oeyen Jan[1], [1]Alexander Koenig Zoological Research Museum, Germany, [2]State University of Campinas (UNICAMP), Brazil

Abstract: The advent of long-read sequencing technologies allow for a much more reliable genome assembly process than short-read sequencing ever did. More and more studies now focus on structural variations (e.g. insertions, deletions, inversions, tandem duplications, transposable element dynamics) between members of the same or closely related species.

Examples of new, unpublished genome data from a bee (Andrena vaga) and a butterfliy (Parnasius apollo) highlight different aspects of the state-of-art sequencing approaches: The apollo butterfly genome underwent a fourfold genome expansion in comparison to other papilionid lineages and exhibits a transposon content of >60%, with LINE elements forming the most abundant repeat class. The genome of the grey-backed mining bee (Andrena vaga) is similar in size, gene and transposon content to other bee genomes. Both genomes were also analysed intensively for gene and transposable element transfer from parasites, endosymbionts and food sources.

Phylogenomic analysis of Orthoptera sheds new light on the evolution of acoustic communication

Authors: Podsiadlowski Lars[1], Simon Sabrina[2], Béthoux Olivier[3], Zhou Xin[4], Donath Alexander[1], Wipfler Benjamin[8], Misof Bernhard[1], D. McKenna Duane[6], Meng Guanliang[5], Letsch Harald[9], Song Hojun[7], Shin Seunggwan[6] and Liu Shanlin[5], [1]Alexander Koenig Zoological Research Museum, [2]Biosystematics group, Wageningen University, Netherlands, [3]Centre de Recherche en Paléontologie – Paris (UMR 7207 – MNHN, CNRS, Sorbonne University), France, [4]China Agricultural University, China, [5]China National GeneBank, BGI-Shenzhen, Guangdong, China, [6]Department of Biological Sciences and Center for Biodiversity Research, University of Memphis, Memphis, United States, [7]Department of Entomology, Texas A&M University, United States, [8]Institute of Systematic Zoology and Evolutionary Biology, Friedrich-Schiller-University Jena, Germany, [9]University of Vienna

Abstract: Orthoptera (crickets, katydids and grasshoppers) is the most diverse group of organisms practicing acoustic communication extensively. Expectedly, it translates into highly diverse communication strategies. Yet, many species neither hear nor sing. Therefore, this group presents a unique opportunity to reveal important insights about the origin and evolution of animal communication. Using both transcriptomes and mitochondrial genomes, and an updated selection of relevant fossil species, we obtained a robust, time-calibrated phylogeny showing that Orthoptera broke silence 300 million years ago. Hearing likely evolved in the context of locating conspecific individuals based on their song. We show that the evolution of hearing and sound producing organs has followed complex and dynamic trajectories, with multiple origins and secondary losses, and that sexual communication using acoustic signalling alone was not a major driving force of orthopteran diversification.

At the miniaturization limit — results and prospects of studying the smallest insects

Authors: Polilov Alexey, Department of Entomology, Faculty of Biology, Moscow State University, Russia

Abstract: Size is one of the most important parameters of living and non-living things. Our age is an age of miniaturization. Miniaturization in electronics has made devices that used to occupy a whole room or even a building small enough to be carried in our pockets. But miniaturization is not only a trend in technology: it is also one of the trends in the evolution of life. Microinsects — the extremely diverse miniature insects less than a millimeter long — are one of the most intriguing components of this microworld. Having evolved to the size of unicellular organisms, the smallest insects managed not only to preserve structural complexity, but also to invent some novel features not found in larger insects. This talk is about comprehensive study of microinsects: from morphology to connectomics, from locomotion to genomics, and also about the potential benefits of the study of microinsects for solving fundamental scientific and biotechnological problems.

Associative learning and memory in thrips

Authors: Polilov Alexey[3], Farisenkov Sergey[1], Fedorova Maria[4], Timokhov Alexander[2], [1]Department of Entomology, Biological faculty, Lomonosov Moscow State University, Russia, [2]Department of Entomology, Faculty of Biology, Lomonosov Moscow State University, Moscow, Russia, [3]Department of Entomology, Faculty of Biology, Moscow State University, Russia, [4]Moscow State University, faculty of Biology, department of Entomology, Russia

Abstract: Associative learning is known in many groups of insects, but little is known about the learning abilities and memory of microinsects. Miniaturization causes many changes in the neural system, including reductions in the number of neurons. Nevertheless, associative learning has been shown in some groups of microinsects, mostly parasitic wasps; among non-parasitic microinsects, only beetles were also tested (Polilov et al., 2019); thrips (Thysanoptera), which are at most 2 mm long, have never been tested .

We designed an experimental setup for microinsects, based on the idea from Ofstad et al. (2011), where it was used for testing the visual place learning in Drosophila melanogaster. Our setup includes a thermal maze and an LED screen surrounding the maze. The temperature in the maze is too high for thrips, but the maze has four cooler spots (which the insect is supposed to find); the spots switch one by one together with the rotating visual stimuli on the screen. Thrips were experimented one at a time. Every experiment consisted of ten trials of searching, each followed by 1 minute of the thrips staying in the cool spot to memorize the visual stimulus. In addition, there were four tests of sector preference for each thrips: before the experiment, immediately after it, in 1 hour, and in 24 hours after the experiment. In these tests, the cool spots were switched off, while the visual stimuli on the screen were random. We checked whether the insect choses the target section (matching the stimulus) according to the visual learning it underwent.

Pairwise comparison of the lengths of the way in every trial shows that significant difference between test and control groups can be seen after 7 trials (t-test, $p < 0.05$). This may indicate that after seven trials the thrips form an association between the visual stimulus and the target spot; this association helps them find the spot sooner. Tests of sector preference performed immediately after all ten trials show that a majority of the insects follow the visual stimulus associated with the comfort spot in the maze (ANOVA Tukey test, $p < 0.05$). In the tests performed 1 hour later, the number of insects who preferred the target sector (supposed to match the cool spot) had decreased, but remained significantly different from the number of insects who preferred either of the three other spots ($p < 0.05$). The number of insects who follow the visual stimulus was also significantly higher in the 1-hour test than in the test before trials or in the control group ($p < 0.05$).

Thus, we have shown that thrips are not only capable of learning, but also have long-term memory that can be retained for at least one hour. Our study is the first to show such abilities in thrips . Learning capacity and retained principal cognitive abilities in these microinsects make them suitable models for cognitive and neurobiological experiments.

Evolutionary genomics and implications of miniaturization in the parasitoid wasp Megaphragma amalphitanum

Authors: Polilov Alexey[1], Benton Richard[9], Nedoluzhko Artem[8], Mazur Alexander[2], Sokolov Alexey[2], Lê Brandon[6], Prokhortchouk Egor[3], Boulygina Eugenia[7], Sharko Fedor[4], Rodriguez Fernando[6], Arkhipova Irina[6], Skryabin Konstantin[4], Evgen'ev Michael[5], Rastorguev Sergey[7] and Tsygankova Svetlana[7], [1]Department of Entomology, Faculty of Biology, Moscow State University, Russia, [2]Institute of Bioengineering, Research Center of Biotechnology of the Russian Academy of Sciences, Moscow, Russia, [3]Institute of Bioengineering, Research Center of Biotechnology of the Russian Academy of Sciences, Moscow, Russia; Lomonosov Moscow State University, [4]Institute of Bioengineering, Research Center of Biotechnology of the Russian Academy of Sciences, Moscow, Russia; National Research Center "Kurchatov Institute", Moscow, Russia, [5]Institute of Molecular Biology RAS, Moscow, Russia, [6]Josephine Bay Paul Center for Comparative Molecular Biology and Evolution, Marine Biological Laboratory, Woods Hole, Massachusetts, United States, [7]National Research Center "Kurchatov Institute", Moscow, Russia, [8]Nord University, Faculty of Biosciences and Aquaculture, Bodø, Norway; National Research Center "Kurchatov Institute", Moscow, Russia, [9]University of Lausanne, Center for Integrative Genomics, Switzerland

Abstract: Body size reduction, also known as miniaturization, is an important evolutionary process that affects a number of physiological and phenotypic traits and helps animals conquer new ecological niches. However, this process is poorly understood at the molecular level. Here, we report genomic and transcriptomic features of arguably the smallest known insect – the parasitoid wasp, Megaphragma amalphitanum (Hymenoptera: Trichogrammatidae). In contrast to expectations, we find that the genome and transcriptome sizes of this parasitoid wasp are comparable to other members of the Chalcidoidea superfamily. Moreover, compared to other chalcid wasps the gene content of M. amalphitanum is remarkably conserved. Intriguingly, we observed significant changes in M. amalphitanum transposable element dynamics over time, in which an initial burst was followed by suppression of activity, possibly due to a recent reinforcement of the genome defense machinery. Overall, while the M. amalphitanum genomic data reveal certain features that may be linked to the unusual biological properties of this organism, miniaturization is not associated with a large decrease in genome complexity.

External morphology of the antennal sensilla of the smallest free-living insect Scydosella musawasensis (Coleoptera: Ptiliidae)

Authors: Polilov Alexey[1], Diakova Anna[2], [1]Department of Entomology, Faculty of Biology, Moscow State University, Russia, [2]Faculty of Biology, Lomonosov Moscow State University, Russia

Abstract: Miniaturization is a major evolutionary trend prominent in insects. Diminution of body size in some insect groups has resulted in insects comparable in size to some unicellular protists. The nervous systems and sense organs of insects have been considerably transformed by adaptation to extremely small size. The miniaturization-related changes in the complex multimodal sense organs of the antennae are of special interest in this context.

Scydosella musawasensis (Coleoptera: Ptiliidae) is the smallest free-living insect, with a body length of the smallest measured specimens only 325 µm. We have studied the antennal sensilla of S. musawasensis using scanning electron microscopy and described their sizes, external morphological features, and distribution. Eight different morphological types of sensilla have been revealed: sensilla chaetica, four types of sensilla trichodea, sensilla styloconica, and two types of sensilla basiconica. The numbers of sensilla of all types are identical in males and females. Comparative analysis with the available published data on the larger Coleoptera has revealed a decrease in the number of antennal sensilla with decreasing body size; S. musawasensis has only 124 sensilla per antenna. The revealed size-related trends in free-living insects have been compared with those determined earlier in the miniature parasitoid wasps Megaphragma spp. (Hymenoptera: Trichogrammatidae), which have a body size of about 200 µm. S. musawasensis has three times as many antennal sensilla as Megaphragma wasps, which demonstrate pronounced sexual dimorphism in the numbers and types of these sensilla.

Our data contributes to the morphological, functional and evolutionary context needed for understanding the effects of miniaturization on the structure of the brain and sensory organs of microinsects. Together with our earlier data, the results of this study reveal the universal principles of antennal miniaturization: extreme level of optimization combined with retention of high functionality of the antennal sensory system.

Flight kinematics of the miniature parasitoid wasp Megaphragma amalphitanum

Authors: Polilov Alexey[2], Lapina Nadezhda[1], Farisenkov Sergey[1], [1]Department of Entomology, Biological faculty, Lomonosov Moscow State University, Russia, [2]Department of Entomology, Faculty of Biology, Moscow State University, Russia

Abstract: The study of insect flight is a large area of modern entomology, closely related to biomechanics and aerodynamics. Studying the flight of microinsects is a technically difficult task. Most work in this area has been done during the last few years.

Our group recentlyaccurately described the morphological and kinematic adaptations to flight at low Reynolds numbers in the miniature beetle Paratuposa placentis. Microinsects are a polyphyletic group, but many of them have acquired similar adaptations to flight at low Reynolds numbers, such as the bristled wings found in most flying microinsects. However, there are important differences in the details of structure of their wing apparatuses, which probably affect the mechanics of flight.

Some of the smallest body sizes among flying insects are found among parasitic wasps of the family Trichogrammatidae. The body length of one of the smallest species of this family, Megaphragma amalphitanum, is only about 250 μm.

We designed an experimental setup that made it possible to perform macro video recording of the flight of M. amalphitanum using four synchronized high-speed cameras. We reconstructed the kinematics of the flight using frame-by-frame triangulation of landmarks on the wing and body. The averaged wing cycle and pitch oscillations of the body were mathematically described in the system of Euler angles. The angles of attack speed of the wings at all stages of the wing cycle, and Reynolds numbers were calculated. Additionally, we reconstructed the flight trajectories of the wasps in spacious boxes and calculated flight speeds and accelerations.

M. amalphitanum is capable of active flapping flight at considerable speeds up to 1000 body lengths per second: average and maximum flight velocity are 0.06 and 0.25 m/s, respectively; maximum acceleration is 4.19 m/s2. The average Reynolds number during the wing cycle is about 3, which means that viscous friction forces are prevalent, and the leakiness between the bristles must be quite low. During both translations, the angle of attack and wing velocity are high: 50 degrees and 0.12 m/s during the downstroke and 80 degrees and 0.27 m/s during the upstroke. During the recovery stroke between downstroke and upstroke, the wings clap and move slowly at near-zero angles of attack, which apparently reduce the unwanted drag of the wings. Stroke amplitude is 140 degrees. Pitch angle reaches its minimum value at the end of translational phase of the upstroke (2 degrees). The maximum angle of attack is reached by the end of the recovery stroke (50 degrees). Deviation angle varies from 17 degrees during the downstroke to 125 degrees during the upstroke. Wingbeat frequency is 276 Hz.

The estimated aerodynamic features revealed in our study and unusual kinematics of the operation of the microwasp wings are an important adaptation to flight at ultra-low Reynolds numbers, under conditions of prevalent viscous friction forces.

Functional mapping of the ommatidia based on a complete reconstruction of the compound eye of Megaphragma (Hymenoptera: Trichogrammatidae)

Authors: Polilov Alexey[1], Makarova Anastasia[2], [1]Department of Entomology, Faculty of Biology, Moscow State University, Russia, [2]Lomonosov Moscow State University, Faculty of Biology, Department of Entomology, Russia

Abstract: Compound eyes are among the most complex and important sense organs. The structure and morphofunctional specializations of the ommatidia in insect compound eyes have been described for years using light and electron microscopy. The current understanding of the cellular organization is based mostly on 2D data collected on single retinotopic sections. The new age of 3D electron microscopy gives access to the precise cellular and subcellular reconstructions of whole eyes as well as synaptic configurations of the insect's visual system. That helps us better understand the analyzer–neuron interactions in visual processing modeling.

The whole head of Megaphragma amalphitanum was scanned on a double-beam microscope (FIB-SEM) with a resolution of 8 nm per pixel for all xyz measurements. As a result, we provide the first detailed complete 3D reconstruction of the compound eye at the cellular and subcellular levels. Our complex morphological analysis of each photoreceptor position, diameters and shapes of the rhabdoms, volumes of cell bodies and rhabdomeres, orientation angles of microvilli along the rhabdom axis, diameters and curvature of each of the lenses and general optic parameters calculations gives us unique data and constitute the first steps of functional mapping of the eye. The shapes and lengths of cones, degrees of lenses curvature, and shapes of the rhabdom are markedly different in the dorsal rim ommatidia and in the regular ones. Specialized microvilli orientation angle along the rhabdom in ommatidia of the dorsal rim area (DRA) most likely indicates an increased sensitivity to polarized light. Our findings show the strict morphological difference between the morphology of seven facets of DRA ommatidia and is consistent with cartridge connectivity trends reconstructed in collaboration with Dmitry Chklovskii team (Flatiron Institute).

The organization of compound eyes and possible functional mapping in minute wasps are of particular interest and show that even the smallest eyes retain functional specialization areas. Due to its small body size and unique adaptations of its miniaturized nervous system, Megaphragma can be used as a model for the study of brain neuroarchitecture.

Wing folding and unfolding in featherwing beetles (Coleoptera: Ptiliidae)

Authors: Polilov Alexey[1], Farisenkov Sergey[1], Petrov Pyotr[1] and Reshetnikova Natalia[2], [1]Department of Entomology, Biological faculty, Lomonosov Moscow State University, Russia, [2]Department of Entomology, Faculty of Biology, Lomonosov Moscow State University, Russia

Abstract: Most adult beetles (Insecta: Coleoptera) are capable of folding their hindwings under the protective cover of the modified forewings (elytra) and unfolding them before flight. Beetles of the family Ptiliidae, which in most cases have a body length smaller than 1 mm and include the smallest free-living (non-parasitic) insects, are no exception: most ptiliids fly and are able to fold and unfold their bristled wings (a condition known as ptiloptery). This ability makes them unique among microinsects. The details of the two processes have been unclear, and the mechanics behind them remains almost a mystery.

We have studied the wings, mechanisms of their folding and unfolding, and various structures involved in these mechanisms, in representatives of different groups of Ptiliidae, and the analyzed distribution of resilin in the wings of some species, using light, scanning electron, and confocal microscopy and high-speed video recording. Our results show that ptiliids have two different types of positioning the folded wings; the wings are folded using a complex mechanism involving several structures and unfolded largely by the elasticity provided by resilin.

In the generally larger and less specialized basal genera, the wings are folded by bending along several diagonal lines and asymmetrically overlap at rest under the elytra, in a manner similar to Staphylinidae (Saito et al., 2014); in the other ptiliid genera, the wings are folded symmetrically, without overlapping, by bending at four points along lines subperpendicular to the axis of the wing. The setae, especially in the smaller, more advanced genera, are also folded, by bending at their bases, and lie subparallel to the wing blade. In the genus Ptenidium the wings have an additional fifth bending line.

The complex mechanism of folding and unfolding the feather-like wings involves several elements of the microsculpture of the elytra and different elements of the pterothoracic and abdominal dorsum, especially abdominal tergites.

Remarkably, the wings of ptiliids contain only a single cavity, situated basally in the petiole and in the proximal portion of RA4 in the wing blade, and no cavities within any other veins. Therefore, the folding and unfolding of the wings largely depend on the flexibility and resilience of the cuticle, and can only partly be guided by changes in the pressure of the haemolymph within the veins.

The distribution of resilin in the wing is uneven: it is concentrated in the areas that bend during folding and unbend during unfolding. Resilin must also play a role in the flexibility of the wing during flight. In the studied ptiliids the wings in flight can bend at an amplitude of at least 17 degrees.

Our results show that ptiliids have evolved a set of features that make their miniaturized wings easily foldable and unfoldable. These features may have contributed to the evolutionary success of ptiliids as the smallest free-living insects.

Colony Decline Influenced by Highbush Blueberry Pollination Services in New Jersey, USA

Authors: Polk Dean[1], Rodriguez-Saona Cesar[1] and Abegg Chelsea[1], [1]Rutgers University, United States

Abstract: On-farm pollination treatments were established to verify colony decline during blueberry pollination services. Four treatments were replicated 3 times, with hives placed on: 1) large farms, 2) small farms, 3) large farms followed by cranberry pollination, and 4) control (no pollination services). Hives were measured throughout the 3-4 week pollination period for brood growth, weight, queen rightness, parasite and disease incidence, and pesticide residues. Colony weight and brood growth differed among treatments. Varroa mites and viruses showed no differences between treatments. Pollen and wax samples were taken during the middle of each pollination period, and subjected to a screening of 199 active ingredient residues or metabolites. We found residues from 7 insecticides, 7 miticides, 9 herbicides and 14 fungicides. Many of these residues result from labeled applications made just prior to and during bloom. Recent research by various investigators has implicated the negative impacts of several fungicides on honey bee health. Some work has shown additive or synergistic effects of certain IRAC insecticide classes when combined with FRAC fungicide groups. Our overall feeding tests have also shown bee mortality. Because of the many residues found in hives used for blueberry pollination, detailed studies on the impact of these materials, and current pest management practices have on colony health are justified.

Comparison of the relative rate of vectoring microbes by a primary and secondary stored product pest, after varying dispersal periods: Which is the greater threat?

Authors: Ponce Marco[2], James Avery[4], Sierra Petra[3], Lizarraga Sandra[1], Morrison William[5] and Kim Tania[2], [1]Cornell University, [2]Department of Entomology, Kansas State University, United States, [3]Kalamazoo College, [4]Kansas State University, [5]USDA-ARS Center for Grain and Animal Health Research, United States

Abstract: Generally, few studies have assessed how stored product insects and stored product microbes interact after harvest. As a result, the relative frequency with which primary and secondary stored product insect species vector microbes has not been extensively studied. Knowing the relative risk posed by each type of insect is important for knowing how likely it is that microbes are to be introduced to postharvest commodities after the immigration of insects to novel food patches at food facilities from the landscape. Thus, the aim of the current study was to evaluate and compare the microbial growth in surrogate food patches after 3 or 5 d of foraging by Sitophilus oryzae (a primary pest) and Lasioderma serricorne (a secondary pest). Prior to entry to the food patch, insects were either given no dispersal period, or a dispersal period of 24 or 72 h in a sterilized environment. Increasing dispersal time resulted in multiple-fold reduced microbial contamination in novel food patches by L. serricorne, and S. oryzae. This was likely attributable to mechanically moving spores after emigration from each food patch. Our data suggests that there an equal and persistent risk of microbial contamination by both species, which has repercussions for food safety at food facilities.

Experiments, simulations, and modelling to assess with how many diets a population is made

Authors: Ponton Fleur[1], Morimoto Juliano[2], Than Anh[3], [1]Macquarie University, Australia, [2]University of Aberdeen, United Kingdom, [3]Vietnam National University of Agriculture, Vietnam

Abstract: While habitat quality early in life has long-lasting consequences to current and future generation' individual fitness, population dynamics and evolutionary trajectories, measuring the degree of heterogeneity in developmental habitat quality from population data can be cumbersome. As a result, heterogeneity in developmental habitat quality is often measured through phenotypic markers (e.g., maternal factors) or the population is assumed to be homogenous with respect to developmental habitats. Here, we provide a mixture-model framework which allows or a refined ecological estimate of habitat-specific population dynamic processes when developmental habitat qualities are unobserved. Combined a fully-factorial experiment with in silico population assembly, we firstly showed that nutrition conspecific density of the developmental habitat can strongly modulate individual fitness and population growth of the polyphagous fruit fly Bactrocera tryoni. We then used a mixture-model approach to infer the range of potential habitats mixtures which compose populations solely from population growth data. Thus, the mixture-model framework can be used to estimate heterogeneity in developmental habitat quality from field data where direct measurement of developmental habitat quality is impractical or unavailable, thereby providing an additional statistical modelling tool to better understand habitat-specific population dynamics in population ecology.

New Methods of rearing Queensland Fruit Fly (Bactrocera tryoni) for sterile insect releases; Gel diets, X-Rays and new strains

Authors: Ponton Fleur[2], Crisp Peter[4], Amanda Choo Dr.[6], Simon Baxter Dr.[5], Phil Taylor Prof.[1] and Marais Terril[3], [1]Department of Biological Sciences, Macquarie University, Sydney, Australia, [2]Macquarie University, Australia, [3]Primary Industries and Regions South Australia, SITplus Facility, Pt Augusta, Australia, [4]South Australian Research and Development Institute, Australia, [5]The University of Adelaide, School of Biological Sciences, Faculty of Science, Adelaide, South Australia, Australia, [6]University of Adelaide, Australia

Abstract: Bactrocera tryoni (Queensland Fruit Fly (QFF)) is the major Fruit Fly pest in Australia and over the past decade has spread to southern New South Wales (NSW) and Victoria into areas previously though unsuitable for its establishment. South Australia (SA), Tasmania and Western Australia remain free of QFF mainly due to stringent internal quarantine and interstate trade requirements. While QFF was the first Tephritid to be managed using SIT in Australia, for eradication of an outbreak in Western Australia, the program has only been serviced by a pilot facility in NSW with flies either used for research or by SA for eradication purposes. In 2013 a decision was made by PIRSA/Biosecurity SA and Horticulture Innovation Australia to build a new facility at Pt Augusta in South Australia, this led to a consortium (SITplus) including Macquarie University, CSIRO, Plant and Food Australia being established to complete the project. To achieve the desired production levels within budget limitations innovations were required within the production system and due to community resistance and the costs associated with Gamma cell irradiators' alternate irradiation systems were investigated. In addition to the facility design and development a research program to develop a Genetic Sexing Strain using genetic techniques such as CRISPR was established to improve the efficiency of the facility and efficacy of releases. An agar based diet gel was developed by Macquarie University that has allowed greater pupae production per unit of floor space and greatly reduced volume of waste. Rearing equipment at the facility has been developed to complement the gel diet and best suit the facility operations. The diet currently produces approximately 15,000 pupae per litre, at a cost of A$2.83 compared to 5-6000 from the long used chaff diet.

Two RadSource X-Ray irradiators have been purchased for sterilisation of pupae, extensive sterility and DNA damage evaluation demonstrate that the relative sterility achieved at a range of doses corresponds to that recorded using a Gamma cell irradiation source. This also provided an opportunity to test the sensitivity and accuracy of a kit developed, as a joint SARDI/Macquarie University project, to measure exposure to prior irradiation for SIT or phytosanitary purposes.

CRISPr was originally assessed as a suitable tool for gene editing in QFF by generating a white eye strain, which is blind, but can potentially be used as a functionally male only strain if the males can be recovered. In the absence of a known tsl gene for tephritids initial edits used the Shibire tsl 1 from Drosophilla and although a heterozygote strain was generated the change was lethal to homozygotes. The project identified a gene associated with pupal colour and a pupal colour mutant strain has been generated using CRISPr. Further strains using other targeted mutations are being developed.

Effects of nutritional status on infection at single and multi-generational levels

Authors: Ponton Fleur[2], Dinh Hue[1], Lundback Ida[1] and Kumar Sheemal[1], [2]Macquarie University, Australia, [1]Macquarie University, Australia

Abstract: Nutrition is a key aspect of individuals' biology. While there is a growing interest on the role of nutrition in lifespan and reproduction, the implications of nutrient choice and intake to infection remain largely unexplored. This is unfortunate because in nature, individuals are exposed to a wide variety of infection challenges that can compromise their fitness and redirect the evolutionary trajectories of populations. The research of my team focuses in better understanding the network of interactions that defines the relationships between nutrition, immunity, and infection, to provide a more comprehensive understanding of the key determinants of the outcome of host–pathogen interactions. During this talk, I will harness the power of the vinegar fly Drosophila melanogaster and the fruit fly Bactrocera tryoni to investigate how nutritional status affects infection at a single and multi-generational levels, manipulating maternal and paternal diets. We performed a detailed investigation of the effects of diet composition pre-infection on host's survival and pathogen population growth after a septic bacterial infection. Nutritional responses and fitness-related traits were also measured. Together, our findings provide a better understanding of the relationship between diet, infection and transgenerational effects, and reveal an important but complex pattern whereby parental diet influences offspring responses to bacterial infections.

Protein changes the relationship between immune gene expression and immunity

Authors: Ponton Fleur[2], Reavey Catherine[1], Randall Joanna[1], Smith Judith[3], Wilson Kenneth[1], Holdbrook Robert[1], Cotter Sheena[4], Simpson Stephen[5] and Tumala Yamini[1], [1]Lancaster University, United Kingdom, [2]Macquarie University, Australia, [3]University of Central Lancashire, United Kingdom, [4]University of Lincoln, United Kingdom, [5]University of Sydney, Australia

Abstract: Nutrition is vital to health and the availability of resources has long been acknowledged as a key factor in the ability to fight off parasites. However, the relationship between resources and immunity has typically been simplified to a single currency, such as ‘energy’, which masks the variablity intrinsic to the diet. Here we use a state-space modelling approach, the Geometric Framework for Nutrition (GFN), to assess how the balance and amount of nutrients affects an animal’s ability to mount an immune response to a pathogenic infection.
Spodoptera littoralis caterpillars were assigned to one of 20 diets that systematically varied in their protein:carbohydrate ratio and their calorie content. Caterpillars were then handled or injected with either live or dead Xenorhabdus nematophila bacterial cells. Gene expression was measured 20 h post immune challenge. For two of the immune genes (PPO and Lysozyme) we also measured the relevant functional immune response in the hemolymph. Gene expression and functional immune responses were then mapped against nutritional intake.
The expression of all immune genes was up-regulated by injection with dead bacteria, but only those in the IMD pathway (responds to Gram -ve bacteria) were substantially up-regulated by both dead and live bacterial challenge. The availability of protein was the most important predictor of the functional (physiological) immune responses but immune gene expression responded quite differently to dietary manipulation, such that the correlation between gene expression and the functional immune response changed with the availability of protein in the diet. Ultimately, we would caution against using gene expression as a proxy for immune investment, as it is unlikely to be reliable indicator of the functional immune response, except under specific dietary conditions.

Potential of biopesticides and optimising the use of conventional insecticides for the control of cabbage stem flea beetle (Psylliodes chrysocephala)

Authors: Pope Tom[1], Hoarau Claire[1], Chandler Dave[2], Prince Gill[4] and Campbell Heather[1], [1]Harper Adams University, United Kingdom, [2]University of Warwick, United Kingdom

Abstract: Cabbage stem flea beetle (CSFB; Psylliodes chrysocephala) is one of the most important pests of oilseed rape. Adults feed on cotyledons and first true leaves, while larvae mine petioles and stems. Yield losses due to adults and larvae typically range between 5 and 15%.

Since the ban in 2018 by the EU on the use of neonicotinoid seed treatments, the only insecticides used to control CSFB are pyrethroids. However, many CSFB populations in the UK have developed resistance against pyrethroids, rendering their use ineffective, and harmful to natural enemies and pollinators.

It is then of the utmost importance to find alternative ways to control CSFB populations. Biopesticides, such as entomopathogenic fungi, bacteria and nematodes, have been subject of many studies over the past decades and their efficacy has been demonstrated against other flea beetles species (e.g. Phylloletra cruciferae). These biopesticides include 1) fungi species of the genus Metarhizium spp. (M. anisopliae and M. brunneum) and Beauveria bassiana; 2) nematodes from the genera Steinernema spp. and Heterorhabditis spp.; 3) bacteria such as Bacillus thuringiensis; 4) plant extracts such as azadirachtin (extract of neem).

The aim of this project is to identify the most effective biopesticides, either applied alone, or combined with each other and/or with pyrethroids. The suitability of the use of these biopesticides in commercial situations will be evaluated, the ultimate goal being to find a feasible solution for oilseed rape producers impacted by this pest.

Towards integrated pest management of vine weevil (Otiorhynchus sulcatus)

Authors: Pope Tom[1], Roberts Joe[1] and Hall David[2], [1]Harper Adams University, United Kingdom, [2]University of Greenwich - Natural Resources Institute, United Kingdom

Abstract: Vine weevil, also known as black vine weevil (Otiorhynchus sulcatus), remains an economically important pest of a wide range of protected crops, including soft fruit and ornamentals. The last 30 years has seen many changes in crop protection practices, including wide-scale adoption of biological controls such as entomopathogenic nematodes in place of conventional synthetic insecticides. Despite these changes, growers continue to report significant crop losses associated with vine weevil infestation. Here we argue that more effective control will only be achieved when biological controls are used as part of an integrated pest management (IPM) programme and not simply as direct replacements for synthetic insecticides. We identify vine weevil biology, forecasting, monitoring and action thresholds as areas in which improved knowledge is required and report results from research addressing these aspects of vine weevil IPM.

Ecological traits of cabbage moth (Mamestra brassicae) in relation to IPM

Authors: Popov Sergei, Russian State Agrarian University - Moscow Timiryazev Agricultural Academy, Russia

Abstract: Cabbage moth, Mamestra brassicae (L.) (Lepidoptera: Noctuidae), is one of the main pests of cabbage in Moscow region, Russia. Different ecological traits of the pest were investigated in laboratory and cabbage fields during a period of 25 years. The aim of those studies was to find bottlenecks in the insect's ecology and, by manipulating them, to reduce the insecticide pressure in cabbage fields. Based on the economic injury level of one 5th instar per cabbage head, we calculated survival coefficients for caterpillars during different developmental age intervals, and created mathematic models (equations) of predicted critical population densities of M. brassicae. On the basis of k-factor life tables constructed for different cultivars of white cabbage, we found that the first two instars suffered the highest mortality. Virtually no biotic mortality factors were detected for those instars, leading to a recommendation to target them with insecticide applications. We also screened the effects of numerous F1 hybrids of white cabbage and broccoli on the life history traits of M. brassicae. Resistant cabbage hybrids could be detected under field conditions were established by quantifying the smallest egg clutches. Our findings allow optimizing the IPM program against cabbage moth.

Searching ants meander regularly and avoid crossing their own paths

Authors: Popp Stefan, University of Arizona, United States

Abstract: The evolution of behavioral traits is shaped by the benefits and costs to fitness they confer; therefore, measuring how these benefits and costs are shaped by the environment is a critical element in studies of evolution. Here I review both theoretical and empirical approaches and their surprising results for what fitness effects communication in social groups can have. Social insects like bees and ants have evolved particularly diverse and sophisticated means of communication, and we demonstrate that these are critically shaped by the resource environment and group size, but not always in intuitive ways. In particular, communication can reduce efficiency through opportunity costs, and reduce flexibility through decreased innovation. The talk will emphasize how models can be integrated with experiments to yield novel insights.

Combining landscape and functional trait research to build natural pest control in crops

Authors: Poppenborg Martin Emily A[3], Steffan-Dewenter Ingolf[3], Dainese Matteo[1], Alexandridis Nikos[2] and Clough Yann[2], [1]EURAC Bozen, Italy, [2]Lund University, Sweden, [3]University of Wuerzburg, Germany

Abstract: Managing agricultural landscapes to support biodiversity and natural pest control could be a key avenue towards sustainable and climate-resilient agriculture that works for farmers. However, precisely how to manage these landscapes – and how effective this will be - is unclear. In a synthesis of data from 49 studies (1,515 landscapes) across Europe, we examined how landscape composition (% semi-natural habitat and arable land) and configuration (density of edges including crop/crop and crop/non-crop boundaries) impact arthropods in fields and their margins, pest control, and yields. We show that edge density interacted with proportions of crop and non-crop habitats, and separating species according to dietary, dispersal and overwintering traits led to contrasting responses. Overall, highest total arthropod densities were reached in landscapes combining high amounts of non-crop habitat and high edge density. In landscapes with high edge density, 44% of natural enemy species, including particularly species not known to overwinter in crop fields, reached highest densities, and pest control improved 1.4-fold. Based on these results and on key combinations of species' traits, pathways to predictively assess natural pest control potential can be derived to anticipate the effects of landscape- and field-scale management, towards a workable ecological intensification of agricultural production under global change.

Two-sex Life Table Analysis and Developmental Rates for Nezara viridula (Heteroptera: Pentatomiade) reared with two artificial diets.

Authors: Portilla Maribel, USDA-ARS-Southern Insect Management Research Unit. Stoneville, MS, United States

Abstract: Two artificial diets, including the fresh yolk chicken egg based-diet (FYD) and dry yolk chicken egg based-diet (DYD) used for Lygus spp. were evaluated as an alternative food source for rearing the southern green stink bug, Nezara viridula (L.) (Heteroptera: Pentatomidae). Fresh and dry yolk diets had survival to adult stages, of 97.33% and 74.57%, respectively. The FYD had 100% survival from first through fourth instars. Adult Development was significantly shorter on the FYD (30.37 ± SE 0.30 days) versus the DYD (32.77 ± SE 0.16 days). Longer male and female longevity, higher fecundity, and larger egg mass sizes were found on the FYD. However, fertility and hatchability was higher on the DYD. A complete cohort life table incorporating both sexes and variable developmental rates among individuals was constructed and a novel rearing method for N. viridula was developed.

Mass rearing of Lygus lineolaris (Palison de Beauvois) (Hemiptera: Miridae) as a possible alternative for mass production of the egg parasitoid Anaphes iole (Giraul)

Authors: Portilla Maribel, USDA-ARS-Southern Insect Management Research Unit. Stoneville, MS, United States

Abstract: Two artificial diets developed for rearing Lygus spp., a none-autoclaved and an autoclaved yolk chicken egg-based diets were evaluated as a media to support a mass rearing system for the tarnished plant bug. This study was carried out at the USDA, ARS, SIMRU in Stoneville, MS. Lygus lineolaris Palison de Beauvois (Hemiptera: Miridae) was reared according to the method described by Portilla et al. 2011. Survival to adult, sex ratio, and first, second, and third instar nymphal mortality were not different between diets. Daily egg production was significantly greater in the none-autoclaved diet with 9806.91 ± 302 versus 5953.32 ± 316 eggs per day/ cage for the autoclaved diet. The cumulative egg production of L. lineolaris was significantly higher in the none-autoclaved diet (over 98,000 eggs produced in 10 days/cage) compared to cumulative egg production observed for the autoclaved diet (59,000 eggs/ cage). The percentage of no-embryo eggs produced per day was lower for the none-autoclaved diet, and the fertility and hatchability rates were higher than in the autoclaved diet. The greater egg production, lower fourth-fifth instar nymphal mortality, and higher hatchability rate obtained in the none-autoclaved diet resulted in a greater biomass accumulation. The none-autoclaved artificial diet was prepared in a single-step process, thereby avoiding the multi-step process for the autoclaved diet. The none-autoclaved diet is less expensive and requires less time for diet preparation than the autoclaved diet. This rearing system will be use in a near future for mass production of Anaphes iole Giraul (Hymenoptera: Mymaridae) egg parasitoid of Lygus spp.

Biological control with parasitoids: from the study of insect ecology to the optimisation of a biological control programme

Authors: Postic Estelle[1], Outreman Yannick[2] and Le Ralec Anne[2], [1]Frais'Nat, France, [2]Institut Agro Rennes-Angers

Abstract: Hymenopteran parasitoids can be mass-reared for release into greenhouse crops, where augmentative biological control is widely used. In particular, parasitoids are reared to control various species of aphid pests. However, in some cases, like in strawberry greenhouses, biological control of aphids remains inefficient. Thus, by studying aphid and parasitoid communities in the main regions of strawberry production in France, we studied the ecological and evolutionary determinants of the effectiveness of a biological control programme. The study of aphid and parasitoid communities spontaneously colonising the greenhouses allowed to identify the species most adapted to aphid regulation. Our work also shows that aphids are often infected by bacterial symbionts that can confer resistance to the released parasitoids. Finally, the analysis of genetic variability within populations of wild and commercial parasitoids revealed a genetic differentiation between these natural and mass-produced beneficials. As this differentiation is associated with a loss of genetic diversity in commercialized populations, the question of their effectiveness against aphids arises. This work led French strawberry growers to create their own parasitoid production specifically dedicated to controlling aphids in strawberry crops. This will make it possible to adapt parasitoid mass-rearing to the particular constraints related to strawberry crops.

Photonic e-traps for Lepidoptera

Authors: Potamitis Ilyas, Hellenic Mediterranean University, Greece

Abstract: Helicoverpa armigera is an insect-pest that belongs to the order of Lepidoptera. It is also known as the cotton bollworm and feeds on a wide range of plants, including many important cultivated crops such as cotton, tomatoes, maize, chickpeas, alfalfa, and tobacco. We monitor automatically their population in the field to detect the onset of the infestation and also assess the current and aftertreatment density of the pest so that we proceed timely to control measures (e.g. spraying). The electronic funnel trap (e-funnel) is an optical counter attached to typical, plastic, funnel traps to automatically count all captured Lepidoptera species with known pheromone. As an insect falls in the bucket, it interrupts a flow of infrared light, and the resulting voltage fluctuation is turned to a count. The counts as well as environmental data and GPS coordinates are transmitted using the GPRS mobile network from the field to a server that streamlines and visualizes data from all e-traps.

We will present detailed analysis of a 3-months monitoring period from 5 e-traps and we will talk about how we can use historical data to predict the future infestation load in the field.

Use of vibratory signals for the detection and monitoring of stored product pests

Authors: Potamitis Ilyas[1], Eliopoulos Panagiotis[2], [1]Hellenic Mediterranean University, Greece, [2]University of Thessaly, Dept. of Agriculture & Agrotechnology, Larissa, Greece

Abstract: Pest detection in grain storages is mainly achieved today by inefficient and time consuming methods such as visual inspection, sieving, Berlese funnels and trapping. Some other analytical and more sophisticated methods such as carbon dioxide measurement, uric acid measurement, near-infrared spectroscopy, and soft X-ray have demonstrated great potential in the lab. However, most of them are cost prohibitive and require complex operating procedures and calibrations. Insect pests of stored grains and pulses produce vibratory signals by moving, feeding or ovipositing inside the grain mass. These sounds can be used not only for detection purposes, but also for population density estimation. During the last decade, several published studies investigated the potential of bioacoustics as an alternative method for accurate, fast, non-destructive and automated detection of the insects' presence inside the stored grain mass. Moreover, reliability and efficacy of acoustic pest detection has been greatly increased in the last few years as a result of the development of improved acoustic devices and signal processing methods. Today, acoustic devices are commercially available for the continuous and automated detection and monitoring not only for adults but also for larval stages that are hidden inside infested kernels. The present study focuses on the advantages of acoustics in comparison with traditional detection methods (trapping, sampling, sieving etc), its potential for improvement (more sensitive sound technology, signal processing, machine learning techniques etc.), acoustic systems that are currently available in the market (probe piezoelectric sensors, amplifiers, software etc), and limitations for practical application (cost of acoustic technology, background noises, interpretation of acoustic emissions, multiple infestations, farmers' technical training etc.). Potential areas for growth in the use of acoustic technology in detecting and monitoring stored product pests are discussed on the basis of Integrated Pest Management in storage facilities.

Insect Surveillance meets IoT and Artificial Intelligence

Authors: Potamitis Ilyas[2], Eliopoulos Panagiotis[4], Rigakis Iraklis[1], Tatlas Nicolaos-Alexandros[1], Ntalampiras Stavros[3] and Potirakis Stelios[1], [1]Department of Electrical and Electronics Engineering, University of West Attica, Athens, Greece, [2]Hellenic Mediterranean University, Greece, [3]University of Milan, Department of Computer Science, Italy, [4]University of Thessaly, Dept. of Agriculture & Agrotechnology, Larissa, Greece

Abstract: Precision agriculture is about managing variations in the field to increase crop yield, raise productivity and reduce consumption of agricultural inputs. Agriculture remains greatly unpenetrated by IoT technologies, but perspectives are positive about future market trends. Especially, as far as crop protection from insect – pests is concerned, numerous automated, electronic devices have been developed, evaluated and marketed as insect monitoring traps.

In our vision a pest-detection device is not just a plastic bucket, it is a 'thing'. That means a cyber physical object. In even simpler words a bucket that can report wirelessly a parameter of interest (usually insect counts, environmental parameters but in some cases, more complex data). Therefore, they have at least a sensor and wireless communication. The trap is addressable meaning through a server you can direct yourself through the network of traps and reach any trap to see what is happening (e.g. listen to vibrations, see pictures, plot counts/per day). You can also see collective results of the network of traps on a map. Finally, telemetry can be applied: Meaning that the functioning of the traps and their internal state can be monitored to predict malfunction, automatic update of firmware etc.

Many traps together that report a small number of parameters (insect counts and environmental data) can form a network that has its own internet functionality (an Internet of Things - IoT). This network based on LoRa/WAN can expand practically to hundred of nodes if the traps are dispersed few kilometers one from another. The traps can be self-organized in networks that collectively report data usually at local and regional level but, in principle, could be expanded at global scales.

Artificial Intelligence comes in when the number of reported records scales to thousands. Then, one needs an automatic method to process the records to infer the infestation state. In this presentation, we will focus only in cases that have reached TRL 9.

The Internet of Bees (IoBee)

Authors: Potamitis Ilyas[5], Salazar Andrés[2], Marsboom Cedric[1], Evans Huw[4], Encarnação Joao[6] and Simon-Delso Noa[3], [1]AVIA-GIS, Belgium, [2]BeeLife European Beekeeping Coordination, Belgium, [3]BeeLife European Beekeeping Coordination; CARI (Apicultural Centre for Research and Information), Belgium, [4]Canetis, Italy, [5]Hellenic Mediterranean University, Greece, [6]IRIDEON, Spain

Abstract: The internet of bees, or IoBee, is a project funded by the European Commission which aims to explore different technologies for the improvement of bee health. Finalising in April 2020, the project helped develop key innovations including (i) monitoring tool for foraging activity at the entrances of honeybee hives; (ii) sensing device for the density and diversity of wild pollinators in the field; (iii) optical-based identification of insects based on colour recognition; and (iv) big data collection and the processing and analysis of spatial information. A bee counter closely monitors activity at the entrance of the beehives, which gives valuable insights into its strength, dynamism, or presence of potential predators. Besides, in-field sensors identify both the density and diversity of pollinators as well as invasive insect species. Sensors can be applied in apiaries, crops and landscape features to establish sentinel networks and the generation of risk/pollination maps. Thirdly, satellite imaging provides phenology historical data and model predictions through the application of Spatial Decision Support Systems (SDSS). Finally, a platform integrating data generated by the ground sensors, coupled with satellite data for vegetation, ground temperatures and other environmental variables, as well as beekeepers' observations, can provide intelligent warning systems. These predictive tools will serve field practitioners such as beekeepers, farmers or land managers to aid management decisions concerning nectar flows, risks of infestations from pests, or pollination potential. The data has the scope to inform public bodies and governmental authorities with decisions on pollinator conservation, land management and climate change.

Feeding Ecology of the Japanese Beetle (Popillia japonica), a Biosecurity Threat to European Agriculture and Beyond

Authors: Potter Daniel, Department of Entomology University of Kentucky, United States

Abstract: The Japanese beetle (JB), among the most destructive invasive pests in North America, was first detected in continental Europe, in northern Italy, in 2014. Because of its broad host range (> 300 plant species) and propensity for its grubs and adults to be transported in commerce, JB is poised to become a major horticultural pest throughout much of temperate Europe. This talk summarizes research on adult JB feeding ecology and applications to pest management. JB are mildly attracted to constitutive volatiles from many plant species regardless of their suitability as hosts. Plant secondary chemistry drives acceptance/rejection at leaf surface. Additional JB are attracted to feeding-induced plant volatiles resulting in aggregation and rapid defoliation of preferred hosts. Most mating occurs on host plants, so induced odors serve as an indicator of others feeding on a high-quality host. JB also bite in to ripe fruits, directly damaging them and contaminating them with yeasts that elicit fermentation volatiles that attract secondary fruit-feeding pests. Applications of this research including use of pheromone-kairomone lures and host plant resistance in management of JB will be discussed.

Japanese beetles' feeding on milkweed flowers may compromise efforts to restore monarch butterfly habitat

Authors: Potter Daniel[1], Baker Adam[2], [1]Department of Entomology University of Kentucky, United States, [2]University of Kentucky, United States

Abstract: The eastern North American migratory population of monarch butterflies (Danaus plexippus) is in serious decline. Habitat restoration, including adding millions of host plants to compensate for loss of milkweed in US cropland, is a key part of the international conservation strategy to return this iconic butterfly to sustainable status. We report here that Popillia japonica, a polyphagous, invasive beetle, aggregates and feeds on flowers of Asclepias syriaca, the monarch's most important larval food plant, reducing fruiting and seed set by >90% and extensively damaging milkweed umbels in the field. The beetle's ongoing incursion into the monarch's key breeding grounds in the US Midwest is likely to limit pollination and outcrossing of wild and planted milkweeds, reducing their capacity to colonize new areas via seeds. Popillia japonica represents a previously undocumented threat to milkweeds that should be considered in models for monarch habitat restoration.

Enhancing biological control of Popillia japonica through a better understanding of parasitoid biology and behavior

Natural habitat mitigates negative pesticide effects on bee diversity in a traditional Andean crop

Authors: Poveda Katja[2], Obregon Diana[1], Stashenko Elena[4] and Guerrero Olger[3], [1]Cornell University, Department of Entomology, Colombia, United States, [2]Entomology Department, Cornell University, Ithaca, New York, United States, [3]Universidad de la Salle, Colombia, [4]Universidad Industrial de Santander, Colombia

Abstract: Wild bee communities provide key pollination services to achieve optimum crop yields. There is evidence that the loss of natural habitat and pesticides are two of the main factors contributing to bee declines, however, the interaction of these two stressors has not been much explored. Solanum quitoense, known as “lulo”, is an Andean fruit used for fresh consumption. Despite the economic importance of this crop for local communities, there is very little information about its pollinator dependency and the bee community-associated. In this study made in the Colombian Andes, we characterized the flower visitors and the change in abundance and richness of bees visiting lulo crops in ten farms that differed in landscape composition and pesticide use. In every farm, we calculated the landcover proportions (natural habitat, pastures, and agriculture) at 500m around the center of every crop field. We collected anthers from ten different plants in every farm to test with UHPLC for nine pesticide molecules commonly used in the area (Methomyl, Abamectin, Bifenthrin, Imidacloprid, Profenofos, Lufenuron, Cymoxanil, Difenoconazole, and Propamocarb). Bees were sampled in three events during the dry season with two observers walking for 30 minutes during warm and sunny days from 9:00 to 16:00h stopping and recording the identity and the number of bees observed visiting the flowers. We also estimated the contribution of pollinators to fruit production (Fruit set, fruit weight, and fruit diameter) in an exclusion experiment bagging inflorescences in 20 plants per farm. We recorded 650 visits from 16 bee species in 6 tribes. Tetragonisca angustula and Paratrigona opaca were two of the most frequent visitors. We found a reduction of 51% in fruit set when visitors were excluded, showing a high pollinator dependency. We also found a 39% decrease in fruit weight and 25% decrease in fruit diameter without bees demonstrating their contributions to crop yield. As the pasture area increased, bee Shannon diversity and richness decreased. We found 5 out of the 9 molecules tested in anthers. Propamocarb was found in 100% of the farms ranging from 1.3 to 399.5 ug/kg and imidacloprid in 80% of the farms ranging from 0.6 to 13063 ug/kg. We found that imidacloprid concentration in the anthers was negatively associated with bee diversity and richness. There was a significant interaction of natural habitat area and imidacloprid on bee richness and bee Shannon diversity index, suggesting that the negative effects of imidacloprid on bee diversity are attenuated by the increment in natural habitat. Our study provides evidence that landscape simplification and pesticides, in particular, imidacloprid, are threats to the bee community in lulo crops. However, the interactive effects between the proportion of natural habitat and imidacloprid concentrations showed that complex landscapes can help to mitigate the pesticide negative effects.

Landscapes of fear: How landscape composition influences the magnitude of antipredator responses in an agricultural insect pest

Authors: Poveda Katja[2], Perez-Alvarez Ricardo[3], Thaler Jennifer[1] and Tigreros Natasha[4], [1]Cornell University, United States, [2]Entomology Department, Cornell University, Ithaca, New York, United States, [3]Leibniz University of Hannover, Germany, [4]University of Arizona, United States

Abstract: Prey organisms often respond to the risk of predation by altering behavioral, physiological, and morphological traits. These antipredator responses increase prey survival, but often come at a cost of reduced feeding and/or reproduction rates, which ultimately may result in decreasing prey populations with cascading benefits for plant production. Although such antipredator responses have been relatively well studied in small scale microcosm environments, they remain largely unexplored for plant-arthropod communities living in heterogeneous agricultural landscapes. Here, we examined how variation in predator abundance across a gradient of landscape complexity influences antipredator responses of a major agricultural pest, the Colorado potato beetle (Leptinotarsa decemlineata). Within the study region (New York State, USA) pest populations were collected in 19 potato fields encompassing a 20-fold natural difference in predator abundance. For each pest population, we measured two behavioral responses to the risk of predation: leaf feeding and intra-clutch cannibalism. Using laboratory trials with stink bug predators (Podisus maculiventris) that were surgically manipulated so they could hunt but not kill, we also tested the magnitude of antipredator responses among pest populations. We showed that predator abundance was higher in agriculturally dominated landscapes (i.e., simple landscapes). Furthermore, pest populations from simple landscapes exhibited significantly higher levels of intra-clutch cannibalism and considerable reductions in plant feeding, behaviors known to reduce the likelihood of being predated. Results from the experiment with “sham predators” further confirm that antipredator responses were stronger in simple than in complex landscapes. Thus, our findings provide empirical evidence that landscape-level variation in predation risk is associated with behavioral changes among population of L. decemlineata. A greater understanding of these indirect landscape effects on pest regulation is necessary to fully explore the range of mechanisms by which biological control could be strengthened in agroecosystems.

All the better to see flowers with?: Eye morphology driven by feeding behavior in sap beetles

Authors: Powell Gareth[1], Bybee Seth[1], [1]Department of Biology, Brigham Young University, United States

Abstract: Nitidulidae, or sap beetles, are an ecologically diverse lineage of Cucujoidea. Members of this single family are reported to exhibit the majority of feeding behaviors known to occur across all Coleoptera. This immense diversity of feeding behavior can be seen both between major lineage such as subfamilies, but also between very closely related species within a genus. This diversity in feeding behavior could drive morphological variation and adaptations to capitalize on various resources, e.g., flower visiting vs. rotting fruit. One system possibly under strong selection is the visual system. Morphological measurements were taken using scanning electron micrographs and high-resolution stacked color images. A discussion of eye size, facet size, and facet density is presented in a phylogenetic context. We specifically tested for significant relationships between overall eye size and the following factors: flower-visiting, day-night activity, body coloration, body size, gender, and phylogenetic position.

Controlling the controller? The effect of microscopic fungi on the ecosystem services provided by ground beetles (Coleoptera: Carabidae)

Authors: Pozsgai Gabor[1], Ben Fekih Ibtissem[1] and You Minsheng[2], [1]Institute of Applied Ecology Fujian Agriculture and Forestry University, China, [2]State Key Laboratory of Ecological Pest Control for Fujian and Taiwan Crops, Fujian Agriculture and Forestry University, Fuzhou, China

Abstract: Ground beetles (Coleoptera: Carabidae) are valuable biological control agents, supporting sustainable agriculture. Microscopic fungi, which themselves often provide valuable ecosystem services by infecting and killing pest species, may reduce this benefit when they act as ectoparasites or entomopathogens of carabids. To what extent this trade-off influences the delivery of ecosystem services ground beetles provide is yet unknown. Here, we gathered literature data using 421 papers from 198 journals in 15 languages on interactions occurring between ground beetles and fungi, and built an interaction network to 1) review available information and identify knowledge gaps, and 2) to assess how fungi can affect the ecosystem services carabids provide. We recorded 651 Carabidae interacting with 902 fungal species in 4528 unique connections, from 148 countries. The predominant interaction type was ectoparasitism between Laboulbeniales fungi and, mostly, Trechinae ground beetles. Entomopathogenic fungi most commonly infected the Harpalinae subfamily that have purely herbivorous or a mixed diet with a substantial amount of plant material consumed. Carabidae consuming fungal hyphae and mutualistic yeasts living in ground beetles' guts were also present in our network but these interactions were both underrecorded and poorly studied. The low number with which predatory ground beetle species were involved in interactions with entomopathogenic fungi suggests a moderate negative effect. Although ectroparasitism are very common, these relationships have subleathal effects, and they are reported to cause no or very little fitness decline. Thus, ecosystem services provided by Carabidae are unlikely to be substantially disturbed by interacting fungi. With numerical parametrization of the interaction links the model would provide a detailed insight into the trade-offs between fungi and Carabidae.

The impact of crop systems on aphid-pathogenic fungi interaction networks

Authors: Pozsgai Gabor[3], Ben Fekih Ibtissem[3], Bruun Jensen Annette[6], Eilenberg Jørgen[2], AG Wyckhuys Kris[1], You Minsheng[5] and You Shijun[4], [1]Chrysalis Consulting - Nature-based solutions for plant health, Vietnam, [2]Department for Plant and Environmental Sciences, University of Copenhagen, Denmark, [3]Institute of Applied Ecology Fujian Agriculture and Forestry University, China, [4]Institute of Applied Ecology, College of Plant Protection, Fujian Agriculture and Forestry University, China, [5]State Key Laboratory of Ecological Pest Control for Fujian and Taiwan Crops, Fujian Agriculture and Forestry University, Fuzhou, China, [6]University of Copenhagen, Denmark

Abstract: The networks formed by the interactions between aphids and their pathogenic fungi are of high importance for an increased use of fungi in biological control. Yet, these networks are poorly known, and particularly the impact of crop systems in shaping these associations are seldom considered. We established a hypothetical interaction network between aphids and their fungal pathogens based on published data to (1) investigate the fungus-host specificity and their dependency on their habitat, and (2) assess the dissemination of aphid mycoses among nine major crop systems. Of the 1400 unique connections between these host and pathogen taxa, we identified pathogen specificity and assessed, which role the most commonly connected aphid species can play in the dynamics of fungal infection within and between crop systems. Fungi within the Entomophthoraceae had the highest number of connections to aphids. Pandora neoaphidis and Entomophthora planchoniana had the most connections to aphid species, suggesting that they are likely to play a key role in the establishment and dispersal of infections in aphid populations worldwide. From the aphids' side, Myzus persicae was the most connected to fungi in the network, followed by the cereal aphids Rhopalosiphum padi and Sitobion avenae, suggesting that these species are highly prone to fungal infections and therefore important players of the fungal dissemination between crop systems. The highest number of aphid species and fungal connections was present in orchards, followed by vegetable and cereal crops. Insights into the correlations between the aphid-fungal pathogen interaction networks and the impact of crops on these associations provide the basis for prediction of the infection pathways in real-life ecological systems.

Effects of naturally derived products on Aculops lycopersici and their effects on a beneficial mite

Authors: Pozzebon Alberto[1], Zanolli Penelope, Tirello Paola, Fabris Beatrice and Duso Carlo, [1]University of Padova - DAFNAE, Italy

Abstract: Tomato russet mite (TRM) Aculops lycopersici is one of the most important pests of tomato Lycopersicon esculentum. The decreasing availability of acaricides and restrictions in their use in several countries is promoting researches on alternatives to conventional pesticides. The efficacy of products based on entomopathogenic fungi (i.e. Beauveria bassiana, Paecilomyces fumosoroseus and Lecanicillium muscarium) or naturally substances (pyrethrins and azadirachtin A) on A. lycopersici was assessed in the laboratory. Mites were exposed to dry residues of products at their maximum rate and a water-treated control was included for comparison. Eriophyoid mite survival evaluated after 72 h was significantly reduced by B. bassiana, azadirachtin A and pyrethrins compared to the control. At 168 hours from applications, mite survival was reduced even on P. fumosoroseus treatment. Beauveria bassiana was associated with the lowest TRM survival rates. Escaping was significantly higher on azadirachtin A, pyrethrins and P. fumosoroseus treatments. The effects of these products were also evaluated on Amblyseius swirskii employed in biological control programmes in greenhouses.

Large-scale field monitoring on the distribution of Trissolcus japonicus and Trissolcus mitsukurii, two egg parasitoids of Halyomorpha halys, in Italy and Switzerland

Authors: Pozzebon Alberto[22], Maistrello Lara[11], Sabbatini Peverieri Giuseppino[5], Haye Tim[3], Marianelli Leonardo[7], Costi Elena[11], Tavella Luciana[24], Zapponi Livia[20], Benvenuto Luca[14], Falagiarda Martina[16], Roversi Pio Federico[6], Mele Alberto[23], Butturini Alda[19], Di Bella Emanuele[12], Tortorici Francesco[10], Vaccari Giacomo[4], Malossini Giorgio[18], Bernardinelli Iris[14], Michelon Lorenza[21], Grazia Tommasini Maria[8], Salvetti Martino[15], Bariselli Massimo[19], Preti Michele[2], Culatti Paolo[17], Zandigiacomo Pietro[9], Schmidt Silvia[13], Teresa Moraglio Silvia[10], Bardella Simone[1] and Caruso Stefano[4], [1]AGRION, Italy, [2]ASTRA Innovation and Development Test Facility, Faenza, Italy, [3]CABI, Delémont, Switzerland, [4]Consorzio Fitosanitario Provinciale di Modena - Plant Protection Service, Italy, [5]Council for Agricultural Research and Economics-Research Centre for Plant Protection and Certification, Italy, [6]CREA - Council for Agricultural Research and Economics – Research Centre for Plant Protection and Certification (CREA-DC), Italy, [7]CREA -Research Centre for Plant Protection and Certification, Italy, [8]CRPV, Cesena, Italy, [9]Department of Agricultural, Food, Environmental and Animal Sciences, University of Udine, Italy, [10]Department of Agriculture, Forest and Food Sciences (DISAFA), University of Torino, Italy, [11]Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy, [12]Dipartimento di Scienze della Vita, Centro BIOGEST-SITEIA, Università di Modena e Reggio Emilia, Reggio-Emilia, Italy, [13]Entomology Group, Institute for Plant Health, Laimburg Research Centre, Italy, [14]ERSA – Regional agency for rural development – Phytosanitary Service of Friuli Venezia Giulia, Italy, [15]Fondazione Fojanini di Studi Superiori, Phytosanitary Service, Italy, [16]Laimburg Research Centre, Italy, [17]Lombardy Regional Plant Protection Service, Italy, [18]Plant Health Service - ERSA - Friuli Venezia Giulia Region, Italy, [19]Plant Protection Service of Emilia-Romagna Region, Italy, [20]Research and Innovation Center, Fondazione Edmund Mach, Italy, [21]Technical Advisory Service, Condifesa Lombardia Nord-Est, Italy, [22]University of Padova - DAFNAE, Italy, [23]University of Padua, [24]University of Torino DISAFA, Italy

Abstract: In Europe and North America, the invasive alien stink bug Halyomorpha halys causes severe damage on agricultural crops, and proposed chemical and physical solutions do not guarantee an acceptable level of long-term pest control. On the other hand, classical biological control using the egg parasitoid Trissolcus japonicus has been identified as the most suitable method to sustainably reduce pest populations in the long-term. Adventive populations of T. japonicus have been discovered in the USA since 2014 and more recently in southern Switzerland (2017) and in north-western Italy (2016). A second Asian egg parasitoid, Trissolcus mitsukurii, was also detected on H. halys eggs in northern Italy in 2018. Considering the exceptional findings of both parasitoids and the perspectives for a biological control program in the two European countries, in 2019 a large-scale field survey in northern Italy and Switzerland was performed to define the abundance and distribution of the two species. A collaborative work plan was established, involving 20 research institutions and plant protection organizations from different Italian and Swiss regions. The monitoring activities were performed from May to September 2019 and focused on detecting naturally laid egg masses of H. halys and other pentatomids. Collected egg masses were reared under laboratory conditions to allow egg hatching or parasitoid emergence. Overall, more than 4,348 egg masses of H. halys and 285 egg masses of other pentatomid species were collected. Results indicate that both T. japonicus and T. mitsukurii are present in several sites in the investigated area, in all the habitat types where H. halys was recorded and southwards from the first Italian records. Both parasitoids were detected on cultivated plants and hedgerows in IPM or organically managed orchards, on tree/shrubs in urban and suburban areas, and in uncultivated landscapes. The distribution of the two parasitoids partially overlapped, and, in a few records, they occurred in the same area or even in the same egg mass. The percentage of parasitized H. halys egg masses ranged between 0.45% and 53.85% and between 0.17% and 20.20% for T. japonicus and T. mitsukurii, respectively, depending on the area of survey (regions, provinces, cantons). The parasitism rate ranged between 71.43% and 100% and between 88.59% up to 97.40% for T. japonicus and T. mitsukurii, respectively. Parasitization by these two parasitoids on egg masses other than H. halys was a rare event: T. japonicus emerged from Palomena prasina egg masses and T. mitsukurii from P. prasina, Dolycoris baccarum, Nezara viridula and from an egg mass ascribed to a pentatomid of the subfamily Asopinae. Trissolcus japonicus and T. mitsukurii displayed both the ability to establish self-sustaining populations in the Swiss-northern Italian climate with relatively high parasitization success of H. halys eggs, suggesting a high potential for the control of the pest in the near future. This study provided key data for the development of the biocontrol program in Europe with the release program of T. japonicus.

Native and exotic egg parasitoids of Halyomorpha halys in Europe

Authors: Pozzebon Alberto[6], Maistrello Lara[5], Sabbatini Peverieri Giuseppino[2], Haye Tim[1], Tavella Luciana[7], Roversi Pio Federico[3] and Tortorici Francesco[4], [1]CABI, Rue des Grillons 1, 2800 Delémont, Switzerland, [2]Council for Agricultural Research and Economics-Research Centre for Plant Protection and Certification, Italy, [3]CREA - Council for Agricultural Research and Economics – Research Centre for Plant Protection and Certification (CREA-DC), Italy, [4]Department of Agriculture, Forest and Food Sciences (DISAFA), University of Torino, Italy, [5]Department of Life Sciences, BIOGEST-SITEIA Interdepartmental Centre, University of Modena and Reggio Emilia, Italy, [6]University of Padova - DAFNAE, Italy, [7]University of Torino DISAFA, Italy

Abstract: Since the accidental introduction of Halyomorpha halys into Europe, many studies focused to identify native natural enemies able to adapt to the new invasive species, especially considering the restrictions to the application of classical biological control. Particular attention was given to egg parasitoids, and field surveys in Switzerland and Italy were performed using sentinel egg masses (frozen or fresh) or collecting naturally laid egg masses. Until 2017, overall egg parasitism ranged from 0.5-4.4% in Switzerland to 1-21% in Italy, and the generalist egg parasitoid Anastatus bifasciatus was the predominant species. Moreover, the following other species were obtained: Trissolcus basalis, Trissolcus belenus, Trissolcus cultratus, Trissolcus kozlovi, Telenomus turesis and the hyperparasitoid Acroclisoides sinicus.

At the same time, the potential of some native egg parasitoid species was evaluated in laboratory no-choice tests. Besides A. bifasciatus, which confirmed its ability to develop in viable H. halys eggs, Ooencyrtus telenomicida showed to parasitize H. halys eggs successfully. In contrast, among the seven tested scelionid species (six Trissolcus spp. and T. turesis), all the Trissolcus spp. caused significantly higher egg mortality in comparison with unexposed eggs, but only T. kozlovi was able to produce offspring from viable H. halys eggs.

Due to its predominance in field surveys and its capability of developing in viable H. halys eggs, A. bifasciatus was selected as a potential candidate for augmentative releases. From 2016 to 2019, this egg parasitoid was released in fruit orchards in Switzerland and Italy. Results were contrasting, but usually unsatisfying for effective pest control. Recently, field surveys performed in Switzerland and Italy allowed discovering the presence of adventive populations of Trissolcus japonicus, considered the most effective egg parasitoids in China. Trissolcus japonicus was found first in Canton Ticino, Switzerland in 2017, and in Piedmont and Lombardy, Italy in 2018. Trissolcus mitsukurii is a second Asian egg parasitoid that was reported first on H. halys eggs in north-eastern Italy in 2018 but, given its spread and abundance, probably its presence dates some years before. Due to the large availability of their host in the field, the distribution and abundance of these exotic egg parasitoids are expected to expand, even in the absence of human intervention. To verify the status of the adventive populations, in 2019 an extensive monitoring was carried out jointly by many researchers to assess the presence and abundance of these two exotic parasitoids, pending the possible authorization for their release in the open field.

The Nearctic leafhopper Erasmoneura vulnerata, an emerging pest in European vineyards

Authors: Pozzebon Alberto[2], Duso Carlo[2], Prazaru Stefan Cristian[2], Rossetto Filippo[2], Carriero Carriero Francesca[2] and Tirello Paola[1], [1]DAFNAE - University of Padova, Italy, [2]University of Padova - Department of Agronomy, Food, Natural Resources, Animals and Environment, Italy

Abstract: The leafhopper Erasmoneura vulnerata is widely distributed in Northern and Central America, where wild and cultivated vines and other host plants are colonized. According to recent literature, E. vulnerata is not considered a major pest for American vineyards. This species was detected for the first time in Europe in 2004, particularly in Northern Italy, where it was mainly observed in neglected vineyards and wild vines for more than a decade. This situation changed in 2016 when the first outbreaks of E. vulnerata were reported in commercial vineyards in the Veneto region (Northern Italy). High population densities were observed despite organophosphates, suggesting that insecticide resistance was a key factor affecting this event. Interestingly, large populations in spring were associated with a decline of native leafhoppers (e.g., Empoasca vitis and Zygina rhamni). Susceptibility to pest infestation is influenced by vine variety. Therefore trials aimed at evaluating the economic thresholds of E. vulnerata gave contrasting results.

A remarkable response to leafhopper infestations by native egg parasitoids has been reported.

A tale of leafhoppers, Aster Yellows, and crops in the Canadian Prairies

Authors: Prager Sean[2], Romero Berenice[2], Olivier Chrystel[1], Wist Tyler[1], [1]Agriculture and Agri-Food Canada, [2]University of Saskatchewan, Canada

Abstract: Phytoplasmas are obligate parasites that cause several plant diseases around the world which affect crop production and reduce crop yield, such as Aster Yellows (AY) Disease. These organisms have been poorly studied due to difficulties in the establishment of in vitro cultures, which has not yet been successful, and also due to their high vector specificity. In the Canadian Prairies, Aster Yellows Disease is caused by the AY 16SrI phytoplasma group and primarily transmitted by Aster leafhoppers (Macrosteles quadrilinea tus Forbes). This disease can have a high incidence in canola fields (<90%) during outbreak years and can also affect other crops like cereals. However, disease dynamics are poorly understood. Moreover, there is no local population of Aster leafhoppers in the area, as these insects are introduced by wind currents in spring and early summer. In order to gain insight into biological aspects of these pathogens and one of the insect species that transmits them, different experiments were conducted, using crop and weed species commonly found in the Prairies. To study Aster leafhoppers´ host-choice behaviour and whether this can be affected by pathogen infection, two-choice bioassays were conducted using only infected and only uninfected leafhoppers. This was complimented with no-choice bioassays on different plant species, in order to evaluate leafhoppers´ oviposition behaviour and nymphal development, and if phytoplasmas can affect leafhoppers´ fitness. Arabidopsis thaliana was also incorporated into these experiments, given its importance as a model system and its relatedness to canola. Altogether, these results provide a better understanding of the AY epidemiology, resulting in management recommendations for local growers in Saskatchewan.

Screening of insect associated fungi for virulence to Tenebrio molitor larvae and potential biostimulation effect to maize

Authors: Praprotnik Eva[1], Lončar Jernej[1] and Razinger Jaka[1], [1]Agricultural Institute of Slovenia

Abstract: Several insect associated fungi have been shown to be effective in insect pest management. The aim of the presented study was to test different fungal isolates for their ability to infect mealworms (larvae of Tenebrio molitor, Coleoptera: Tenebrionidae) and stimulate maize growth. Seventy-one isolates of Metarhizium, Beauveria and Trichoderma species were isolated either from insect larvae of Galleria mellonella (Lepidoptera: Pyralidae) and T. molitor used as baits in soil samples, or from naturally occurring mycosed insect cadavers collected in the field. Some additional strains were obtained from serially diluted soil suspensions plated on semi-selective media. Virulence of isolates was tested by immersing mealworms in a conidial suspension at a concentration of 1 x 108 conidia ml-1 and assessing their mortality rate for 14 days. The isolates Metarhizium brunneum (1154) and Beauveria bassiana (2121) were found to be the most virulent, causing 100 % mortality of mealworms. In the virulence analysis, we also considered the origin of the fungi, the insect host, and the isolation method and found that fungi isolated from wild adult mycosed insects, mainly from the order Lepidoptera, and isolated from meadow soil, could potentially cause higher mortality in mealworms. Also, the role of insect associated fungi in fungus-plant systems is still poorly understood. Therefore, we additionally tested each of the isolates for their ability to stimulate maize growth. Maize seeds were submersed in a conidial suspension at a concentration of 1 x 108 conidia ml-1 and then planted in twice autoclaved commercial planting soil. Sprout emergence was monitored daily and root length, shoot length and dry weight of the plants were measured after three weeks. Prolongation of emergence time was observed in more than 60 % of the isolates. Maize root length was significantly increased by M. robertsii isolates (2691, 2693, and 2688) and reduced by Metarhizium robertsii isolates (2243 and 2636). Maize shoot length was significantly increased by Trichoderma atroviride (2882) and Trichoderma gamsii (2883) and reduced by B. bassiana isolate (2299). Plant dry weight was significantly increased by M. robertsii isolates (2146 and 2794) and reduced by B. bassiana isolates (2299 and 2300) and M. robertsii isolate (2011). Described method enabled identification of the M. robertsii isolate (2693), which caused the death of 73 % of T. molitor larvae and at the same time showed a positive effect to all measured growth parameters of maize.

The four way interactions among host plant-whitefly-virus-endosymbionts in insect and disease development

Authors: Prasannakumar Nr[1], Maruthi MN[2], [1]Division of Entomology and Nematology, ICAR-Indian Institute of Horticultural Research, Hessraghtta Lake, Bengaluru, India, [2]Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, United Kingdom

Abstract: The whitefly, Bemisia tabaci (Gennadius) (Hemiptera; Aleyrodidae) is a highly polyphagous pest reported to infest over 600 plant hosts globally. About 42 genetic groups/cryptic species of B. tabaci exist in the world on different hosts. The species have variable behaviour with respect to feeding, development and transmission of viral diseases. Feeding on diverse host plants affect both whitefly development and the population of the endosymbionts harboured by the insects. Due to changes in the level of endosymbionts, the virus transmission efficiency by the vector also gets affected. We investigated these interactions on five host plants – egg plant, tomato, beans, okra and cotton - using a single whitefly species Asia 1 infected with three different bacteria Portiera, Wolbachia and Arsenophonus. The Asia 1 transmits the Tomato leaf curl Bangalore virus (ToLCBV) effectively and thus was used in the interaction studies. We found a significant impact of hosts on whitefly growth and development; eggplant was most favourable host, while okra and tomato were least favourable. Among the endosymbiotic bacteria, the titre of Wolbachia was significantly affected by feeding of B. tabaci on different host plants whereas Arsenophonus and Portiera were unaffected. When whitefly fed on ToLCBV-infected tomato plants, the Arsenophonus population was significantly increased, indicating its previously confirmed role in ToLCBV transmission. Further, screening of total proteins of B. tabaci Asia 1 genetic group interacting with ToLCBV coat protein was carried out using Y2H system. Some of the proteins found to be interacting with ToLCBV CP were HSPs 70kDa, GroEL, nucleoproteins, vitellogenins, apolipophorins, lachesins, enolase. The reported protein thus would be the potential targets for novel whitefly control strategies such as RNAi or novel insecticide target sites for sustainable whitefly management after confirmation of genuine proteins.

Bottom-up and top-down effects of changing soil fertility on herbivory in a grassland food web

Authors: Prather Rebecca[1] and Kaspari Michael[2], [1]Florida State University, United States, [2]Geographical Ecology Group University of Oklahoma, United States

Abstract: Anthropogenic nutrient deposition is rapidly increasing, producing numerous interacting effects on grassland food webs by simultaneously changing soil and plant fertility, plant and arthropod communities, and herbivory. Understanding how increased nutrient deposition will change these interactions is important for the future maintenance of grassland food webs and ecosystems. We created a 40-fold gradient of fertilization and tracked its effects through a grassland food web, measuring changes to soil and plant nutrients, plant biomass and richness, herbivore abundance, predator abundance, and the amount and type of herbivory plants experience. We sought to uncover the mechanisms driving herbivory within and across fertilizer durations and quantities. Changing soil fertility had rippling effects on the abundance and function of a prairie food web. As eutrophication transitions from an episodic to a multi-year phenomenon, we demonstrate a shifting response in the abundance and impact of prairie herbivores. The mechanisms we uncover could help predict responses to eutrophication.

Eusociality and the evolution of ageing: investigating the basis of positive fecundity-longevity associations.

Authors: Prince David[1], Bourke Andrew[1], Collins David[1], Donelan Jenny[1] and Chapman Tracey[1], [1]University of East Anglia, United Kingdom

Abstract: Eusocial insects present an apparent exception to the classical predictions of the evolutionary theory of ageing in that queens exhibit a positive fecundity-longevity association. This has led to the hypothesis that social insect queens lack the fecundity-longevity trade-off observed in other species, and therefore do not experience costs of reproduction. A recent study in eusocial bumblebees (Bombus terrestris) showed that reproductive workers exhibit a positive fecundity-longevity association, but that the fecundity-longevity association becomes negative when workers are experimentally forced to reproduce. This suggests an alternative hypothesis that reproductive workers, and by extension eusocial queens, are analogous to intrinsically high-quality individuals in non-social organisms, such that costs of reproduction are latent but not usually expressed. We have tested these two hypotheses by experimentally manipulating costs of reproduction experienced by Bombus terrestris queens, and comparing their longevities. The existing hypothesis predicts that the manipulation will not affect the longevity of the queens, as there are no costs of reproduction. The alternative hypothesis predicts that manipulated queens experiencing increased costs of reproduction will have reduced longevity. Our results help discriminate between these two hypotheses and elucidate the mechanisms governing ageing and longevity in social insects.

The Cognitive Ecology of Buzz Pollination

Authors: Pritchard David, University of Stirling, United Kingdom

Abstract: While most studies of cognitive ecology of pollination have focussed on pollinators foraging for nectar, over the past decade, there has been increasing interest in the cognitive ecology of pollen foraging. Most of these studies have focussed on plant species in which pollen is presented externally to bees and requires little effort to access. In contrast, to extract pollen from "buzz-pollinated" flowers, bees must vibrate anthers, producing accelerations over 10 times that produced during flight (Pritchard & Vallejo Marin, in review). Despite the effort required to extract pollen, buzz pollination is a relatively common behaviour, having evolved at least 45 times in bees and employed by 6% of all flowering plants. Buzz pollination offers several fruitful avenues for studying the cognitive ecology of pollination. Although, likely more costly that foraging from pollen using other methods, the impact of the cost of flower handling on decision making by foraging bees is still largely unknown. Also, while we have found that buzz pollinating bees collect more pollen with experience, the manner in which learning shapes buzz-pollination remains elusive. In this quick talk, I will present our results on the cognitive ecology of bumblebees (Bombus terrestris) foraging on a range of Solanum species, examining the costs of this behaviour, as well as our results on the role of learning in modifying how bees buzz flowers.

Phylogenomic insights into the evolution of ponerine ants

Authors: Procopio Camacho Gabriela[1], Blaimer Bonnie[1], Branstetter Michael, Longino John, Fisher Brian and Ward Philip, [1]Museum für Naturkunde, Berlin

Abstract: Among the different methods that use genomic data to study the evolutionary history of recent groups, the ultraconserved elements (UCEs) have proven to be ideal markers for such inferences at different time scales. The taxonomy and internal phylogeny of Formicidae have been extensively studied and have stabilized significantly in the last decades due to the active study of ant systematics on a macroevolutionary scale. The evolutionary history of Ponerinae, however, has never been extensively studied using molecular approaches. Thus, we will use ultraconserved elements to reconstruct the phylogeny of Ponerinae, in order to elucidate the internal relationships in the group, as well as the biogeographic patterns of the genera, and assist in the delimitation of the tribes and genera. For this, we targeted a set of 2,500 UCE loci using target enrichment and multiplexed sequencing of over 1000 species of Ponerinae. Specimens were selected to include nearly all major species groups from all terrestrial biomes, resulting in a comprehensive evolutionary tree of ponerines that will inform revisions of generic boundaries and classification. By combining phylogenetic inference methods with dating and biogeographic analysis, we will provide a phylogenetic framework for the knowledge of the evolutionary history of these ants.

Hidden cuticular microstructures revealed by application of modern microscopy techniques on the compressed fossils and amber inclusions

Authors: Prokop Jakub[1], Rosová Kateřina, Batelka Jan and Pecharová Martina, [1]Charles University, Department of Zoology, Prague, Czech Republic

Abstract: The integumental surface microstructures play a crucial role in the current morphology and taxonomy studies of extant insects / arthropods. However, their proper recognition and visualization on the fossil species often represent obstacle due to preservation of insect exoskeleton in various sedimentary rocks or amber resin. Moreover, the common uniqueness of fossil specimens requires to apply solely non-destructive microscopy techniques. By using environmental electron scanning microscopy on compressed fossils, inverted light or fluorescence microscopy, and confocal laser scanning microscopy applied on various amber inclusions we demonstrated capabilities of these tools on the larval and adult stages of selected insect groups. Our results based on case studies revealed details of the cephalic structures like mouthparts, thoracic structures like legs with specialized pretarsus, wings with sensory organs, and abdominal structures like terminalia, etc. With modern microscopy tools it is possible to enter cuticular microstructures on the Paleozoic and Mesozoic insects much more deeply and elucidate their functional significance. Hence, the efficient application of these modern techniques provides another perspective along the classical microscopy and should be more frequently applied in contemporary studies. This research is a contribution to the project of the Grant Agency of the Czech Republic (No. 21-05216S).

High diversity of the northern sawfly genus Euura (Hymenoptera, Tenthredinidae)

Authors: Prous Marko, University of Oulu, Finland

Abstract: The genus Euura (~650 described species) is the largest genus within subfamily Nematinae and second largest among sawflies (largest is Tenthredo, more than 1000 species) and it shows the strongest pattern of reversed latitudinal gradient in species richness, i.e. becoming more species rich towards higher latitudes and altitudes. Taxonomy of the genus is challenging due to large number of similar species and further complicated by often large within species variation. Frequently, males and females have been wrongly associated. Despite of about 130 new proposed synonymies, about 270 species are recognised in the West Palaearctic. Based on genetic data (at least mitochondrial COI and two nuclear genes), there are about 45 distinct lineages, which are not always clearly different from each other based on female or male morphology (but usually at least one of the sexes shows clear differences from the others). Most of these lineages contain multiple species where mitochondrial DNA barcoding does not allow species identification, while nuclear DNA usually does. Remarkably, about 10% of the specimens harbour multiple mitochondrial variants (heteroplasmy), which can be up to 9% different. Based on current data, species boundaries are entirely unclear in some cases due to remarkable morphological and genetic variation.

Landscape scale ecological networks as a mitigation measure against global insect declines

Authors: Pryke James[1], Roets Francois[1] and Samways Michael[1], [1]Stellenbosch University, South Africa

Abstract: Mammals are globally in decline, with habitat loss a primary driver. How this activity affects functional associations of insects with large mammals, especially across transformed landscapes has received little attention. We assess how well dung beetle diversity tracks large African mammal herbivore diversity across a forestry plantation land use gradient by assessing how dung beetle richness and diversity compares to large mammal diversity and constructing a dung beetle-to-mammal interaction network. Dung beetles responded positively to an array of large mammals than to land use intensity, as they showed a strong preference for specific mammalian dung. Land use intensity categories had distinct mammal and dung beetle assemblages. Transformed areas also have conservation value, provided that there is functional connectivity between remnant vegetation within the modified landscapes. The loss of any native large mammal, especially African elephants, from transformed landscapes is likely to lead to a decline in insects. This suggests that protected areas are essential for the conservation of native insects and its interactions, while well designed and managed transformed areas have additional conservation value. African conservation managers and landowners should be encouraged to maintain a diversity of large mammals on their properties to maintain insect diversity and ultimately ecological resilience.

Complementary and protection value of a Biosphere Reserve buffer zone for increasing local representativeness of ground-living arthropods

Authors: Pryke James[1], van Schalkwyk Julia[1], Samways Michael[1] and Gaigher René[1], [1]Stellenbosch University, South Africa

Abstract: Biosphere reserves (BRs) are areas of high biodiversity value that promote conservation and sustainable development. BRs consist of core, buffer, and transition zones. Buffer zones are where human and ecological activities overlap, and are key functional spaces that can have important complementarity value. We test this using ground-living arthropods in the highly biodiverse Kogelberg Biosphere Reserve in South Africa. We use generalized dissimilarity modelling to describe the compositional dissimilarity of assemblages as a function of environmental correlates between pairs of survey sites. Transformed spatial predictors were used as surrogates for biodiversity to assess complementarity. Important correlates of arthropod species turnover were related to mesoclimate, fire history, and geology. Buffer areas had important complementary value. Current habitat transformation across core and buffer zones does not change this, as results were the same when removing all transformed areas from the analyses. Important areas in buffer zones that increased local representativeness coincided with areas of increased intra-annual temperature variability. Orchards in transformed areas also influenced arthropod diversity in adjacent natural vegetation by <1 km from orchard edges. This edge effect influenced both core and buffer sites due to the lack of a continuous buffer, indicating that the buffer zone is important for protecting the core. As fire management is an important correlate of arthropod turnover here, the complementary value of the buffer zone can have a strong temporal dimension. Given the important complementary value of the buffer zone, conservation management should not be restricted to core areas only, especially when maximising local representativeness.

Benefits of memory use depend upon forage availability in bumblebees

Authors: Pull Christopher[1], Leadbeater Ellouise[3] and Petkova Irina[2], [1]Royal Holloway University of London, United Kingdom, [2]School of Biological Sciences, Royal Holloway University of London Current affiliation: Norwegian University of Life Sciences, Norway, [3]School of Biological Sciences, Royal Holloway University of London, United Kingdom

Abstract: Enormous variation in cognitive abilities is evident within animal populations, yet we currently understand little of the ecological selection pressures that shape the evolution of learning and memory. Here, we capitalize upon the unique tractability of a social insect system to quantify the relationship between cognitive performance and resource availability in the natural environment. We assayed the short, medium and late long-term memory of individual bees from 26 parasite-free colonies in the laboratory, using a radial arm maze (RAM) – a classical psychological apparatus used historically to assess working memory in rodents. Following cognitive testing, colonies were given unrestricted access to the surrounding environment (a university parkland campus), and the lifetime foraging efficiency of each tested worker monitored. We simultaneously surveyed floral resource availability within the bees' foraging range. Using a continuous, staggered design that encompassed the entire foraging season (early spring to late autumn), we were thus able to assess how changes in floral resources affect memory use. In contrast to our expectation that cognitive abilities might be most important when forage availability is low, we found that all bees performed poorly when forage was scant, while the benefits of memory performance emerged in weeks when forage was richest. Our preliminary results are the first to link memory performance with ecological selection pressures, opening the door to a link between environmental complexity and selection on cognitive performance that invites further exploration.

The evolutionary consequences of macronutrient intake in Drosophila melanogaster

Authors: Pum Lee Kwang[1] and Jang Taehwan[1], [1]Department of Agricultural Biotechnology, Seoul National University, South Korea

Abstract: The consumption of macronutrients has profound consequences for fitness and its related traits in insects. While the effects of macronutrient intake on life-history phenotype occurring within a generation are well documented in insects, studies that examine how insects respond to variations in dietary macronutrients across evolutionary time scale are scarce. In this study, we took a laboratory-based experimental evolution approach to study whether and how multiple life-history and physiological traits related to fitness would evolve in response to changes in macronutrient availability and balance in a model insect, Drosophila melanogaster. To this end, we established 36 independent replicated D. melanogaster populations, which were subjected to natural selection under one of six nutrient selection regimes representing all combinations of three yeast-to-sugar ratios (Y:S = 1:4, 1:1 or 4:1) and two yeast plus sugar concentrations (Y+S = 100 or 200 g L-1). After more than 70 generations of selection, D. melanogaster flies from each selection regime were shown to have evolved into distinct metabolic and life-history phenotypes reflecting their adaptations to imbalances in dietary macronutrient composition. Most strikingly, D. melanogaster flies selected under a condition where carbohydrate was severely limited (Y+S = 100 g L-1 with Y:S= 4:1) grew much larger and stored substantially more lipids compared to those selected under the other regimes. Such evolved improvement in energy utilization and storage might have conferred fitness advantages to those flies that had chronically faced energy shortage throughout their selection history. In stark contrast, D. melanogaster flies selected under carbohydrate-rich conditions (Y:S=1:4) had evolved into a lean phenotype, indicating their metabolic adaptation to counteract the adverse consequences of excess fat storage resulting from ingesting too much carbohydrates. To conclude, this study provides insights into the role of macronutrients in driving the evolution of life-history and physiological traits in an insect.

Early Intervention Strategy for spruce budworm: Can we contain outbreak spread?

Authors: Pureswaran Deepa[1], Johns Robert[3], Edwards Sara[4] and Owens Emily[2], [1]Canadian Forest Service, Laurentian Forestry Centre, Quebec, Canada, [2]Natural Resources Canada, Canadian Forest Service, Fredericton, New Brunswick, Canada, [3]Natural Resources Canada, Canadian Forest Service, Fredericton, New Brunswick, Canada, [4]Population Ecology Group, Faculty of Forestry and Environmental Management, University of New Brunswick, Fredericton, NB, Canada; Forest Protection Limited, Canada

Abstract: Spruce budworm (Choristoneura fumiferana Clemens) (Lepidoptera: Tortricidae) is the major defoliating pest of spruce (Picea sp.) and balsam fir (Abies balsamea (L.) Mill) in northeastern North America. The recent resurgence of a budworm outbreak in northeastern North America has rekindled interest and discussion around how best to manage its potential impact across the region.

Early Intervention Strategy (EIS) is an area-wide management program aimed at containing the spread of spruce budworm in Atlantic Canada. In brief, intensive regional monitoring is used to help identify emerging ‘hot spots’ along the leading edge of outbreak, which are then treated with relatively narrow-spectrum insecticides (i.e., Btk or tebufenozide) to slow or prevent further population expansion. Our research represents a large-scale test of the efficacy of the EIS approach and has many key features, including work on population and community ecology, pest monitoring, public outreach, and citizen science (i.e., Budworm Tracker). Results from the first 6 years of this program indicate that under the right conditions the EIS approach has strong potential for containing budworm outbreaks with minimal impacts on non-target species

Spruce budworm disturbance ecology – what does this outbreak tell us?

Authors: Pureswaran Deepa[2], De Grandpré Louis[1] and Bourassa Stephane[1], [1]Canadian Forest Service, Canada, [2]Canadian Forest Service, Laurentian Forestry Centre, Quebec, Canada

Abstract: Spruce budworm outbreaks cause large scale damage to Canada’s boreal forest. The current outbreak started further north compared to past outbreaks, in regions where trees have not co-evolved with this disturbance. We are measuring spruce budworm population dynamics and measuring ecosystem impacts from the outbreak foci to the expanding northern front of its range.

In addition to permanent plots that we have been sampling since 2006, we have established a transect that runs 600 km north of Baie-Comeau, the northern most parts of which extend beyond provincial aerial survey routes. In 2018, moth captures averaged over 4500 at our northern-most site (km 568), however, there were no L2s nor L4s observed on sampled branches. Defoliation was estimated to be below 10% on both spruce and fir. The southern most sites (e.g. km 237) had medium defoliation on black spruce and high defoliation on balsam fir with an average of 20 L4 per branch and 3300 moths captured in pheromone traps. Moths are dispersing significantly north, but are not yet contributing significantly to population growth nor defoliation. We are examining the processes and patterns of disturbance in this northern boreal ecosystem to better understand the impacts due to climate change.

A conceptual framework for the spruce budworm Early Intervention Strategy: can outbreaks be stopped?

Authors: Pureswaran Deepa[3], Johns Robert[5], Bowden Joe[1], Edwards Sara[7], James Patrick[10], Cooke Barry[2], Richard Brigitte[2], Norfolk Chris[6], Kneeshaw Dan[8], Quiring Dan[9], MacLean David[9], Carleton Drew[6], Owens Emily[5], Moise Eric[1], Emilson Erik[2], Mott Gordon[4], Régnière Jacques[2] and Stastny Michael[2], [1]Canadian Forest Service, Atlantic Forestry Centre, Corner Brook, Memorial University (Grenfell Campus), School of Science and Environment, Corner Br, Canada, [2]Canadian Forest Service, Canada, [3]Canadian Forest Service, Laurentian Forestry Centre, Quebec, Canada, [4]Maine, United States, [5]Natural Resources Canada, Canadian Forest Service, Fredericton, New Brunswick, Canada, [6]NB DNR, Canada, [7]Population Ecology Group, Faculty of Forestry and Environmental Management, University of New Brunswick, Fredericton, NB, Canada; Forest Protection Limited, Canada, [8]University of Montreal, Canada, [9]University of New Brunswick, Canada, [10]University of Toronto, Canada

Abstract: The spruce budworm, Choristoneura fumiferana, Clem., is the most significant defoliating pest of boreal balsam fir (Abies balsamea [L.] Mill.) and spruce (Picea sp.) in North America. Historically, spruce budworm outbreaks have been managed via a reactive, foliage protection approach focused on keeping trees alive rather than stopping the outbreak. However, recent theoretical and technical advances have renewed interest in proactive population control to reduce outbreak spread and magnitude, i.e., the Early Intervention Strategy (EIS). In essence, EIS is an area-wide management program premised on detecting and controlling rising spruce budworm populations (hotspots) along the leading edge of an outbreak. In this article, we lay out the conceptual framework for EIS, including all of the core components needed for such a program to be viable. We outline the competing hypotheses of spruce budworm population dynamics and discuss their implications for how we manage outbreaks. We also discuss the practical needs for such a program to be successful (e.g., hotspot monitoring, population control, and cost-benefit analyses), as well as the importance of proactive communications with stakeholders.

Circadian control of synaptic plasticity in the fly's visual system

Authors: Pyza Elzbieta[3], Jasinska Malgorzata[2], Damulewicz Milena[1] and Woznicka Olga[1], [1]Department of Cell Biology and Imaging, Institute of Zoology and Biomedical Research, Jagiellonian University, Krakow, Poland, [2]Department of Histology, Jagiellonian University Medical College, Krakow, Poland, [3]Institute of Zoology and Biomedical Research, Jagiellonian University, Poland

Abstract: Circadian clocks generate circadian rhythms in various processes, including synaptic plasticity in the brain. In the visual system of Drosophila melanogaster, the number of synapses and synaptic protein levels oscillate during the day and night. One type of synaptic contact, tetrad synapses, which form between the retina photoreceptor terminals and their post-synaptic partners in the first optic neuropil (lamina), increases in frequency at the beginning of both the day and night.
In the present study, we examined at high resolution the ultrastructure of tetrad presynaptic elements at different times during the day, particularly during the morning peak of locomotor activity, and during sleep at night using transmission electron microscopy (TEM). We reconstructed the cytomatrix called the T-bar and synaptic vesicles from TEM serial sections of the lamina using the TEM tomography method. The study was carried out using wild-type Canton S flies, flies with BRP170 or BRP190 mutations of the main cytomatrix scaffolding protein Bruchpilot (BRP), and cry01 null mutants that do not synthesize the CRYPTOCHROM (CRY) protein. We found that the number of synaptic vesicles, both translucent and dense, in tetrad presynaptic sites is similar during the morning peak of activity (ZT1) and during sleep (ZT16); however, the number of tetrad synapses is lower at ZT16, but their T-bar platform is larger at ZT16 than at ZT1. In brp?170 and cry01 flies, there were fewer vesicles than in Canton S at ZT1, but the same number was observed during the night (ZT16). As a result, day/night changes in the number of synaptic vesicles were larger in both mutants than in Canton S. A daily rhythm was not observed; however, in brp?190 and in the case of this mutant, the number of synaptic vesicles was similar to Canton S at ZT1. This pattern was observed for all vesicles, translucent and dense, but in the case of dense vesicles, their number was smaller or the same in Canton S relative to mutants at ZT1 and ZT16. Moreover, we found that the morphology of the T-bar changes during the day and night in Canton S, but this rhythm was not observed in all mutants studied. The obtained results also indicate that the CRY protein is crucial for maintaining the appropriate number of synaptic vesicles and morphological plasticity of the presynaptic T-bar during activity and the sleep cycle.

Pollination for oilseed rape employed by Chrysomya megacephala after cold acclimation

Authors: Qi Xuewei[1], Niu Changying[1], [1]Hubei Key Laboratory of Insect Resource Application and Sustainable Pest Control, College of Plant Science & Technology, Huazhong Agricultural University, Wuhan

Abstract: With the agricultural ecological intensification, pollination services are declining in landscapes with field and semi-natural habitats, especially in the early spring when few pollinators are available in nature. In this study, we used Chrysomya megacephala to replace honeybee to pollinate for important crop oilseed rape, Brassica napus. Firstly, we carried out the developmental cold acclimation (DCA) to offset the phenological mismatch of oilseed rape and C. megacephala, which increased significantly the cold tolerance of the flies. Fruit setting rate (FSR) was improved by employing C. megacephala treated by DCA. Secondly, field cage experiment showed that C. megacephala had a good ability to visit flowers and carry pollen in oilseed rape. Although FSR of oilseed rape employed C. megacephala was lower than that of Apis cerana cerana, there was no significant difference of pod length and seed number per pod for oilseed rape pollinated by two insect pollinators. Overall, C. megacephala has great potential to pollinate for crops and DCA improves the thermal adaptability of C. megacephala towards crops. Our results provide an effective pollinator alternative to the honeybees for pollination of facility agriculture crops as well as early spring wild crops.

Inheritance and fitness cost of triflumezopyrim resistance in the brown planthopper, Nilaparvata lugens

Authors: Qin Yao, College of Plant Science and Technology, Huazhong Agricultural University, China

Abstract: Nilaparvata lugens (Stål) (Hemiptera: Delphacidae) is an important agricultural insect pest all around the world due to its serious damage to rice plants. Triflumezopyrim, a novel commercialized mesoionic chemical insecticide, functions by inhibiting the orthosteric binding site of nAChRs and makes insects lethargic, poisoning them by competitive binding to the orthotopic site of nAChRs. Here, a laboratory triflumezopyrim-resistant strain (TR) and an isogenic susceptible strain (TS) were established to characterize the inheritance and fitness costs of triflumezopyrim resistance in N. lugens. The LC50 values from progenies (F1RS and F1SR) of reciprocal crosses between TR and TS strains suggested that triflumezopyrim resistance in N. lugens was autosomal and codominant. The chi-square analyses of self-bred and backcrossed progenies suggested that the resistance results from a polygenic effect. Compared to the TS strain, the TR strain exhibited a relative fitness of 0.62 with a significantly decreased female adult period, longevity, total fecundity, egg hatchability, intrinsic rate of increase (r), finite rate of increase (λ), net reproductive rate (R0), and prolonged pre-adult period and total preoviposition period (TPOP). The current study provides valuable information for optimizing resistance management strategies to delay triflumezopyrim resistance development and maintain sustainable control of N. lugens.

Volatile mediated tritrophic interactions determine behavioral changes in the pest mite B. yothersii (Acari: Tenuipalpidae), in presence of the predator E. concordis (Acari: Phytoseiidae), in citrus.

Authors: Queiroz Maria Cristina Vitelli[1] and Sato Mario Eidi[1], [1]Instituto Biológico de São Paulo

Abstract: Mites of the genus Brevipalpus (Acari: Tenuipalpidae) have economic importance because they are vectors of viruses in several cultures, especially CiLV-C (Citrus leprosis virus C), transmitted by the species B. yothersi. Volatile organic compounds (VOCs) associated with arthropods seem to be involved in inducing the anti-predator response. Experiments were carried out using orange leaves, without symptoms of virus, consisting of 3 treatments: T1) Without previous exposure to any mite species (control); T2) Previous exposure to the pest mite B. yothersi for 24h; T3) Previous exposure to B. yothersi and the predatory mite Euseius concordis (Acari: Phytoseiidae) for 24h. VOCs were collected in passive mode and the profile of compounds was determined by GC-MS. The results showed that the average movement time in T3 was longer than in the 2 previous treatments. The presence of acetic acid, benzene and toluene was identified in all 3 treatments, which could be characteristic of the plant. Compounds present in treatments T2 and T3 (benzoic acid, coumarin and vanillin), were probably released by the pest or by the plant in response to the attack; and compounds present only in T3 (ethanol, N-benzylidene-dimethylammonium chloride), are likely signs of the predator's presence.

Short-term spatial niche partitioning between the larger grain borer and the maize weevil: do semiochemicals play a role?

Authors: Quellhorst Hannah[3], Zhu Kun Yan[2], Morrison William[4] and Kim Tania[1], [1]Department of Entomology, Kansas State University, United States, [2]Kansas State University, [3]Kansas State University, United States, [4]USDA-ARS

Abstract: Prostephanus truncatus (Horn), the larger grain borer, is endemic to southern North America and Central America, but invaded Africa with severe economic consequences for maize and cassava production. Its main competitor is the cosmopolitan Sitophilus zeamais (Motschulsky), the maize weevil. While competition between these two species has been studied extensively, there is little information on spatial partitioning in bulk storage of grain. Thus, our aims were to evaluate the short-term niche partitioning behavior of P. truncatus and S. zeamais when placed in a monolayer column of grain. The monolayers were divided into 24 equally-sized vertical and horizontal zones to track location of the insects on maize in each zone. After one and then seven days, monolayers were placed on their side, and the grain and insects from each zone were removed. We found that both species generally aggregated together and preferred the bottom of the grain mass. To determine whether semiochemicals played a role, volatiles were collected from maize with P. truncatus, S. zeamais, or both species using headspace collection and gas chromatography coupled with mass spectrometry. Then, preference was evaluated in a 4-way olfactometer among the stimuli. We found maize volatiles were important for orientation of P. truncatus, but not S. zeamais, suggesting a confluence of factors other than volatile semiochemicals may lead both species to choose the bottom of the grain column. These data may help improve targeting of pest control tactics by identifying the position of these insects in the grain mass.

Ecology of wild bee’s pollination in agricultural landscapes: a pollen DNA approach

Authors: Querejeta Marina[2], Marchal Lorène[2], Pfeiffer Paul[2], Gaba Sabrina[1], Bretagnole Vincent[1] and Boyer Stéphane[2], [1]Centre d’Etudes Biologiques de Chizé (CEBC), Villiers-en-Bois, France, [2]Institut de Recherche sur la Biologie de l’Insecte (IRBI), Tours, France

Abstract: Wild pollinators, play an essential role in agricultural landscapes with up to 80% of all crops being pollinator dependant. However, many insect populations face declines, and even extinction in the coming decades due to intensive agriculture and, specifically, the use of chemical pesticides. One potential solution to decrease the negative impacts of intensive agriculture is ecological intensification, which relies on ecological processes to maintain or increase crop yield. For such strategy to work, a better understanding of the functioning of crop ecosystems is needed. In this work, we aimed to describe the pollination activity of wild bees in sunflower crops in Chizé (France). Pollen grains were collected from wild bees using a washing protocol and plant DNA was amplified to prepare metabarcoding library, which was sequenced using Illumina MiSeq. Our analysis identified the most commonly visited plants families as Asteraceae and Brassicaceae. We found significant differences in relation to the type of agriculture (organic / conventional), the developmental stage of the crop (pre-flowering / flowering), bees’ body size and, also, their level of sociality. This study provides valuable information about which floral resources are needed in agroecosystems for wild bees to survive, and what parameters may influence their pollination pattern.

Management of adult and immature large pine weevil (Hylobius abietis L.) using novel local-provenance entomopathogenic fungi and nematodes on different soil types.

Authors: Quinzo-Ortega Luis Miguel, Liverpool John Moores University, United Kingdom

Abstract: The large pine weevil (LPW) is a widespread forest pest in conifer clearfell restocking areas. Biological control agents are the best candidates to replace widely used synthetic chemicals with potential side effects on the environment and humans. Entomopathogenic nematodes (EPN) and fungi (EPF) are successful at controlling its immature stages and also present additive effects when applied together to tree stumps. We propose a new approach that also targets the adults that survived the control of immatures. Surviving emerging adults will be lured with volatiles like alpha-pinene to traps containing an EPF. A large-scale soil sampling campaign within various habitats has provided new locally sourced EPF to be used together with commercial EPN strains. High diversity of EPFs has been obtained from soil using a dual baiting method with larvae of Galleria mellonella (Lepidoptera) and Tenebrio molitor (Coleoptera). The local strains of EPF are tested for pathogenicity on LPW to select the best entomopathogenic agent for adult traps and to study their additive/synergistic effects with commercial EPN. To test the efficacy of the approach in the field, mark-recapture experiments will be conducted, which will inform the development of an efficient chemical-free method to control H. abietis on forest clearfell areas.

Conservation and augmentation of ladybeetles for management of Asian citrus psyllid vector of huanglongbing, a devastating disease if multi-billion dollar citrus industry

Authors: Qureshi Jawwad, University of Florida, Department of Entomology and Nematology, Southwest Florida Research and Education Center, Immokalee, Florida, United States

Abstract: Huanglongbing (HLB) or citrus greening disease caused by the phloem-restricted bacteria Candidatus Liberibacter asiaticus (CLas), is transmitted by the Asian citrus psyllid (ACP) Diaphorina citri. Control of the ACP is critical for area-wide management of this vector-disease complex and sustainable citrus production. Ladybeetles are an important component of biological control of ACP. In experiments using 17 generations of ACP under field environment, we observed more than 90% mortality of its populations from biological control mainly ladybeetles. However, foliar sprays of insecticides particularly during growing season when biological control is common significantly reduce the populations of ladybeetles and other predator species. Insecticidal control is most effective when ACP adults are few and other life stages largely absent due to lack of foliar flush, mainly because the insect needs newly developing leaf tissues for oviposition. This opportunity occurs during winter months when trees go through dormancy and do not produce new growth which is needed by the ACP for reproduction, so overwintering adults of ACP are common waiting for the new growth to begin in spring. In large-scale field studies, we showed that limiting the use of broad-spectrum insecticides such as organophosphates and pyrethroids to dormant winter months provides significant suppression in ACP populations lasting into growing season thus effective for integrated management of ACP. Ladybeetles were common during the growing season in blocks treated or not with broad-spectrum insecticide during dormant winter months. This suggest that reduced use of insecticides during growing season help conserve populations of ladybeetles whereas their use during dormant winter months is less damaging because most beneficial insects leave groves as most mature trees go through dormancy not producing the new growth thus limiting psyllid reproduction and ultimately prey for the natural enemies. Studies using commercial predators have shown significant role of additional predator species to enhance vector control. Conservation and augmentation of ladybeetles for ACP control will be discussed.

The Farmers Application and Quality Control Analysis of Biological Control Agents Product in East Java, Indonesia

Authors: Rachmawati Rina[1] and Himawan Toto[1], [1]Plant Protection Department, Faculty of Agriculture, Brawijaya University, Malang, Indonesia

Abstract: Biological Agents Postal Service (PPAH) is an institution that performs production and develops biological agent in small-scale farmers group in Indonesia. They are monitored and managed directly by government institution namely the Pest and Food Crops and Horticulture Observers Laboratory (LPHPTPH). Biological agents products have been developed by PPAH and distributed among farmers. However, there are reports of problems regarding the production process, quality control, and the use of biological agents on several cities in East Java, Indonesia. The feasibility of biological agent products is determined through quality control, and the quality control activities conducted by several PPAH do not have clear standards and affects the quality of biological agent products. This study aims to investigate the use of biological agents conducted by farmers and to evaluate the quality control held by PPAH and LPHPTPH, in East Java, Indonesia.

This study took place in five cities around East Java, namely Blitar, Lamongan, Madiun, Malang and Pamekasan. Four PPAH in each cities have been selected as object to review in accordance to LPHPTPH recommendation. Using a qualitative method made by observation research and interviews with respondents who were determined to obtain descriptive data, respondents were selected using non-probability sampling and snowball technique. During the observation, product sampling of biological agents were collected to Biological Control Laboratory, Plant Protection Department, Brawijaya University in order to obtain information about product description and quality of biological agent product including the density of spores, viability, and pathogenic bacteria test on quality assay as safely indicator of biological agents product. The data then were analysed descriptively, the interviews and observations data were rated and assessed accordingly.

PPAH-guided farmers have been successfully using biological agents to deal with pests and plant diseases in great measure. The type of biological agent that is widely used by farmers are varied among cities. In the use of biological agents, farmers in those five cities generally have been able to apply the biopesticide to some extent. Although in several cases, farmers have been utilizing biological agents and chemical pesticide simultaneously; 85% in Madiun, 62,5% in Blitar, 17,25% in Malang, and 16% in Lamongan.

The quality control of biological agents produced by several PPAH in East Java are varies. In Pamekasan, the value of the assesment can be classified as good, ranged at 73.3. In Malang, Blitar, and Lamongan, the assesment ranged at 54.2, 53.5, and 46,5 respectively which classified as adequately good. The assesment in Madiun however, only ranged at 38 and classified as not good. Only two types of biological agents in Pamekasan matched the product packaging label while the presence of contamination are also showing, namely Escherichia coli and Salmonella sp.

Climate change associated water stress and aphid herbivory interactively reduce faba bean yield while the insect pollination benefit is conserved

Authors: Raderschall Chloë A.[2], Taylor Astrid R.[3], Lundin Ola[2], Vico Giulia[1] and Bommarco Riccardo[2], [1]Department of Crop Production Ecology, Swedish University of Agricultural Sciences, Sweden, [2]Department of Ecology, Swedish University of Agricultural Sciences, Sweden, [3]Swedish University of Agricultural Sciences

Abstract: Extreme weather events, such as prolonged dry spells, are hampering crop production and are expected to occur more frequently and become more severe under climate change. In addition, warmer temperatures will increase herbivory due to more abundant insect pests. Consequently, crop production will be increasingly impacted by both abiotic and biotic climate change stressors. While such climate change stressors can cause extensive yield losses, crop yields also benefit from a suite of ecosystem services such as insect pollination, which might mitigate yield losses. Despite the importance of understanding how interactions among climate change associated stressors and ecosystem services affect crop yield, most examinations concern benefits of single ecosystem services in isolation under favourable plant growing conditions. We experimentally tested the single and interactive effects of water stress, insect herbivory and insect pollination on faba bean yield. To this aim, we used 24 rainout shelters that allowed us to simulate a period of precipitation deficit in line with climate change scenarios. Half of the plots were subjected to no water input for 46 days, while the other half was irrigated thrice per week replenishing losses via evapotranspiration, to sustain well-watered conditions. To create two levels of insect pollination, we supplemented half of the cages of each water treatment with buff-tailed bumble bee hives (Bombus terrestris). To create two levels of herbivory, a subset of plants in each plot was inoculated with black bean aphids. We found that water stress and aphid herbivory interactively reduced yield by 84% while insect pollination increased yield by 68% irrespective of water stress and insect herbivory. Our results suggest that water withdrawal for irrigation should be prioritised in crop fields with high levels of herbivore control.

Entomological mosquito surveillance for West Nile, Usutu virus and Dirofilaria spp. in Apulia region (Southern Italy) (2021)

Authors: Raele Donato Antonio[1], Vasco Ilaria[1], Marino Leonardo[1] and Cafiero Maria Assunta[1], [1]Istituto Zooprofilattico Sperimentale di Puglia e Basilicata

Abstract: The entomological survey is a fundamental action of the national surveillance plan of arboviruses (PNA, 2020-2025) at a level region to prevent risk of pathogen transmission by arthropods, including mosquitoes species. This work reports the results obtained in Apulia region in 2021 year. Adult mosquitoes were captured in areas at risk by CDC and BG-sentinel. After morphological/molecular identification, mosquito pools were prepared and tested for WND and Usutu virus, Dirofilaria (D.) repens, D. immitis by qPCR. A total of 4751 (4432 F, 319 M) mosquitoes from 8 genera and 15 species (Aedes albopictus, Ae.vexans, Anopheles algeriensis, An. maculipennis s.l. (= An.labranchiae), Coquillettidia richardii, Culex (Cx) modestus, Cx,pipiens, Cx. theileri, Culiseta (Cul.) annulata, Cul.longiareolata, Ochlerotatus (Ochl) caspius, Ochl. communis, Ochl. detritus, Orthopodomyia pulcripalpis, Uranotaenia unguiculata) were collected from 13 stations for a total of 488 capture sessions. All of 445 tested pools resulted negative for viruses; D. repens DNA was detected in 3 (3/445) pools from Cx. pipiens, Ochl. caspius and D. immitis DNA was identified in 5 (5/445) pools in Ochl. caspius, Ae. Albopictus and Cx. pipiens. Our results show the presence of mosquito species capable to be vectors of a variety of human pathogens and suggest to increase monitoring.

Evolution and function of tick endosymbionts

Authors: Raghavan Rahul, Portland State University, United States

Abstract: Ticks feed only on vertebrate blood. Hence, symbiotic bacteria likely provide the nutrients not present in blood—as has been observed in blood-feeding insects. Two common putative nutritional symbionts in ticks are Coxiella-like and Francisella-like endosymbionts (CLEs and FLEs). Both symbionts evolved from pathogenic ancestors and have lost the genes that likely made their ancestors virulent. Independent evolution of nutrient-provisioning endosymbionts from pathogenic bacteria in multiple lineages of ticks indicate that this process occurs efficiently in ticks. Rapid attenuation of virulence, and the ability of bacteria to invade ovaries and salivary glands that facilitate tick-to-tick transfer could contribute to this speedy transformation. Interestingly, unlike insects, most tick lineages do not form long-term symbiotic partnerships with a specific bacterium. For example, some species of Amblyomma (hard ticks) have CLEs, whereas others have FLEs as their primary endosymbionts. Similarly, even though FLEs are the primary endosymbionts in Ornithodoros moubata and Argas persicus (both soft ticks), each tick acquired their respective FLE independently from disparate sources. This apparent lack of selection pressure to maintain long-term symbionts suggest that ticks have ready access to a large pool of bacteria—probably pathogens encountered in vertebrate blood, that could easily be domesticated into nutrient-provisioning endosymbionts. Long-term bacterial endosymbionts tend to become inefficient provisioners of critical nutrients due to genome degradation caused by genetic drift. Ticks might be able to avoid this fate by frequently replacing old symbionts with new bacteria that have enhanced metabolic capabilities.

Current models of diapause and quiescence, with some examples from bark beetles

Authors: Ragland Gregory, University of Colorado-Denver, United States

Abstract: Overwintering insects use a startlingly wide array of physiological and developmental strategies to appropriately time their seasonal windows of growth and reproduction. In this talk I will provide a brief review of our current understanding of stereotypical ‘types’ of overwintering that has been refined through the liberal application of ‘omics approaches over the last decade. In addition, I will address how genetic and environmental variation influence the flexibility of these ‘types’, including some current findings from bark beetles.

Divergence between populations and strong local adaptation may limit adaptive response to climate change with cascading effects on the community

Authors: Ragland Gregory[2], Lackey Alycia[1], Hahn Dan[3], Feder Jeffery[4] and Powell Thomas[1], [1]Binghamton University, United States, [2]University of Colorado-Denver, United States, [3]University of Florida, United States, [4]University of Notre Dame, United States

Abstract: Consequences of a population’s evolutionary response to climate change are not limited to extinction or survival of the focal population. Rather, phenotypic shifts in one species can ripple out to affect coevolved species in the community. We measured the response to climate change in ecologically divergent populations of Rhagoletis pomonella and the cascading effects on their wasp parasitoids. Fly life cycles are synchronized with host fruit availability via regulation of diapause (dormancy). Adaptation to different host plants with different phenologies drives divergence between fly populations. Parasitoids of these fly populations have also diverged in kind, yielding a cascade of diversification. We experimentally tested the response to increased temperature of two sympatric, recently diverged (~150 generations) fly populations that infest different host plants (hawthorns and apples) and their associated parasitoid communities. We measured survival and phenology for fly and wasp populations in control or warmed (+3 degC) temperature treatments that matched daily, natural fluctuations of the sampling site. Our design allows us to parse three different responses: survivorship within populations, phenological synchrony across trophic levels, and changes to allochronic (temporal) isolation between divergent populations. The effects of increasing temperature differed markedly between populations. Apple flies suffered high mortality before breeding and are likely near their physiological temperature threshold for diapause development. Flies of both populations shifted their life cycles significantly earlier under warmed temperature regimes. However, parasitoid wasps did not shift their life cycles in response to temperature, which would cause asynchrony across trophic levels. Lastly, shifts in fly life cycles will increase the overlap in breeding seasons of the two populations, dramatically increasing potential gene flow and limiting further divergence. Given the wide-ranging importance of phenology and potential for strong local adaptation, high-confidence predictions of responses to climate change will require similar experiments that determine environmental thresholds.

Mapping spatial distribution, identifying risk factors and predicting the abundance of dengue vector Aedes aegypti in northeastern Thailand

Authors: Rahman MD Siddikur[1], Overgaard Hans J[2], [1]Department of Medical Microbiology, Faculty of Medicine, Khon Kaen Univeristy, Thailand, [2]Norwegian University of Life Sciences, Norway

Abstract: Aedes aegypti is the main vector of dengue globally. The variables that influence the abundance of dengue vectors are numerous and complex. To help guide and improve vector-control efforts, this study identified and predicted the ecological, social, and other environmental risk factors that affect the abundance of adult females and immature Ae. aegypti in households in urban and rural areas of northeastern Thailand.

A total of 128 cohort households were mapped and a cross-sectional entomological survey was conducted in urban and rural areas near or along the Mekong River in north-eastern Thailand between January and December 2019. Information on the socio-demographic; self-reported prior dengue infections; housing conditions; durable asset ownership; water management; characteristics of water containers; knowledge, attitudes, and practices (KAP) regarding climate change and dengue; and climate data were collected. Negative binomial generalized linear models (GLMs) were fitted to identify the risk factors associated with the abundance of adult females and immature Ae. aegypti. Five popular supervised learning models, logistic regression (LR), support vector machine (SVM), k-nearest neighbor (kNN), artificial neural network (ANN), and random forest (RF), were used to predict female adult Ae. aegypti abundance (high/low). Urban areas had a higher abundance of female adult Ae. aegypti compared to rural areas. Overall, study respondents in both urban and rural areas had inadequate KAP regarding climate change and dengue. The fitted GLM showed a higher abundance of adult female Ae. aegypti was significantly ($p < 0.05$) associated with many factors, such as a low education level of household respondents, crowded households, poor premise conditions, surrounding house density, bathrooms located indoors, unscreened windows, high numbers of wet containers, a lack of adult control, prior dengue infections, poor climate change adaptation, dengue, and vector-related practices. Among all assessed models, RF showed the best prediction performance for female adult Ae. aegypti abundance. The identified risk factors are important for the critical first step toward developing routine Aedes surveillance and reliable early warning systems for effective dengue and other mosquito-borne disease prevention and control strategies at the household and community levels in this region and similar settings elsewhere.

Cross talk of juvenile hormone, ecdysone and insulins in regulation of mosquito metabolism

Authors: Raikhel Alexander[1] and Ling Lin[1], [1]University of California Riverside, United States

Abstract: Being the principal vector for dengue, yellow fever, chikungunya virus and recently Zika virus, the mosquito Aedes aegypti is an extremely important organism for investigation. Many unique physiological features contribute to the incredible evolutionary success of mosquitoes, placing high energy demands on a reproducing female mosquito. Therefore, metabolism must be synchronized with these needs. We have shown that the developmental hormones, juvenile hormone and 20-hydroxyecdysone, acting through their respective receptors, Methoprene-tolerant (Met) and Ecdysone Receptor (EcR), function as regulatory switches for synchronization of metabolic events with the energy requirements of a female mosquito. Met controls downregulation of metabolic genes during the previtellogenic phase, while EcR - their upregulation during the post-blood meal, vitellogenic phase of the reproductive cycle. Insulin-like peptides (ILPs) are important regulators of metabolism in insects. CRISPR-Cas9 disruption of the mosquito ilp6 and ilp2 genes resulted in reduced body size and decreased lipid accumulation, while CRISPR-Cas9 ilp5 interference had the opposite effect increasing body size and significantly elevating lipid stores. JH/Met and 20E/EcR signals act antagonistically on the expression of ilp6 and ilp5. The EMSA and Chip assays have shown direct binding of Met and the 20E downstream factor, E74, to the regulatory region of ilp6 gene. Moreover, CRISPR-Cas9 assisted labeling of FOXO has permitted us to visualize the differential effect of Met and its downstream factor Kruppel homolog 1 as well as EcR/E74 on a subcellular localization of the downstream insulin pathway factor, FoxO. In turn, FoxO was involved in regulation of metabolic genes; the Chip analysis has demonstrated direct binding to its conserved motifs in promoters of these genes. Thus, ILPs interact with JH and 20E hormones coordinating metabolic genes to determine the exact status of metabolism and development. This study advances significantly our understanding of mechanisms governing a metabolic program in female mosquitoes.

Post-eclosion temperature effects on insect cuticular hydrocarbon profiles

Authors: Rajpurohit Subhash, Ahmedabad University, India

Abstract: The insect cuticle is the interface between internal homeostasis and the often harsh external environment. Cuticular hydrocarbons (CHCs) are key constituents of this hard cuticle and are associated with a variety of functions including stress response and communication. CHC production and deposition on the insect cuticle vary among natural populations and are affected by developmental temperature; however, little is known about CHC plasticity in response to the environment experienced following eclosion, during which time the insect cuticle undergoes several crucial changes. We targeted this crucial phase and studied post-eclosion temperature effects on CHC profiles in two natural populations of Drosophila melanogaster. A forty-eight hour post-eclosion exposure to three different temperatures (18, 25, & 30 °C) significantly affected CHCs in both ancestral African and more recently derived North American populations of D. melanogaster. A clear shift from shorter to longer CHCs chain-length was observed with increasing temperature, and the effects of post-eclosion temperature varied across populations and between sexes. Overall, our results demonstrate strong genetic and plasticity effects in CHC profiles in response to environmental temperatures experienced at the adult stage as well as associations with desiccation tolerance, which is crucial in understanding holometabolan responses to stress.

Emerging challenges of invasive whiteflies (Hemiptera: Aleyrodidae) in trees of India

Authors: Ramachandran Sundararaj, Forest Protection Division, Institute of Wood Science and Technology, Malleswaram, Bangalore, Karnataka, India

Abstract: The enormous increase in the volume, diversity and swiftness of movement of plant products throughout the world has led to a proliferation and dissemination of invasive species, particularly ones closely associated with plants, such as scales and whiteflies. Such biological invasions are a great concern as they have a pronounced impact on the native ecosystem, biodiversity, and the economy. More than 110 exotic insect species had been reported from India, of which, whiteflies and mealybugs constitute a major part of the invasion. Most alien species of whiteflies are accidentally introduced with their host plant due to their small size and cryptic nature of their and immature stages being attached to the host-plant. Due to these characteristics, they are one of the most commonly transported and most successful arthropod groups invading new geographical areas. Moreover, exotic whitefly pests can multiply in large proportion in a short time and with their high phenotypic plasticity and strong potential compete with native species and cause damage to economically important crop plants. The spiralling whitefly Aleurodicus dispersus Russell which invaded about 25 years back has been reported on over 320 plant species belonging to 225 genera and 73 families in India including economically important tree species. Recently there was a surge of invasion of whiteflies in India as within a span of last five years, seven species of whiteflies viz., solanum whitefly, Aleurotrachalus trachoides (Back) infesting on 37 plant species; rugose spiraling whitefly, Aleurodicus rugioperculatus Martin on 40 host plants; nesting whiteflies, Paraleurodes bondari Peracchi on 34 host plants and P. minei ?accarino on 25 host plants; legume feeding whitefly, Tetraleurodes acaciae (Quaintance) on 2 host plants; palm infesting whitefly, Aleurotrachelus atratus Hempel on 3 host plants and woolly whitefly, Aleurothrixus floccosus (Maskell) infesting guava. Extensive surveys revealed that all the invasive whiteflies of India except A.floccosus were found infesting severely on important tree species, like Acacia auriculiformis, Bauhinia variegata, Ficus spp., Leucena leucocephala, Pongamia pinnata, Magnolia champaca, Morinda citrifolia, Saraca asoca, Samanea saman, Syzygium cumini, Syzygium jambos, Tectona grandis, Terminalia arjuna, Thespesia populnea, Santalum album, Vitex altissima, etc., They are also found infesting many medicinal plants and expanding their range of distribution. This communication describes the emerging threat of invasive whiteflies on important tree species of India and the need to develop preventive measures to contain the spread of these invasive species.

Development and piloting of sustainable pest management strategies in vegetable production systems in South- and Southeast Asia

Authors: Ramasamy Srinivasan, World Vegetable Center, Taiwan

Abstract: Vegetables are cultivated in 42.44 million ha with an annual production of 0.88 billion tons in Asia, but the productivity (20.72 t/ha) is far below the North America (34.39 t/ha) and Europe (26.25 t/ha). One of the major constraints is the pests and diseases, including invasive species, which have been exacerbated by climate change. They can lead to complete crop failures if timely control measures are not initiated. In order to produce blemish-free vegetables that would fetch higher market prices and to avoid serious economic losses, farmers in Asia predominantly rely on chemical pesticides. Calendar-based application of pesticide cocktails (mixture of 3-4 pesticides) is common. Indiscriminate pesticide use escalates the production costs and poses serious threats to human and environmental health. Hence, it has become highly imperative to develop alternatives. World Vegetable Center has developed and piloted integrated pest management (IPM) packages through farmer participatory approaches for tomato, yard-long bean and leafy brassicas. The IPM packages are composed of sequential application of bio-pesticides, which were on par with Farmers' practice (calendar-based pesticide application) in reducing the pest infestations, without compromising yield. Hence, the IPM packages provide sustainable solutions for managing key pests on vegetable crops in South- and Southeast Asia.

Maintenance of flower color polymorphism in Lupinus polyphyllus and modification of pollinator mediated selection by abiotic conditions

Authors: Ramula Satu, University of Turku, Finland

Abstract: Variation in flower color within species is commonly thought to be caused by variation in pollinator-mediated selection. However, abiotic factors can modify selection caused by pollinators and contribute to the maintenance of this polymorphism in nature. Lupinus polyphyllus (Fabaceae) is a short-lived perennial outcrossing herb that has large showy racemens with multiple flowers. The species has a color polymorphism with blue, red and white flowers. Blue flowers are typically most common but the proportions of the different color morphs vary between populations. The main pollinators are bumble bees (Bombus sp.), that have species specific innate preferences for the different color morphs, but interestingly their preferences are also affected by ambient temperature in this system. Abiotic conditions thus have the potential to modify pollinator-mediated selection on flower color in L. polyphyllus. In this research we study populations along a latitudinal gradient from south of Finland to the species northern range edge in central Finland that differ substantially in temperature and early growing season light conditions. We combine data from pollinator observations, long term climatic conditions and population genetics to addresses the question of how pollinator community composition, pollinator behavior and abiotic factors synergistically affect the maintenance of color polymorphism in this species.

Association between Host Tree Chemistry and Ambrosia Beetle Host Selection Behavior

Authors: Ranger Christopher, USDA, United States

Abstract: Ambrosia beetles are among the true fungus farming insects, whereby they cultivate fungal gardens within host trees on which the larvae and adults must feed to obtain nourishment. Ethanol is emitted from trees in response to a variety of physiological stressors, and acts as a strong attractant for ambrosia beetles seeking a host tree. Despite the antimicrobial activity of ethanol, ambrosia beetles specifically select host trees tissues containing ethanol for establishing their fungal gardens and producing offspring. Our objective was to assess the influence of ethanol on the colonization success of Xylosandrus germanus and its associated fungal symbiont. Attacks were induced by X. germanus and other species by baiting healthy trees with ethanol lures, but none of the foundresses established fungal gardens or produced broods unless tree tissues contained in vivo ethanol resulting from irrigating with ethanol solutions. More X. germanus brood were also produced in a rearing substrate containing ethanol. Ambrosiella and Raffaelea fungal isolates from ethanol-responsive ambrosia beetles also exhibited higher biomass on media containing ethanol, while the growth of “weedy” fungal garden competitors (Aspergillus, Penicillium) were suppressed. Faster alcohol dehydrogenase enzymatic activity was also exhibited by Ambrosiella and Raffaelea fungal symbionts compared to fungal competitors. These results demonstrate the affinity of ambrosia beetles for ethanol is due in part because it benefits their fungus farming by promoting the growth of their fungal gardens while inhibiting the growth of “weedy” fungal competitors. The presence of ethanol within host trees also indirectly benefits ambrosia beetle colonization success because foundresses do not begin laying eggs until their fungal gardens are flourishing. The influence of ethanol on ambrosia beetle fungus farming will also be discussed in the context of non-ethanol responsive ambrosia beetles.

Spatio-temporal patterns of the habitat is a key for the conservation of beetles inhabiting tree cavities

Authors: Ranius Thomas, Swedish University of Agricultural Sciences Dept. of Ecology, Uppsala, Sweden

Abstract: In ancient trees, cavities containing wood mould are formed. Wood mould is loose material mainly consisting of dead wood. Cavities with wood mould constitute natural mesocosms. Among inhabiting invertebrates, many are specialised to wood mould, especially beetles, but also pseudoscorpions, mites, and dipterans. Since ancient trees are decreasing world-wide, many of these species are today decreasing and threatened.

Among this fauna, we have in particular studied one beetle species, Osmoderma eremita. The presence of O. eremita indicates a higher probability of presence also of other specialised beetle species. One possible explanation for this is that O. eremita seems to act as an ecosystem engineer, by increasing the amount of wood mould and its content of nutrients. We have studied the species' occurrence patterns and made direct observations of dispersals. We have also studied the dynamics of the habitat and the species' populations over time. In Sweden, most O. eremita individuals remain in the same cavity throughout their entire life-time. Occurrence patterns suggest that the species is dispersal limited; species' occupancy increases with the amount of dispersal sources within a radius of 200 m. An effect of dispersal sources in the surrounding has also been revealed for other beetle species in this community, but for most species the scale of response is larger, up to 2 km. Many beetle species occur more frequently in cavities with characteristics reflecting a warmer or more stable microclimate. The population size of O. eremita varies widely among cavities, and is correlated with the amount of wood mould. Trees with cavities may persist for decades and centuries, and thus inhabiting species may remain in the same cavity over a long time. The population fluctuations are narrow in comparison to many other insects. For metapopulation dynamics, the number of cavities and their quality are important, as well as the spatial location of the cavities. Thus, the spatio-temporal dynamics of the habitats is a key for long-term preservation of O. eremita and other species in this community.

We have created artificial mesocosms by filling boxes with artificial wood mould. They are utilized by a lot of deadwood-dependent beetles, even though some specialised species such as O. eremita, only rarely use them. When using such boxes in experiments, we have found that the decomposition of wood mould is affected by the inhabiting beetle fauna, and then especially large-bodied beetle species are important.

Why do bumble bees die after foraging on linden (Tilia sp.)?

Authors: Rao Sujaya[2] and Lande Claire[1], [1]Department of Crop and Soil Science, Oregon State University, United States, [2]Department of Entomology, University of Minnesota, United States

Abstract: Linden (Tilia spp.), also known as basswood or lime, is a profusely flowering temperate tree that provides bees with vital pollen and nectar. On occasion, however, bees foraging on linden trees in Europe and North America have been observed to fall, crawl and ultimately die. These bee deaths have been attributed, with inadequate evidence, to toxicity from mannose in nectar or starvation due to low nectar in late blooming linden. We investigated both factors by analyzing nectar from trees below which crawling bees were observed, and comparing healthy foragers and crawling bees using a biochemical approach. Our results showed that nectar did not contain mannose but alkaloids were detected. Principal component analysis of muscle metabolites produced distinct clustering of healthy and crawling bees, with significant differences ($P<0.05$) in > 30 metabolites. In the presentation, we will provide details of the study and the results, which provide an explanation for the intriguing linden-bee mortality phenomenon.

The effect of elevation gradients and phytochemical diversity on arthropod community changes

Authors: Rasmann Sergio, University of Neuchâtel, Switzerland

Abstract: Addressing species' responses to climate change in the absence of long-term time series data is a challenge that can be achieved by substituting space for time. For example, elevation gradients can be used to address communities responses to temperature and precipitation changes. To measure climatic clines in the top-down potential of predators on herbivores, we first studies community composition of arthropod herbivores and predators at low, mid and high elevations in the Alps. Next, to address the bottom-up forces driving herbivores' communities variation, we manipulated plant phytochemical diversity at each elevation site and recorded the surrounding arthropod community composition. First, we found that while overall biodiversity is greater at low-to-mid elevation, the biocontrol control potential of predators was stronger at low elevation. Second, we found that high community-level phytochemical diversity decreases the colonizing arthropod herbivore abundance, but mainly at low elevation. Our results, suggest that temperature changes can modify the top-down versus bottom-up control of herbivores in natural systems.

Plant species diversity influences tri-trophic interactions along environmental gradients

Authors: Rasmann Sergio[1], Fernandez-conradi Pilar[1], Courrier Pierre[1], [1]University of Neuchâtel, Switzerland

Abstract: Theory predicts that mixed cultures are more resistant to pests than monocultures through increased top-down controls by natural enemies (i.e. associational resistance). However, whether plant diversity effects remain stable along elevation gradients has yet to be verified. Along elevation gradients, a general pattern is that herbivores and predators are abundant at low elevation and progressively diminish at higher elevations. To determine how plant species diversity influences top-down control of herbivores along such elevation gradients, we performed reciprocal transplant experiments manipulating plant species diversity and root herbivore pressure. Additionally, we measured soil nematode abundances. Without herbivores, nematode abundance was higher in mixed cultures than in monocultures. In the presence of root herbivores, nematode recruitment was higher in plant species mixtures. The magnitude of this effect was higher at low elevation sites, where nematode abundance was more important. We also explored the effect of root herbivory and plant diversity on plant root volatile profiles, using gas chromatography–mass spectrometry (GCMS). Overall, our results provides new insights into how species respond to environmental gradients, and highlight the importance of accounting for plant species diversity in trophic interactions.

Halyomorpha halys and Trissolcus mitsukurii in Friuli Venezia Giulia (Northeastern Italy)

Authors: Raso Rosario[2], Oian Barbara[2], Benvenuto Luca[3], Malossini Giorgio[4], Bernardinelli Iris[3], Roversi Pio Federico[1], Marianelli Leonardo[1] and Giovannini Lucrezia[1], [1]CREA -Research Centre for Plant Protection and Certification, Italy, [2]ERSA, [3]ERSA – Regional agency for rural development – Phytosanitary Service of Friuli Venezia Giulia, Italy, [4]Plant Health Service - ERSA - Friuli Venezia Giulia Region, Italy

Abstract: In North America and Europe Halyomorpha halys causes high damages on crops; chemical and physical solutions do not guarantee an acceptable level of long-term pest control. In the Friuli Venezia Giulia (FVG) region in North-Eastern Italy, the first detection of H. halys occurred in 2014 and in the following five years it spread over the whole region; the most damaged crops are apples, pears, peaches and kiwi. Monitoring by visual inspections and lured traps permitted to define the spreading of H. halys in the region, which is characterized by a fragmented landscape, with orchards surrounded by arable crops. A new perspective for a long-term solution for H. halys control is given by the discovery in FVG of an Asian egg parasitoid, Trissolcus mitsukurii, found in three different sites on H. halys eggs in August 2018. The egg parasitoid was detected on hedgerows and cultivated plants in IPM or organic orchards. T. mitsukurii was also found in 2019 in more than 25 sites across the region, showing its ability to disperse and establish in the northern Italian climate. Parasitization success of H. halys egg masses is relatively high. In 2019 the average parasitization rate was at least 25% of the total egg masses collected (mean of parasitized eggs/egg masses was 66%). In organic kiwifruit orchard it reached 82% of egg masses parasitized on 44 collected (mean of parasitized eggs/egg masses was 71%). In the same orchard in 2018 the parasitization rate was higher: 84% of egg masses parasitized on 19 collected (mean of parasitized eggs/egg masses was 87%). Surprisingly, starting from 2019, in the H. halys oldest infested areas (sites A) for the first year we observed a decrease of the bug populations, while in the new ones (sites B), in the southern part of the region and in the north close to the Alpine areas, the BMSB population increased considerably; these areas are also with the lower presence of T. mitsukurii. As an example, considering the total bug catches, the 42% reduction in sites A and 20% in sites B from 2018 to 2019 was observed. Considering the presence of H. halys juveniles only, the decrease was even higher (48% in sites A and 29% in sites B). This event was concomitant with the findings of T. mitsukurii in the same sites. In many areas, the decreasing trend of H. halys was observed also in 2020 and in 2021. In the part of the region where the occurrence of T. mitsukurii was low or absent, the population of H. halys at contrary continuously increased over years. Damages on fruit orchards in 2018 and 2019 were still considered high and “stay green” effect was very evident and widespread on soybean fields, while in 2020 and 2021 a general damage reduction was observed. Data collected could suggest that natural biological control of T. mitsukurii has started and should presumably develop in the coming years across the region.

Exploiting trap color to improve survey and detection of native and exotic longhorn beetles (Coleoptera, Cerambycidae)

Authors: Rassati Davide[2], Faccoli Massimo[2], Cavaletto Giacomo[2] and Marini Lorenzo[1], [1]Department of Agronomy, Food, Natural Resources, Animals and the Environment. University of Padua, Italy, [2]University of Padova, Italy

Abstract: Longhorn beetles (Coleoptera, Cerambycidae) are among the most significant groups of invasive forest insects worldwide. Hidden within live plants and wood-packaging materials, these beetles can escape routine inspections at entry points and some become major pests in the invaded environment. Traps baited with blends of pheromones and kairomones and set up in and around entry points are commonly used to improve chances of intercepting exotic species soon after their arrival. Factors able to affect longhorn beetle catches in traps have been extensively studied in the last years. Nonetheless, one aspect is still largely overlooked, that is the effect of trap color. In a trapping study carried out in 2019 at 16 forest sites in northern Italy, we investigated the response of longhorn beetles to baited traps of eight different colors (i.e., black, yellow, green, red, purple, grey, brown and blue). In total, 6,001 individuals were trapped, belonging to 56 species, 54 native and two exotic. Longhorn beetle species richness and total abundance were significantly affected by trap color; in particular, yellow traps allowed to catch a significantly greater number of species and individuals than the commonly used black traps. In addition, trap color affected the abundance of several species, but the response was mainly species specific. Color preferences of different longhorn beetle species are likely linked to either their food habit or their sexual behavior. In general, these results indicate that trap color can strongly affect longhorn beetle catches in traps and suggest that trap of different colors should be used in surveillance programs carried out at entry points.

Life-history trade-offs in variable environments

Authors: Ratikainen Irja, Norwegian University of Science and Technology, Norway

Abstract: The world is a variable place and a part of that variation is unpredictable to animals, but all animals have evolved ways to cope with such variable and uncertain environments.

I will discuss how environmental variation and unpredictability can affect different life-history trade-offs and how different life-history traits can co-evolve to deal with environmental variation.

As one example of this we have seen that the trade-off between reproduction and survival can be affected by environmental variation in unexpected ways. Classic theory suggests that variable environments result in evolution of long life, but novel theoretical and empirical work show that environmental variation can instead select for short lifespan and early reproduction. If reversibly plastic responses can evolve as well, we should expect that long life and environmental variation is not merely a context that sets the stage for lifelong plasticity but plasticity itself can select for longevity. Considering niche construction as an alternative to plasticity for achieving tolerance to environmental variation can reveal how the theoretical developments can help us understand social insects, and how social insects can help us understand life-history trade-offs in variable environments.

Effect of large scale disturbance on native cerambycid communities

Authors: Ray Annie[3], Traylor Clayton[2] and Franzen Emily[1], [1]Department of Biology, Xavier University, United States, [2]Department of Entomology, University of Georgia, United States, [3]Xavier University, Cincinnati, OH, United States

Abstract: The ecological and economic consequences of biological invasion have compelled research to identify mechanisms for resistance against the establishment of nonnative species. There is a growing body of evidence that suggests that biodiverse communities can be resistant to invasion (i.e., biotic resistance) due to either complementary niche partitioning or the likelihood of a highly competitive species being present. One example of niche partitioning is the pheromone niche hypothesis, where low levels of diversity in cerambycid communities allow “pheromone free space.” Pheromone niches are specific chemical, habitat, and temporal characteristics that each species uses for mating or aggregation attraction. Potential invaders are more likely to establish if they possess a pheromone niche that is free, because cross-attraction between invasive and native species will not occur. Furthermore, high intensity disturbances generally facilitate invasion by reducing native species richness, allowing invaders to establish. Most previous studies investigating these mechanisms have focused on grassland or algal communities; very few have concentrated on insects. Because of the economic importance of exotic and potentially invasive longhorn beetles, we investigated the effects of intense tree removal on cerambycid diversity in Clermont Co., OH, at a forested site inside of the Asian Longhorned Beetle eradication zone. Cerambycids were collected from April to September of 2017-2020, and abundance and diversity was compared to a similar site outside of the eradication zone. To date, we’ve found limited differences in species composition between sites, suggesting that the disturbance has not substantially altered the cerambycid community. It is possible that it is too soon to detect the impacts of large-scale disturbance on cerambycid communities and additional research is needed over a longer time period to detect community changes.

Enneothrips n. sp. (Thysanoptera: Thripidae): unraveling the real identity of the South American peanut thrips?

Authors: Rayane Silva de Alencar Aquila, Universidade Federal do Piauí, Campus Amílcar Ferreira Sobral, Brazil

Abstract: The peanut thrips is the key pest of peanut (Arachis hypogaea) in South America, where it can cause yield losses of up to 85%. So far, the species was recognized as Enneothrips flavens, but access to the holotype of this species and freshly collected material from Brazil and Paraguay revealed that specimens commonly collected on peanut crops have consistent morphological differences when compared with E. flavens. The objective of this work is to report evidences that the name currently applied to the peanut thrips is not appropriate and propose the description of a new species to this taxon. Specimens of the peanut thrips have been collected in the states of Acre and São Paulo, Brazil, and in Asunción, Paraguay. Also, specimens to which the name E. flavens could be morphologically applied were collected from different hosts in the states of São Paulo and Minas Gerais, Brazil, areas close to the type locality of the species. All the specimens were prepared in permanent microscope slides (Canada Balsam) and are deposited in the Coleção de História Natural da UFPI, Floriano, Piauí State, Brazil. In addition, to assure a correct identification, type material of all Enneothrips species currently known have been examined from California Academy of Sciences (San Francisco, CA, USA) and Smithsonian’s National Museum of Natural History (Washington, D.C., USA). Direct comparison of the peanut thrips slides with the holotype of Enneothrips flavens allowed to observe morphological differences between these two taxa, namely: (i) absence of internal markings in the metanotal reticles of the peanut thrips; (ii) coloration of abdominal tergites lighter and more uniform in the peanut thrips; (iii) closer sculpture lines in the mesonotum in the peanut thrips. Moreover, males collected together with females of the species to which the name E. flavens can be morphologically applied are macropterous, instead of brachypterous as in the species collected from peanut crops. Taking into account that the pest species have consistent differences in relation to E. flavens, and that it does not belong to any other species described in the genus, it is proposed that the peanut thrips should be described as a new species to science. Molecular studies are currently being carried out to further support this assumption.

Applying social evolution theory to design cheat-proof insect pathogen selection experiments

Authors: Raymond Ben[1], Dimitriu Tatiana[1], Souissi Wided[2] and Crickmore Neil[2], [1]University of Exeter, [2]University of Sussex

Abstract: Cooperation and social conflict are important for the virulence of the insect pathogen Bacillus thuringiensis, especially the expression Cry proteins, their obligate virulence factors. Any selection regime aiming to increase the virulence of B. thuringiensis therefore needs to prevent the emergence of social cheats that do not produce these costly proteins.

Here we used a passage experiment to increase the virulence of Bacillus thuringinensis against a resistant population of diamondback moth, Plutella xylostella. We used two selection treatments: pooling of infected cadavers and competition between subpopulation in an insect metapopulation. We also investigated the value of increased mutation supply by using wild type bacteria and a mutator. We found that the metapopulation regime and the use of mutators both facilitated increases in virulence. However, selection in a meta-population was the most effective method for preventing the emergence of cheats, bacteria no longer produced Cry toxins. The metapopulation structure of host and pathogen is vital for ensuring that selection at the right scale can operate and provide a selective advantage for virulent mutants. Not only does this indicate how selection for pathogen virulence might occur in the field but also how we can re-model pathogen passage for social microbes.

Bioaugmentation of entomopathogenic fungi for sustainable wireworm management in maize and potatoes

Authors: Razinger Jaka[1], Praprotnik Eva[1] and Schroers Hans-Josef[1], [1]Agricultural Institute of Slovenia

Abstract: Soil microorganisms influence biotic and abiotic stress tolerance of crops. Most interactions between plant symbiotic and non-symbiotic soil microorganisms and plants occur in the rhizosphere and are sustained through plant exudation/ rhizodeposition. Bioaugmentation, i.e., applying microbes with plant beneficial traits into the rhizosphere, specifically bioaugmentation of entomopathogenic fungi (EPF), could alter microbial rhizosphere communities towards increased ecological service provision and potentially replace environmentally unfriendly insecticides. Wireworms, the soil-burrowing larval stages of click beetles (Coleoptera: Elateridae), are major pests of crops including maize, wheat and potatoes, worldwide. They can be effectively controlled using granular organophosphates or pyrethroids, but these insecticides are already restricted in several countries and are gradually being phased out. Therefore a potential wireworm biological control strategy involving maize seed and potato tuber coating with soil EPF was investigated. The plant biostimulation potential to maize and wheat as well as virulence of several EPF isolates to Agriotes lineatus wireworms was assessed in a series of laboratory experiments. One M. brunneum strain was further evaluated in field settings to examine its ability to protect three maize cultivars from wireworm damage and promote plant growth, whereas four M. robertsii and two M. brunneum isolates were assessed in potato field trials. In-house reared wireworms were dipped for 10 s in a 1 × 108 ml-1 conidial suspension; maize and wheat seeds and potato tubers were coated with fungal conidia. Additionally, in the potato field trials, six EPF isolates were formulated on rice and applied as soil granular bioinsecticide, and their efficacy compared to ATTRACAP. Several EPF strains significantly increased wireworm mortality and colonized maize and wheat rhizoplane in laboratory settings to a varying extent. The strains tested were seldom isolated as endophytes. Maize plants originating from seeds treated with conidia of Metarhizium brunneum strain HJS 1868 showed significantly less wireworm damage at emergence resulting in significantly higher initial and final maize stand in field experiments. The mix of six EPF strains evaluated in potato field trials offered protection against wireworm drilling at par with bioinsecticide ATTRACAP, however, only when formulated on rice; soaking potato tubers in the conidial mix annulled this effect. The implications of EPF × plant interactions are discussed in the context of exploiting plant-microbe interactions for low input sustainable agriculture.

Acknowledgments
The research was financed partly by the Slovenian Research Agency (ARRS) (Next Generation Agriculture program group, grant number P4-0431 and a grant to EP, 1000-18-0401), and H2020 projects ECOBREED (grant 771367) and EXCALIBUR (grant 817946).

Wild cotton landraces as a source of host plant resistance to reduce thrips injury

Authors: Reay-Jones Francis[1], Reisig Dominic[4], Conzemius Sophia[3], Campbell Benjamin[2] and Greene Jeremy[3], [1]Clemson University, Department of Plant and Environmental Sciences, Pee Dee Research and Education Center, Florence, South Carolina, United States, [2]Coastal Plain Soil, Water and Plant Conservation Research, USDA-ARS, Florence, SC, United States, [3]Department of Plant and Environmental Sciences, Clemson University, Edisto Research and Education Center, Blackville, SC, United States, [4]North Carolina State University, United States

Abstract: Thrips are problematic pests of many agricultural, horticultural, and ornamental crops. Preventative insecticidal sprays are often necessary for managing thrips (Thysanoptera) on cotton (Gossypium spp.) throughout the United States. Host plant resistance could protect vulnerable cotton seedlings and reduce further development of insecticide resistance in thrips populations. Our work has investigated the potential for thrips resistance among the landrace collection maintained by the U.S. National Plant Germplasm system, which is a largely untapped source of genetic diversity. Identification of thrips-resistant landraces began with field trials using insecticide treated and untreated plots. Putatively resistant and susceptible lines underwent free-choice and no-choice tests with tobacco thrips (Frankliniella fusca Hinds). With further analyses of metabolomics and volatile analyses, we plan to identify the underlying causes of thrips resistance in cotton.

Development of Helicoverpa zea on transgenic maize expressing Bt toxins in the southeastern United States

Authors: Reay-Jones Francis[2], Reisig Dominic[5], Musser Fred[4], Greene Jeremy[3], Turnbull Matthew[1] and Bilbo Thomas[2], [1]Clemson University, Department of Plant and Environmental Sciences, Department of Biological Sciences, Clemson, South Carolina, United States, [2]Clemson University, Department of Plant and Environmental Sciences, Pee Dee Research and Education Center, Florence, South Carolina, United States, [3]Department of Plant and Environmental Sciences, Clemson University, Edisto Research and Education Center, Blackville, SC, United States, [4]Mississippi State University, United States, [5]North Carolina State University, United States

Abstract: The corn earworm, Helicoverpa zea (Boddie) (Lepidoptera: Noctuidae), can be managed in the United States using transgenic maize hybrids that express insecticidal proteins from the bacterium Bacillus thuringiensis (Bt). While practical resistance has developed in H. zea to a several Cry toxins, Bt traits still provide efficacy for reducing ear injury compared to non-Bt maize. Fitness costs or the effects of sublethal doses of Bt toxins are apparent by delayed development and reduced pupal weights on Bt maize hybrids. A longitudinal study from 2012-2019 characterized changes over time in the reduction in H. zea pupal weight on Bt maize in North and South Carolina. As H. zea has developed resistance to Bt toxins, the effects of Bt toxins on pupal weights have lessened over time. On-going research is aiming to identify potential fitness costs and their implications for insecticide resistance management. In addition, development of H. zea was examined in the field by measuring the instar- and tissue-specific feeding behavior of larvae in Bt and non-Bt hybrids. Concentrations of Cry1F and Cry2Ab2 toxins quantified using ELISA varied significantly with silk age and both were generally greater in the silk and tip tissue compared to kernels and husk. Hybrids with pyramided toxins lead to delayed development of H. zea and had reduced injury to the silk, tip, and kernel ear tissues, which was less clear with single Bt toxin hybrids. The pyramided hybrid expressing Vip3A had no injury to the ear tip or kernels, and only eight 1st instar larvae were found in the silk out of 520 ears. Larval age varied among tissues but not between hybrids. We did not detect differences in feeding behavior between Bt and non-Bt hybrids. Implications for resistance management strategies such as seed mixtures will be discussed.

Aphid parasitism in organic wheat systems of the US Southern Plains

Authors: Rebek Eric[1], Butler Haley[1], Royer Tom[1], Giles Kristopher[1] and Elliott Norman[2], [1]Oklahoma State University, United States, [2]USDA-ARS, United States

Abstract: A unique set of climatic conditions in the US Southern Plains allow conventional winter wheat producers to grow this crop as forage for cattle, for dual purpose (cattle + grain), or for grain only on over 5 million hectares. The success of this crop is directly attributable to well-established pest management programs that allow producers to significantly reduce inputs while effectively managing pests. Indeed, researchers in the region have demonstrated over the past several decades that low-input winter wheat serves as the primary winter habitat in the Southern Plains for a broad range of insect natural enemies, but more importantly, these natural enemies regularly maintain insect pests below economic injury levels, and subsequently reduce the need for curative insecticide applications. In fact, the effects of parasitoids on aphids in wheat are so predictable that they have been incorporated into sampling and management decisions. The increasing number of organic winter wheat systems in the Southern Plains should significantly benefit from the effects of aphid parasitoids because their numbers and diversity are likely to be conserved in the absence of detrimental, broad-spectrum, synthetic insecticides, which still are included occasionally in conventional production systems. We hypothesized that winter wheat fields on organic farms will provide habitat for parasitoids of aphid pests and prevent outbreaks, but also serve as sources of natural enemies for organic spring crops (vegetables, fruits, and herbs) common in the landscape of most organic farms. Based on methods from previous aphid parasitism studies, sentinel wheat plants in pots with aphids (bird cherry oat) were used to describe pest suppression by parasitoids in organic wheat fields versus nearby conventional wheat fields (paired and min 10 km away) over a range of growing conditions in Oklahoma. Pots/vegetation were retrieved and predators removed before being placed in emergence canisters to estimate parasitism rates and pest suppression. Preliminary observations reveal relatively high levels of parasitism in organic wheat fields by commonly described cereal aphid parasitoids in the region, similar to levels and species found in conventional wheat systems. Observations of parasitism in organic wheat systems suggest that producers should be able to adopt aphid-parasitoid management decisions utilized in conventional wheat systems throughout the region.

Attachment ability of the parasitoid Anastatus bifasciatus to its host eggs

Authors: Rebora Manuela[1], Salerno Gianandrea[3], Piersanti Silvana[4], Kovalev Alexander[2], Gorb Elena[2] and Gorb Stanislav[2], [1]Perugia University, Dipartimento di Chimica, Biologia e Biotecnologie, Italy, [2]University of Kiel, Germany, [3]University of Perugia

Abstract: Egg parasitoids attack eggs of many arthropod species and play an important role in biological control of pest species. During coevolution with their hosts, egg parasitoids have developed great ability to locate their host using chemical cues. A considerable amount of literature is available on this topic while nothing is known about a possible adaptation of egg parasitoids to the mechanical features of the egg surface and its shape when attaching to the host egg for oviposition.

In the present investigation, the attachment ability of adults of both sexes of the ooparasitoid Anastatus bifasciatus (Hymenoptera, Eupelmidae) to artificial and natural surfaces (eggs of Halyomorpha halys and Nezara viridula) with different roughness and wettability was measured with centrifugal force tester and traction force experiments. The parasitoid attachment devices and the egg surface were characterised under cryo-SEM, the wettability and the roughness of natural and artificial surfaces were also measured. Differences in the attachment devices and attachment ability of the two sexes have been observed. The collected data reveal a special ability of the female to attach to the eggs of the host species, thus suggesting an adaptation of the female to the mechanical features of the eggs during oviposition.

Application of entomopathogens for the management of wireworm in spring wheat

Authors: Reddy Gadi[3], Sharma Anamika[1], Shaprio-Ilan David[2] and Kaur Sandhi Ramandeep[1], [1]Montana State University-Bozeman, United States, [2]USDA-ARS, Southeastern Fruit and Tree Nut Research Lab, Byron, GA, United States, [3]USDA-ARS, United States

Abstract: Wireworms are major pests of spring wheat and barley around the world. Insecticides as seed treatments only work as repellents. Environmentally friendly management strategies are needed to manage wireworms to conserve the environment. At the Golden Triangle Area of Montana, we are using entomopathogenic fungi (EPFs) and entomopathogenic nematodes (EPNs) to develop a cost-effective management strategy. Polenta, millet, and couscous were used as a nutritive carrier to increase the efficacy of EPFs by regrowth and conidiation after application. The tested EPFs were Beauveria bassiana GHA, Metarhizium robertsii DWR356, M. robertsii DWR2009, B. bassiana ERL836 and M. brunneum F52 on polenta, couscous and millet carrier. In 2017, at Valier, DWR356 and DWR2009 on a millet carrier at 22.4 kg ha-1, provided greater yield but all the treatments at the lower rate were cost-effective. In 2018, GHA and ERL836 on millet carrier obtained cost-effective results at irrigated and non-irrigated sites in 2018. Millet as carrier worked better than the other carriers. Further evaluation of the different carriers under various field conditions is required. The study with EPNs involves laboratory, indoor and field experiments to evaluate ten EPN strains against sugar beet wireworm, Limonius californicus. Steinernema carpocapsae, S. riobrave, S. rarum, and Heterorhabditis bacteriophora killed 50-60% of L. californicus larvae in the laboratory. Similarly, S. riobrave and S. carpocapsae were able to kill 50% wireworm larvae under shade house conditions. However, these EPN species were not found very effective for protecting wheat and barley plants due to wireworm damage. Also, Montana native EPN species (S. feltiae and H. bacteriophora) were observed to be virulent against L. californicus under laboratory conditions but not in shade house experiments. These results suggest that EPNs may have significant potential for protecting spring wheat crops from wireworms and need to be explored further.

In cold blood: deciphering the mechanisms underlying mosquito-frog interactions

Authors: Reinhold Joanna[2], Lahondère Chloé[2] and McLeod David[1], [1]James Madison University, United States, [2]Virginia Polytechnic Institute and State University, United States

Abstract: Mosquitoes can feed on almost any animal, including other mosquitoes. While most research involves species that feed on humans, one species, Culex territans, specializes in feeding on ectotherms, primarily amphibians and reptiles. Although this species is fairly widespread in North America and Europe, surprisingly little is known about its biology and ecology. For this project, we are particularly interested in understanding: 1) How do the mosquitoes locate their cold-blooded host? 2) How do they manage imbibing cold and viscous blood? 3) What is their role in disease transmission? To better understand the cues Cx. territans uses to find its hosts, we performed olfactometer experiments and feeding assays coupled with thermographic imaging with green frogs and bullfrogs, two of the common hosts this mosquito feeds on in the wild. We also used SPME scent collection coupled with GC/MS to analyze the scents of these two species of frogs. Using electro-antennograms coupled with gas chromatography, we determined the compounds emitted by the frogs that the mosquito antennae detect. Antennae transcriptomic analyses allowed us to get hints in the specificity in odorant receptors this species has and overall on some of the adaptations developed by this species to feed on ectotherms. Finally, we know that Cx. territans transmits trypanosomes to amphibians, but it is unclear if they vector any other diseases. In order to understand the effects that this mosquito has on amphibian health, we screened blood fed mosquitoes from the field and from our feeding assays for trypanosomes as well as Ranaviruses using PCR and plaque assays. Together, this data is helping us to build a more complete picture of the evolution of blood-feeding on warm-blooded vertebrate hosts, including humans, in mosquitoes and to learn about the role Cx. territans plays in the decline of amphibian populations worldwide.

An overview of stink bugs (Euschistus servus and Nezara viridula) as pests of US corn

Authors: Reisig Dominic, North Carolina State University, United States

Abstract: Previously the stink bug Euschistus servus was a major problem in corn, but primarily isolated to corn fields bordering wheat. After wheat was harvested, E. servus would disperse into and damage neighboring corn fields. During the past 10 years, the stink bugs E. servus and Nezara viridula have become the most problematic insect pest of corn, and continue to be major pests of soybean and cotton across the southern US. Also during the past 10 years, these stink bugs have been problematic in corn fields that are not associated with wheat. This presentation details past, recent, and future studies describing the ecology and management of stink bugs in corn.

A cotton tissue-based resistance monitoring procedure for Helicoverpa zea in Bt cotton

Authors: Reisig Dominic[3], Goldsworthy Emily, Del Pozo-Valdivia Alejandro[4], Babu Arun[2] and Amir-Aghaee Mohammad[1], [1]Bayer Crop Science, United States, [2]North Carolina State University, Department of Entomology and Plant Pathology, United States, [3]North Carolina State University, United States, [4]University of California Division of Agriculture and Natural Resources, United States

Abstract: Current methods to identify Helicoverpa zea (Lepidoptera: Noctuidae) practical resistance to Bt cotton rely on the relationship of diet-based bioassays to field injury, measured as square or boll injury. However, these are often confounded by environmental variation in the field. We developed an experiment to identify quantifiable and reliable in-field plant injury as a supplementary resistance monitoring tool. Plant-based tissue bioassays have been used reliably in other systems, but are not available for Helicoverpa zea. In field experiments, we identified H. zea larval feeding patterns on cotton plants that could be indicative of selective feeding. Bolls were proposed as the target candidate for a plant bioassay because they are not prone to abscission under diverse environmental conditions, thus avoiding confounding the effect of insect feeding from abiotic conditions. We present our ongoing efforts to link feeding on bract tissue from bolls to correlate with Bt resistance in H. zea.

Global mechanisms of Bt resistance in a field strain of the cotton bollworm, Helicoverpa zea: the expected and unexpected

Authors: Reisig Dominic[3], Kurtz Ryan[1], Lawrie Roger[3], Del Pozo-Valdivia Alejandro[4], Marcel Deguenon J.[3], Ponnusamy Loganathan[3], Michael Roe R[2], [1]Cotton incorporated, United States, [2]Department of Entomology and Plant Pathology, North Carolina State University, United States, [3]North Carolina State University, United States, [4]University of California Division of Agriculture and Natural Resources, United States

Abstract: Evolved resistance to genetically modified crops including economically important products such as cotton, corn, soybeans and many others has become rapidly and globally widespread over the last 20 years. Numerous economically important agricultural pests of crops expressing Bt (Bacillus thuringiensis) bacterial proteins (Cry1Ac, Cry1F, Cry2Ac) have evolved resistance to these Bt-toxins. RNA-seq is a method to quantitatively measure total gene expression in an organism. This method was used to measure differences in global gene expression between a Bt-susceptible and a Bt-resistant strain of the Cotton Bollworm (Helicoverpa zea), where the differences in susceptibility to Cry1Ac +Cry1F toxin was 100-fold. Quantitative PCR was later used to confirm expression levels in the two strains of bollworm. We found gene expression differences that would be expected based on our current understanding of Bt mode of action and resistance including increased expression of proteases and reduced expression of Bt-interacting receptors in Bt-resistant bollworms. We have also found additional expression differences between the two strains of bollworm in genes that have not previously been thoroughly investigated. This suggests that there are multiple different mechanisms influencing the development of Bt-resistance in addition to potential previously unrecognized pathways of resistance in this agricultural pest species. Also important to consider is how investigation into the genetic mechanisms of Bt-resistance will aide in the understanding of how resistance in insects develops. Due to prevalence of insecticidal use, biology of insects, and other factors; resistance to any IPM technique is likely inevitable. Ideally this knowledge can then be applied to reduce the vulnerability of novel and next-generation integrated pest management technologies to evolved resistance in agricultural pest species.

Comparative Behaviors of Old and New Foes: Oviposition of the Container Aedes spp.

Authors: Reiskind Michael[2], Reinbold-Wasson Drew[1], [1]Department of Entomology and Plant Pathology North Carolina State University Raleigh, NC, United States, [2]North Carolina State University, United States

Abstract: Container Aedes spp. mosquitoes are known to oviposit is a variety of natural and artificial containers. Various container factors have been explored in the literature, including size, nutrients, presence of predators, presence of conspecifics, and presence of competitors to assess preferred containers. However, there has been little work on the basic behavior that is being assumed in preference studies, that of “skip oviposition.” Here we present data comparing three container Aedes with different evolutionary history and ecological backgrounds: Aedes aegypti, Aedes albopictus, and Aedes triseriatus. We find both subtle and striking differences in their oviposition behavior and their propensity to skip oviposit. These differences have important implications for the interpretation of preference studies and the utility of autodissemination as a control strategy.

Investigating small RNA profiles of honey bee viruses in parasitic mites

Authors: Remnant Emily[1], Norton Amanda[1], Ashe Alyson[1], Buchmann Gabriele[1] and Beekman Madeleine[1], [1]University of Sydney, Australia

Abstract: The honey bee parasitic mite, Varroa destructor, is a major threat to beekeeping worldwide. One consequence of Varroa infestation is increased prevalence of viruses that are vectored by mites. While viruses are known to cause immune responses in honey bees, there have been few studies investigating the impact of viruses on Varroa mites themselves. The RNA interference (RNAi) pathway is a major antiviral immune pathway in insects and involves active degradation of viruses by Dicer into small RNA fragments of 21-22 nucleotides. Here, we examine the RNA interference response of Varroa mites to honey bee viruses. We performed deep sequencing of small RNA fragments in Varroa destructor to determine if mites mount an active response to viruses infecting honey bees. While honey bee RNA interference profiles display a classical Dicer-mediated response to viruses, the viral small RNA profile in Varroa is novel and distinct from the profile observed in bees. These results indicate that viruses are processed differently between bees and their mite parasites, and point to alternate viral RNAi pathways within these two Arthropod lineages. Further, active degradation of viruses in Varroa indicates that honey bee viruses elicit a host-mediated antiviral response by the Varroa immune system, suggesting these viruses may therefore be genuine mite infections.

How does vector transmission by Varroa mites influence the evolution of Deformed wing virus in honey bees?

Authors: Remnant Emily[1], Norton Amanda[1], Beekman Madeleine[1] and Blacquiere Tjeerd[2], [1]University of Sydney, Australia, [2]Wageningen University and Research, Netherlands

Abstract: Evolutionary theory predicts that the arrival of a vector alters the trade-off between virulence and transmission of pathogens. As the vector now transmits the pathogen between hosts, pathogen transmission is no longer dependant on extended host survival, allowing a pathogen to evolve towards higher virulence. The increase in the prevalence and abundance of the honeybee RNA virus Deformed wing virus (DWV) with the global spread of the ectoparasitic mite, Varroa destructor, nicely fits the pattern predicted by theory. DWV is vectored by the mite during feeding on the bees' fat bodies. Without the use of miticidies, honey bee colonies infested with V. destructor typically die within 6-24 months, and colony deaths have been largely attributed to DWV. Previous studies suggest that Varroa-mediated transmission places a selective bottleneck on DWV genotypic diversity, and potentially selects for increased virulence in DWV strains. At the same time, small isolated populations of honey bees around the world have developed tolerance to V. destructor, with colonies surviving without the use of miticides. Some studies have suggested that perceived Varroa tolerance is attributed to high DWV diversity and the absence of virulent strains within the given honey bee population. While these Varroa-tolerant honey bee populations differ both genetically and geographically, their common thread is an ability to keep Varroa numbers low. Clearly, mite numbers matter. The question is why. We hypothesised that if Varroa places selective pressure on DWV, then DWV diversity should be altered when the number of passages (e.g. bee-to-bee transmissions) increases. Conversely, increased transmission with no change in DWV diversity over time would suggest that Varroa transmission is non-propagative. Instead some viral variants may have increased fitness in honey bees, or may be better adapted to vector transmission. To determine the role the mite plays in the diversity of DWV we studied two honey bee populations in the Netherlands with equal mite numbers, One population is Varroa tolerant (and chemically untreated since 2008) and the other treated annually with miticides. We experimentally increased the number of Varroa mites within multiple colonies of both populations. We monitored the change in viral abundance and DWV diversity over a period 10 months, and evaluated what effect increased mite numbers have on DWV genotypic diversity. The results of this study will improve our understanding of the role Varroa transmission has on DWV evolution. This will have significant ecological and economic implications, both in managing honey bee health and in improving our understanding of disease emergence and virulence evolution.

Nitrogenous waste recycling mediated by gut microbes in oriental fruit flies for environmental stresses

Authors: Ren Xueming[1], Niu Changying[1], [1]Hubei Key Laboratory of Insect Resource Application and Sustainable Pest Control, College of Plant Science & Technology, Huazhong Agricultural University, Wuhan

Abstract: Microbes are major contributors to insects coping with multiple environmental stresses, among them nitrogen stress is one of the critical challenges to herbivorous insects. The oriental fruit fly, Bactrocera dorsalis, is a polyphagous agricultural and horticultural pest of economically important across the world. The larvae are fruit-boring maggots, living in an independent and enclosed environment within the infested fruits. Up to now it is unknown upon which strategy employed by B. dorsalis to overcome nitrogen stress and develop successfully in the fruits. In this study, we analyzed microbial community diversity and expression profile across different life stages using metagenomics and metatranscriptomics sequencing technology, and investigated the potential functions of microbes in pupae, larvae and adults. Combining with verification tests in vitro, we compared pathway completeness of nitrogenous waste recycling (NWR) and biological nitrogen fixation (BNF) in B. dorsalis based on the annotation results of transcript sequences and KEGG database. The results showed that NWR could be efficiently driven by microbes including Enterobacterales, Flavobacteriales, Lactobacillales, Pseudomonadales and Rhodospirillales. Whereas BNF is ineffective due to its failure at the level of transcription. In addition, dominant microbes mediate essential amino acid biosynthesis by ammonium assimilation and transamination. Our study proposed a novel strategy regarding nitrogen sustainable recycling by gut microbes from nitrogenous waste to amino acid in tephritid fruit fly pests.

Insect odorant receptors: evidence for odorant-binding site access to the lipid bilayer of olfactory receptor neurons

Authors: Renthal Robert[1], Chen Liao, [1]University of Texas at San Antonio, United States

Abstract: The cryo-electron microscopy structure reported for the odorant receptor (OR) from the jumping bristletail Machilis hrabei (MhOR5) shows that the binding site for eugenol, a possible odorant ligand, is blocked from access to the surface of the receptor that faces the antennal lymph. Presumably the odorant is admitted to the ligand-binding site via a protein conformational change that opens up access. In order to explore possible opening mechanisms, we ran molecular dynamics (MD) simulations of MhOR5 and then analyzed the MD trajectories using Caver software to reveal molecular tunnels. Surprisingly, the main tunnel we observed leading out from the eugenol site does not end at the antennal lymph surface but instead connects to the lipid bilayer of the olfactory receptor neuron (ORN) membrane. This tunnel, which we call the lateral port, is located between helices 3 and 4. The MD trajectory shows that a bottleneck in the lateral port transiently opens the eugenol site to the lipid bilayer for 1 to 2 nanosecond periods over a 70 nanosecond interval. Using steered MD, we found that eugenol can dissociate from its binding site and pass through the lateral port bottleneck during transient openings to reach the lipid bilayer, with an energy input of little more than the free energy of binding. The lateral port could be an exit site for odorant deactivation. By entering the lipid bilayer, odorant molecules could become susceptible to deactivation by cytoplasmic P450 enzymes. Alternatively, the lateral port might be the odorant entrance site. The activation of ORs via the lipid bilayer would have interesting implications for the air-to-ORN transport mechanism. The delivery of water-insoluble odorants to ORs, either by odorant-binding proteins or pore tubules, would be able to access a much larger target if the odorants first enter the ORN membrane and then diffuse to the OR binding site.

Urbanization on Aedes sp. (Culicidae) performance: Bottom-up effects on larval habitats along an urbanization gradient in Puerto Rico

Authors: Reyes-Torres Limarie[1], Sweet-Coll Daniela[3] and Guzman-Hernandez Itzel[2], [1]University of Southern Misssissippi, United States, [2]University of Tennessee at Chattanooga, United States, [3]Wesleyan University, United States

Abstract: Urbanization is an important global issue that leads to environmental changes. Mosquito larval habitat bottom-up and top-down effects can change as a result of urbanization. These can in turn influence the abundance and biomass of larvae inhabiting those systems. Aedes aegypti (yellow fever mosquito) and Aedes mediovittatus (Caribbean treehole mosquito) are medically important mosquito species as the former vectors dengue, Zika, chikungunya, and yellow fever, while the later has been shown to vector dengue in Puerto Rico. The objectives of this study were to determine (1) how urbanization influences detrital inputs, nutrients (C and N), and larval competition in containers, and; (2) how these these parameters influence the species performance. Containers were sampled along an urbanization gradient in the San Juan Metropolitan Area in Puerto Rico. Detritus type, composition, and biomass were determined along with mosquito larval, adult, and water nutrients. Urbanization and environmental data was collected. Aedes aegypti and Ae. mediovittatus abundance (larvae and adult) and biomass were recorded from every container and were related to the previously mentioned variables. Twenty six containers were sampled and 1,314 fourth instar Aedes sp. larvae were collected. This study aimed to provide knowledge on how human activity e.g. urbanization, influences the first stage of these medically important mosquitoes, which affect adult population and therefore disease dynamics.

Spatial cognition in the context of foraging styles and information transfer in ants

Authors: Reznikova Zhanna, Institute of Systematics and Ecology of Animals of Siberian Branch of Russian Academy of Sciences, Russia

Abstract: Ants are good candidates for studying cognitive aspects of navigation because they are central-place foragers, always returning to a nest, which demands the ability to encode relationships between features in an environment or an individual's path through the landscape. The distribution of these cognitive responsibilities within a colony depends on the ants' foraging style. Solitary foraging and leader-scouting are the most challenging tasks in the context of ants' spatial cognition requiring exploration, learning, and memory. Solitary foraging was found in species of almost all subfamilies of ants, whereas distant homing based on leader-scouting has been discovered as yet only in the Formica rufa group of species (redwood ants). Surprisingly, these systems, although enormously different in their levels of sociality, have many common traits of individual cognitive navigation, such as the primary use of visual navigation, excellent visual landmark memories, and the subordinate role of odor orientation. However, in contrast to Cataglyphis, the modeling genus for studying cognitive navigation, in which chronological age and physiological development strongly determine their short out-nest life, redwood ants live long, and workers lack pronounced age polyethism. Numerous experiments on spatial cognition in redwood ants treat them regardless of their task-group membership. However, in the leader-scouting species, spatial cognition and abilities to transfer the information about a location dramatically differ among scouts and foragers depending on their cognitive specialization. The ability of scouting individuals to encode sequences of turns along the "binary tree" maze and share this information with foragers can be considered a specific cognitive adaptation closely connected with their searching patterns within the tree crown. Still, it is unknown how redwood ants translate the code in their communication into a trip to their destinations. There is much work to be done to understand what cognitive mechanisms underpin route planning and communication about locations in ants. Studying cognitive navigation in the context of information transfer can provide new insights into spatial cognition in social insects.

Anatomy and function of the olfactory system of malaria mosquitoes Anopheles gambiae

Authors: Riabinina Olena, Durham University, United Kingdom

Abstract: Anopheles gambiae mosquitoes are the major vector of malaria, a disease that affects more than a half of the world's population and results in more than 400.000 deaths every year (WHO report, 2018). Larval and adult mosquitoes rely on their sense of smell to find food sources and avoid repellent substances in their environment. However, the genetic tools to study and alter the function of olfactory neurons are currently very limited. In this talk I will highlight the recent insights into Anopheles olfaction that were acquired with the help of new genetic approaches.

Nesidiocoris tenuis induces type-IV glandular trichomes and acylsucrose- production: implications to control whitefly-transmitted viruses in tomato

Authors: Riahi Chaymaa[4], Urbaneja Alberto[2], Pérez-Hedo Meritxell[2], Fernández-Muñoz Rafael[1] and Moriones Enrique[3], [1]Instituto de Hortofruticultura Subtropical y Mediterránea "La Mayora", [2]Instituto Valenciano de Investigaciones Agrarias, Spain, [3]nstituto de Hortofruticultura Subtropical y Mediterránea "La Mayora", [4]Valencian Institute for Agricultural Research, Spain

Abstract: A trichome-based resistance (WF-resistance) introgressed into cultivated tomato from the wild tomato Solanum pimpinellifolium was shown to be effective to control Bemisia tabaci and Trialeurodes vaporariorum whiteflies (Hemiptera: Aleyrodidae). Protection was based on antixenosis and antibiosis against the whiteflies, associated with the presence of acylsucrose-producing type-IV glandular trichomes. Whitefly resistance was demonstrated to be effective to limit the spread of the begomovirus tomato yellow leaf curl virus (TYLCV) and the crinivirus tomato chlorosis virus (ToCV). Limited protection, however, was observed at the early developmental stages of tomato plants because of reduced acylsucrose production levels. Nevertheless, early induction of type IV glandular trichomes using methyl jasmonate (MeJA) applications helped increase resistance to whiteflies and whitefly-transmitted viruses in young plants. The predatory bug Nesidiocoris tenuis (Hemiptera: Miridae) is frequently used in biological control programs against pests including whiteflies, usually by pre-establishing populations during nursery stages. The phytophagy of N. tenuis was demonstrated to modulate jasmonic acid and salicylic acid signalling pathways in tomatoes. Interestingly, the inoculation of N. tenuis on WF-resistant tomato plants resulted in effective induction of type-IV glandular trichomes and acylsucrose-production. Thus, combining conventional breeding and biological control strategies in IPM programs may control whiteflies and whitefly-transmitted viruses in tomatoes.

The role of phytochemical diversity on multi-trophic interactions

Authors: Richards Lora[2], Philbin Casey[2], Jefferey Christopher[2] and Dyer Lee[1], [1]Biology Department EECB Program University of Nevada Reno, United States, [2]University of Nevada at Reno, United States, [4]University of Nevada, United States

Abstract: Background/Question/Methods
Variation in phytochemical composition and diversity between and within plant species is an important dimension of biodiversity and mediates plant-herbivore-parasitoid interactions. Previous work comparing multiple species in the tropical genus Piper, found that phytochemical diversity is a predictor of herbivore diet breadth, diversity and parasitism. To expand on this work, we will address two main questions: 1) How does variation in phytochemical diversity between Piper species affect caterpillar immune response and thus parasitism? 2) How does abiotic factors, such as light, contribute to variation in phytochemical diversity of a single species of Piper and what are the potential implications to herbivores? To address these questions we took a holistic approach to investigate multiple aspects of phytochemical diversity by analyzing methanolic plant extracts using 1H-NMR and LC-MS. We combined immune data with chemical data to address the first question. For the second question we experimentally placed plants in varying light conditions and quantified the variation in phytochemical diversity and herbivory.

Results/Conclusions
How does variation in phytochemical diversity between Piper species affect caterpillar immune response and thus parasitism? We found that the immune function of specialist caterpillars was negatively associated with the phytochemical diversity of the Piper host plants, and rates of parasitism decreased with higher immune function.
How does abiotic factors, such as light, contribute to variation in phytochemical diversity of a single species of Piper and what are the potential implications to herbivores? We found that phytochemical diversity was inversely related to direct light transmittance. In partitioning phytochemical diversity, we found variation in compound composition and structural complexity. These differences in phytochemistry among individual plants caused by light heterogeneity significantly decreased herbivory. Feeding assays demonstrated a negative photoactive effect on generalist, but not specialist caterpillars.

Conclusion
Variation in phytochemical diversity between species and within species can structure plant-herbivore-parasitoid communities across the landscape and contribute to the maintenance of multi-trophic diversity.

Exploring the potential of gene silencing to manage forest pests: Prospects for the future

Authors: Rieske-Kinney Lynne, Department of Entomology, University of Kentucky, Lexington, KY, United States

Abstract: RNA interference (RNAi) is a highly specific cellular pathway that causes gene knockdown and can result in rapid insect mortality when essential genes are silenced. We are evaluating the use of gene silencing as a means of suppressing wood-boring forest pests. The endemic North American southern pine beetle, Dendroctonus frontalis, undergoes population eruptions and is expanding its geographic range in response to a changing climate. The exotic invasive emerald ash borer, Agrilus planipennis, is rapidly expanding its invaded range throughout North America. Both beetles are responsible for the loss of millions of trees in urban and wildland forests. We have shown that the RNAi pathway can be induced in both insects, and we can cause rapid and extensive mortality of both beetles when essential genes are silenced. Current efforts are focused on identifying optimal target gene(s), assessing effects on potential non-target organisms, and evaluating effective means of delivery. RNAi has potential as a pest management strategy. If this technology can be moved to the deployment phase it could provide an additional tool for integrated pest management against forest pests.

Sensory basis of nectar feeding in mosquitoes

Authors: Riffell Jeff, University of Washington, United States

Abstract: Mosquitoes are important vectors of disease and require sources of carbohydrates for reproduction and survival. Unlike host-related behaviors of mosquitoes, comparatively less is understood about the mechanisms involved in nectar-feeding decisions, or how this sensory information is processed in the mosquito brain. Here we examine the olfactory and visual preferences and neural bases of nectar preferences in Aedes spp. mosquitoes. Using a unique mosquito-flower mutualism, we show that Aedes spp. mosquitoes, including Aedes aegypti, are effective pollinators of the Platanthera obtusata orchid, and demonstrate this mutualism is mediated by the orchid's scent and the balance of excitation and inhibition in the mosquito's antennal lobe (AL). The P. obtusata orchid emits an attractive, nonanal-rich scent, whereas related Platanthera species—not visited by mosquitoes— emit scents dominated by lilac aldehyde. Calcium imaging experiments in the mosquito AL revealed that nonanal and lilac aldehyde each respectively activate the LC2 and AM2 glomerulus, and remarkably, the AM2 glomerulus is also sensitive to N,N-diethylmeta-toluamide (DEET), a mosquito repellent. Lateral inhibition between these 2 glomeruli reflects the level of attraction to the orchid scents. Whereas the enriched nonanal scent of P. obtusata activates the LC2 and suppresses AM2, the high level of lilac aldehyde in the other orchid scents inverts this pattern of glomerular activity, and behavioral attraction is lost. These results demonstrate the ecological importance of mosquitoes beyond operating as disease vectors and open the door toward understanding the neural basis of mosquito nectar-seeking behaviors.

Single Founding Event of an Ambrosia Beetle and Its Fungal Symbiont Threaten Entire Plant Family in North America

Authors: Riggins John[2], Chupp Adam[6], Duerr Don[7], Koch Frank[7], Bares Hannah[1], Smith Jason[5], Formby John[3], Oten Kelly[4], Hughes Marc[5], Dearing Natalie[1] and Brown Richard[1], [1]Mississippi State University, United States, [2]Mississippi State University, United States, [3]New Mexico State Forestry, United States, [4]North Carolina Forest Service, United States, [5]University of Florida, United States, [6]University of South Alabama, United States, [7]USDA Forest Service, United States

Abstract: Laurel wilt is a non-native tree disease that is affecting naïve plants of the family Lauraceae in the southeastern United States. This disease is caused by an introduced vector (Xyleborus glabratus) and a pathogenic fungal symbiont (Raffaelea lauricola). All North American shrub and tree species in the plant family Lauraceae that have been tested thus far are susceptible. We estimate that over 300 million redbay trees (Persea borbonia), or >1/3 of the pre-invasion population, succumbed to the disease within about 15 years of the invasion. We utilized phylogeographic methods to discern the number of introduction events and cold temperature ecophysiology to model the likely eventual range of the beetle. Genetic markers were used to test the hypothesis that the vector and pathogen entered North America as a single introduction, and a single X. glabratus haplotype was detected in the USA. Similarly, amplified fragment length polymorphisms indicated that 54 of 57 examined R. lauricola isolates were of a single clonal genotype; only minor variation was detected in three polymorphic isolates. These data suggest that a single founding event and subsequent anthropogenic terrestrial movement are responsible for the laurel wilt epidemic in the United States. Cold temperature ecophysiology of X. glabratus indicates that less than 1% of sassafras trees in North America occur in a climate cold enough to limit the beetles' eventual range. With such minor limitations on the spread of LWD, trophic cascades in the wake of this devastating invasion are possible. To document this, we compiled a literature-based catalogue of imperiled arthropod herbivores of North American Lauraceae, which yielded a list of 178 associated species, at least 24 of which may suffer substantial declines alongside their lauraceous hosts. Overall, the lack of effective control options and a vector with biology well-suited to invading new territory have enabled LWD to become one of the most destructive plant diseases on record.

Sublethal effects of neurotoxic insecticides in non-model insect pollinators: a new approach to studying acute and chronic neurophysiological effects in living animals

Authors: Rigosi Elisa[1], Nagloo Nicolas[1] and O'Carroll David[1], [1]Lund University, Sweden

Abstract: Insect pollinators are important for natural ecosystems and the human economy, yet are threatened by common agrochemicals in both rural and urban environments. Most insecticides act as neurotoxins in the insect nervous system, however, their more subtle modulation of neural activity at sublethal concentrations are often overlooked. While navigating through the environment, flying insects rely mainly on visual information. Yet how the processing of this information is affected by neurotoxic insecticides is an open question. The majority of studies on this topic have focused on bees despite recent literature showing large variability in insecticide sensitivity across species. This highlights the importance of extending the analysis of sublethal insecticide effects to non-model organisms. Here, we introduce the pollinator fly Eristalis tenax as a new model to study sublethal neurophysiological effects in living individuals stimulated by relevant sensory stimuli for natural behaviour. We developed a new system to orally expose flies and then assess visually sensitive neurons in whole, living animals, viewing computer generated visual scenes. We performed electrophysiological recordings from visual neurons involved in motion detection and flight stabilisation. We compared their physiological responses in chronically exposed animals (and controls) in vivo at different timepoints after exposure. Our data show how the visual neuropils of Eristalis are physiologically resilient to field relevant, chronic exposure of imidacloprid, a widely used cholinergic pesticide. Our techniques could reveal new insights into the neurophysiological impact of virtually any neurotoxic pesticides and open the door for employing the same experimental approach to other insect species.

Invasion of Brown Marmorated Stink Bug in California Crops: What are the Risks to the Almond and other Crop Industries

Authors: Rijal Jhalendra[1], Zalom Frank[2] and Fisher Joanna[2], [1]University of California Agriculture and Natural Resources, United States, [2]University of California Davis, United States

Abstract: Brown marmorated stink bug (Halyomorpha halys) (BMSB) is an invasive insect species from Asia first detected in the United States in the late 1990s and currently spread to over 43 U.S. states, several Canada provinces, and several other countries in Europe. Both adults and nymphs (2nd-5th instars) actively feed on the fruiting structure of the host plants that includes more than 170 species of ornamental and landscape trees, field, vegetable, and tree crops. In California, a large population in the Central Valley region since 2013 in residential areas. BMSB has been spread and established in 16 California counties. We reported the established BMSB population in commercial orchards (peach in 2016; almond in 2017) in the San Joaquin Valley as the first report of crop infestation by BMSB in California. In 2017 and 2018, we conducted monitoring of BMSB in several peach and almond orchards using two types of traps (black pyramid, and sticky panel), baited with BMSB lures. Both BMSB adults and nymphs were captured in several peach and almond orchards in both years indicating the spread of BMSB to a wider area than previously known. California almond is >5 billion USD industry. California is home to over 500, 000 ha of almond production which is accounted for >80% of the world's production. The risk associated with the BMSB infestation in this high-value crop is tremendous. In this presentation, we will report the current status of BMSB invasion and establishment in California agriculture, and associated risks to the whole industry.

Context-dependent selection of sampling plans for Tuta absoluta: dealing with economic uncertainty and risk aversion

Authors: Rincon Diego F.[1], Sánchez-Vivas Diego F.[1] and Borrero-Echeverry Felipe[1], [1]Unit of Biological Control, Tibaitata Research Center, Colombian corporation for agricultural research - AGROSAVIA

Abstract: Decision-making for pest management in agriculture is often assisted by sampling plans that guide users in classifying pest populations and in determining the need for an intervention. Effective procedures that help farmers make informed decisions on pest management favor intrinsic system controls over corrective interventions and reduce costs and detriments to the environment and health. Even though Tuta absoluta is easily recognizable by most tomato growers and that several sampling plans have been developed, adoption of decision-making systems for this pest is still incipient, particularly in developing countries. Two potential reasons are the high start-up investment (greenhouse facility) that makes tomato farmers particularly risk-averse, and the difficulty to estimate economic thresholds because of tomato market price uncertainty. Both, market uncertainty and risk aversion could be dealt with by using sampling plans that allow farmers to plan interventions according to reliable estimations of pest densities and easily adjustable economic thresholds, based on real-time, up-to-date market information. In this study, we developed five different sampling plans and evaluated them using computer simulations and field trials. We compared the efficiency and the ability of each plan to both estimate the actual mean number of larvae per plant and to classify pest populations according to a predefined economic threshold. We also analyzed the time spent, distance walked, and plants examined by human subjects applying each plan on a tomato crop with a T. absoluta infestation slightly over a predefined economic threshold. We show that, even though all sampling plans were originally developed for classifying pest populations, those that deliver the most precise classifications, are poorest in delivering pest density estimations and vice versa. Our findings are consistent for both human subjects and computer simulations. However, the sampling effort as measured by the average number of samples by simulations does not reflect the effort and time spent by human subjects sampling real plants, especially when it comes to binomial sampling, since the ability of humans to detect infested plants increases with experience. Our results show that variable-intensity, as opposed to sequential, plans can provide reliable information on a current level of T. absoluta infestation which can be used by farmers to decide on the level of reaction required to prevent the pest from reaching the economic injury level. We stressed on the benefits of plans that promote an increase in the distance walked within crops, especially for systems that regularly require intensive labor and are exposed to a wide diversity of pests and diseases, such as greenhouse tomato. The adoption and applicability of the developed sampling plans are assessed in light of crop size and phenology, presence of other sanitary problems and farmer´s willingness to reduce risk by collecting additional data.

Tsetse microbiota: Why where matters

Authors: Rio Rita, West Virginia University, United States

Abstract: Convergent evolution is exemplified by digestive tract microbiota that enable animal survival on restricted diets. Although the proclivity of these microbiota towards providing essential nutrients is similar, the specific metabolites provisioned are largely shaped by host dietary ecology. The strictly hematophagous tsetse fly (Diptera: Glossinidae), the sole vector of lethal African trypanosomes, contains a naturally simple microbiota with members exhibiting relations spanning from mutualism to parasitism. Various sequencing platforms coupled with targeted experimental assays support interdependence between tsetse and its microbiota towards metabolic provisioning, tsetse fitness, immunological priming and vector competence. Here, we detail tsetse global metabolomics obtained through nuclear magnetic resonance (NMR)-based spectrometry. Principal component analyses indicate significant metabolic differentiation between the tsetse bacteriome (the organ that exclusively harbors the ancient mutualist Wigglesworthia glossinidia) and the midgut (predominantly housing the facultative Sodalis glossinidius). Symbiont removal via antibiotic administration significantly alters the abundance of the majority of amino acids (i.e. 14 of 21) within the gut. Simultaneously, significantly higher levels of citrate (a TCA cycle intermediate) and uridine indicate impacts towards tsetse energy expenditure upon symbiont loss. Lastly, we discuss distinctions in Wigglesworthia activity following host species co-diversification. Despite only minor genome differences between Wigglesworthia isolates, transcriptional profiles within different tsetse species were significantly different in Clusters of Orthologous Groups of proteins (COGs) involved in carbohydrate, amino acid and lipid transport and metabolism. These results support symbiont functional differences arising from co-speciation. Manipulation of tsetse-microbiota metabolic coordination offers novel control strategies towards vector population control.

Grapevine cultivar affects insect vector fitness and feeding behavior

Authors: Ripamonti Matteo, Galetto Luciana, Marzachì Cristina, Cornara Daniele, Fereres Alberto, Rossi Marika and Bosco Domenico

Abstract: Scaphoideus titanus is the main vector of the Flavescence dorée (FD) phytoplasma, a wall-less bacteria associated with the FD disease of grapevine. This disease is causing severe losses to European viticulture and is continuously spreading year after year. The main preventive measures rely on insecticide treatments against the vector in the vineyard, removal of feral host grapevines outside the field, and use of healthy plant material. For a more sustainable viticulture, effective and environment friendly measures are needed. One of the possibilities to fulfil this objective is represented by plant resistance against the insect vector or the disease. After having defined a susceptibility range to FD among several grapevine cultivars, three of them were selected at the extremes of the range to describe S. titanus fitness and feeding behavior: Barbera as extremely susceptible to FD, Brachetto and Moscato as (partially) resistant to FD. Some preliminary results suggested the possibility that Moscato may resist to FD by indirectly acting against the leafhopper vector. To test this hypothesis, leafhopper fitness parameters were measured on the three cultivars, as well as feeding behaviors. Fitness was estimated by measuring nymphal developmental time, nymphal mortality, adult longevity, and female prolificacy. Feeding behavior was described using the electropenetrography (EPG) technique. In all the experiments, significant differences in fitness and feeding behavior were found among the grapevine varieties. Nymphal developmental time and mortality were significantly higher on Moscato and Brachetto, compared to Barbera. On the former two varieties, adult longevity and female prolificacy, measured as number of mature eggs per female and vitellogenin gene expression, were reduced. S. titanus feeding behavior was heavily affected by the cultivar, in particular after the first phloem contact. On Barbera, the leafhopper was able to sustain longer phloem phases with less frequent salivations, compared to Brachetto and especially Moscato. In this latter cultivar, S. titanus showed the most disturbed behavior, with less, shorter and more interrupted phloem phases. These results suggests that Moscato and Brachetto are less preferred than Barbera for S. titanus. We suggest that the impaired fitness of S. titanus on Moscato, may be due to antibiosis. while the impaired feeding behavior may be due to antixenosis mechanisms acting against the leafhopper. These two resistance mechanisms could represent a viable and successful way to counteract the spread of S. titanus and of FD phytoplasmas.

Variability of a cooperative defense behavior in social pine sawflies

Authors: Ritter Raphael[2], Wutke Saskia[1], Helanterä Heikki[4], Tynkkynen Riikka[3] and Lindstedt-Kareksela Carita[2], [1]University of Eastern Finland, [2]University of Helsinki, [3]University of Jyväskylä, [4]University of Oulu

Abstract: To determine the evolutionary potential of cooperative traits, we need to identify the genetic and environmental sources of their phenotypic variation upon which selection acts. In addition to collecting phenotypic data from wild and lab-reared populations, this also requires using quantitative genetic and molecular methods. By doing so, we studied the sources of variation in a cooperative behavior using the socially behaving pine sawflies Diprion pini and Neodiprion sertifer. During the larval stage both species feed and defend gregariously in groups of 20-100 individuals. They are specialized on pines from which they sequester defensive compounds for their defense. When attacked, the larvae raise their head and regurgitate a resinous fluid in concert which makes them less profitable for predators and parasitoid wasps. The advantage of this system is that there is natural variation in the benefits and costs of cooperation as well as in the expression of this behavior. We can also quantify the individual contribution to cooperation. This gives us the possibility to measure correlations between investment into cooperation and other life-history traits and to identify potential phenotypic and genetic constraints. We discuss how these results will increase our understanding of the mechanisms shaping cooperative behaviors.

Use of I Imaging Mass Spectrometry to Assess the Distribution of Pesticides in Insects

Authors: Riveron Miranda Jacob[2], Milnes Phillip[1], Hawkins Joe[1] and Johnson Stephen[1], [1]Syngenta, [2]Syngenta, United Kingdom

Abstract: Developing new eco-friendly pesticides, able to break the resistance of agricultural pest, is critical to secure food production. However, it is not an easy task. In many early-stage development projects, the compound's in vitro activity and the compound's in vivo efficacy do not correlate as expected. This lack of translation between in vitro and in vivo activity leads to investigating aspects of the bio-delivery pathway and its associated ADME processes. The analysis of the location of xenobiotics compounds, once it goes into the organism, gives useful information to understand the factors that limit the compound's in vivo activity. However, the study of the location of compounds in arthropod pests presents a big challenge. These include: the arthropod's small size, the difficulties in dissecting organs, the use of unlabelled compounds and low sub-lethal dosages. In collaboration with the National Physical Laboratory, Syngenta has explored the uses of new spectrometry imaging to measure compound uptake, distribution within the insect, and most importantly, if it is reaching the target site. Our results show that, although it is a promising technique, when applied in environmentally relevant doses, improving the methods for the sample preparation as well as the sensitivity of the techniques is necessary.

Chemical Ecology of Belowground Plant-Herbivore Interactions

Authors: Robert Christelle[1], Ali Jared[2], [1]Institute of Plant Sciences, University of Bern, Switzerland, [2]Multi-trophic Interactions & Chemical Ecology, Pennsylvania State University, United States

Abstract: While recognized as crucial drivers of many ecological processes, belowground interactions remain overlooked. This session aims at gathering the state-of-the-art knowledge on the infochemical pathways shaping interactions between plants, herbivores and soil-dwelling communities. Upon herbivory, plants dynamically reallocate their resources through changes in primary and secondary metabolisms affecting their above and belowground systems. These changes can result in the production of toxic secondary metabolites as well as in the release of exudate and volatile compounds. Yet, it is becoming increasingly evident that some belowground specialist herbivores have evolved the ability to utilize secondary metabolites for their own benefit, including feeding site selection, nutrition and protection against natural enemies. The role of herbivore gut microbiome in such adaptations will be highlighted and may lead to the development of further efficient pest management strategies. On the other hand, the production and release of exudates and volatiles in the rhizosphere has been reported as an efficient indirect defense strategy, attracting the predators of the herbivores. However, these signals may alter the behavior and performance of the herbivores themselves, as well as of neighbouring plants. The consequences of root signals for plants and herbivores will be discussed. The root metabolism, and its reconfiguration upon herbivory, shapes the physical, chemical and biological properties of the surrounding rhizosphere. For instance, soil-dwelling microbial communities are affected by these changes and can in turn alter the plant defense against herbivores. Because belowground interactions depend on the soil properties, they also depend on the soil history, location and use. Soil feedbacks and plant diversity are two examples that will be presented during the session. Overall, our understanding of belowground chemical interactions has been rapidly advancing. This symposium aims at consolidating the knowledge of leading research in the field, while stimulating future directions.

Understanding Environmental Risk Assessment for GE Crops and What it Means for Current and Future Pest Protection

Authors: Roberts Andrew, Agriculture & Food Systems Institute, United States

Abstract: The earliest regulatory frameworks for genetically engineered (GE) organisms were conceived in the mid 1980s, and the first commercial applications for GE crops arrived less than a decade later. These were accompanied by the development of environmental risk assessment frameworks that were informed by prior experience primarily from two sources: chemical risk assessment and biological risk assessments associated with sanitary and phytosanitary regulations. The resulting paradigm, refined over more than 30 years, has proven to be effective in ensuring that GE crops released for use in agriculture don't have unacceptable harmful impacts on the environment. Understanding this paradigm, and the principles behind it, now recognized internationally and applied by nearly every regulatory system in the world that addresses GE plants, offers some insight into how future technologies may be regulated.

Characterizing the Role and Transmission of Endosymbionts of the Spotted Lanternfly

Authors: Roberts Dana, Pennsylvania State University, United States

Abstract: While many insects are known to harbor obligate bacterial endosymbionts, members of the Hemipteran suborder Auchenorrhyncha (the lineage comprising planthoppers, and their sister lineage, Cicadomorpha, comprising tree+leafhoppers, cicadas, and spittlebugs) represent an extreme in that they exhibit a "hunger for symbionts". Spotted Lanternfly (and other Fulgoridae) harbor three obligate endosymbionts: Sulcia muelleri, Vidania fulgoroideae, and a newly described Gammaproteobacterium. Results of genome sequencing of these three endosymbionts will be presented, as these reveal the roles each endosymbiont plays in Spotted Lanternfly biology. Results will also be presented that characterize the stages of female reproductive development in which organs housing each endosymbiont (bacteriomes) change in morphology and position in order to facilitate transmission of bacteria to developing eggs.

Planthopper Endosymbionts: What we currently know about transmission, function, and diversity within Fulgoroidea

Authors: Roberts Dana, Pennsylvania State University, United States

Abstract: The planthopper superfamily, Fulgoroidea, is a speciose lineage of hemipteroid insects that relies upon bacterial and fungal symbionts with which they have co-evolved for tens of millions of years. Although other sap-feeding hemipteroids also harbor symbionts, planthoppers are unique in the way they house these symbionts. Endosymbionts are housed in organs or bacteriomes that vary considerably in their position and morphology across the 21 planthopper families. This variation in bacteriomes has implications for how these insects manage endosymbiont function and transmission. It may also contribute to the remarkable turnover and replacement of endosymbiont "species" observed throughout the superfamily. This presentation will present data from surveys of bacterial symbionts sampled from planthoppers representing 18 of the 21 planthopper families to summarize known endosymbionts and replacement events across the planthopper phylogeny. It will also present data on the function of the three endosymbionts of the invasive spotted lanternfly, Lycorma delicatula (Hemiptera: Fulgoridae) as inferred through endosymbiont genome sequencing. Data will also be presented on the phenology of female spotted lanternfly development that identifies key stages in the transmission of endosymbionts from bacteriomes to ovarioles. Comparison will be made to the rice pest Nilaparvata lugens (Hemiptera: Delphacidae) to identify key similarities and distinctions of symbiont dynamics in this distantly related pestiferous planthopper.

Using chemical ecology to enhance biocontrol of aphids

Authors: Roberts Joe[3], Bruce Toby[4], Ali Jamin[4], Pickett John[2], Birkett Michael[1], Woodcock Christine[6], Martin Janet[6], Smart Lesley[6], Wadhams Lester[6] and Jacobson Rob[5], [1]Biointeractions and Crop Protection Department, Rothamsted Research, United Kingdom, [2]Cardiff University, United Kingdom, [3]Harper Adams University, United Kingdom, [4]Keele University, United Kingdom, [5]Rob Jacobson Consultancy, United Kingdom, [6]Rothamsted Research, United Kingdom

Abstract: Chemical ecology explores the chemicals involved in ecological interactions between living organisms. Natural enemies of aphids have evolved intricate ways of efficiently detecting and locating their prey. They respond to signals associated with herbivore damaged plants and can “eavesdrop” on pheromones of their prey and use them as foraging cues. If we could enhance and manipulate such cues and signals in agricultural ecosystems, perhaps we could improve biocontrol of aphids?

There are a number of possible strategies for using chemical ecology to enhance biocontrol of aphids:
1. Activation of plant defence e.g. with cis-jasmone. A plant defence activator may make plants more attractive to natural enemies.
2. Improving plant signalling – this strategy uses aphid responsive crop varieties that release induced volatiles to attract natural enemies when they are attacked by aphids. Induced indirect defence may be amplified if there is plant-plant communication where plants are sensitive to aphid induced stress signals from their neighbours or if there are warning signals conducted through mycorrhizal connections between plants.
3. Attraction of natural enemies to dispensers (or engineered plants) releasing aphid pheromones such as alarm pheromone, (E)-ß-farnesene or aphid sex pheromone, nepetalactone.
4. Lure and reward – attracting natural enemies to supplementary food sources. This may reinforce behavioural responses to infochemicals through positive associative learning (honest signalling), as well as providing nutritional resources to sustain natural enemy populations when prey populations are low.
5. Lure and kill – this is a different strategy and deploys infochemicals attractive to the aphids themselves to lure aphids to killing agents which, in this context, would be biocontrol agents such as entomopathogenic fungi.
6. Suppression of hyperparasitoid populations – if hyperparasitism could be reduced, for example by trapping hyperparasitoids with baited traps, then the efficiency of primary aphids parasitoids would be improved.

Insect responsiveness to infochemicals can vary over time and space according to the condition of the insect and the environment. Insects process volatile signals and react differently to them according to the blend composition, the context within which they are perceived, previous experience and how the odours are released over time. For example, Aphis fabae, is attracted to a blend of host odours but repelled by the same compounds if released individually and Sitobion avenae is repelled by alarm pheromone (E)-ß-farnesene but only if exposed to a short burst and not if there is prolonged exposure. Adjusting behavioural responses gives insects the flexibility to adapt to changing environments with different host availability and by integrating many signals they get a more robust picture of their external environment. These factors need to be considered when designing control strategies based on infochemicals.

Novel delivery of phytochemicals for sustainable crop protection

Authors: Roberts Joe[3], Bruce Toby[4], Buss David[5], Alsuraifi Ali[1] and Hoskins Clare[2], [1]College of Dentistry, University of Basrah, Iraq, [2]Dept. of Pure and Applied Chemistry, University of Strathclyde,United Kingdom, [3]Harper Adams University, United Kingdom, [4]Keele University, United Kingdom, [5]School of Life Sciences, Keele University, Staffordshire, United Kingdom

Abstract: New solutions are urgently needed for managing insect pests of crops as they evolve resistance to currently available insecticides. This project integrates chemistry, nanotechnology and entomology to provide a new way of delivering bioactive phytochemicals via nanotech complexes for use against insect pests.
Over millions of years, wild plants have evolved effective insecticidal and repellent defensive phytochemicals. However, some of these compounds have been subsequently lost from commercial crops during the breeding process, making the crops more vulnerable to insect attack and thus requiring human intervention for protection. Applying phytochemicals to crops can redress this balance. We hypothesise that this effect is bigger if phytochemicals from outside the crop metabolome are used, as pests of that crop may not have a history of exposure to them and thus may not have evolved resistance to them. However, there are multiple difficulties in using these products in a commercial setting: 1) Many are hydrophobic, and thus do not dissolve easily in water, making application difficult. This applies especially to essential oils. 2) Their volatile nature and low environmental persistence reduces any effectiveness in the field. 3) These same characteristics make storage and transport challenging.
This project uses new developments in nanotechnology to overcome these difficulties. In order to provide an environmentally friendly final product, we have developed a second-generation polymer composed solely of MHRA- and FDA-approved materials. This polymer encapsulates the active ingredient, the phytochemical. This new formulation is now hydrophilic, allowing suspension in water and therefore much easier utilisation and application. It also has modified physical properties giving greater effectiveness in the field.
In total, 32 essential oils and 20 pure compounds have been formulated and assessed for toxicity to the aphid Myzus persicae. Treatments were assessed under fumigant and ventilated conditions and for phytotoxicity, and from this several promising candidates, with good performance against the target pest (> 70% mortality and complete shutdown of aphid reproduction) but low phytotoxicity, have been selected. Promising formulations have also been successfully assessed against Western Flower Thrips, Frankliniella occidentalis.

Role of Nutrition in Resistance to Viral Challenge

Authors: Roberts Katherine[2], Longdon Ben[2] and Boots Mike[1], [1]University of California, Berkeley, United States, [2]University of Exeter, United Kingdom

Abstract: Nutrition is critical in determining a host's ability to resist or tolerate a parasite challenge. This is due not only to a challenged host having to meet the potential associated costs of launching an immune response, but also the fact that both tolerance and resistance mechanisms may compete with other traits for finite resources.

Laboratory experiments into the outcomes of viral infection in invertebrates are often carried out in ad libitum - resource rich environments. These are not only unrealistic of interactions that would other wise be occurring in a variable natural world, but can lead to masking of any real costs associated with a defensive response or at worst misleading conclusions.

Here, I present work that highlights the importance of nutrition across a number of biological scales. From the within individual response to viral infection, to the evolution of population level immunity when evolved in the presence of a viral pathogen in a nutrition poor environment.

At an individual level, we find that the immune response is polygenetic, but the number of genes responding after viral challenge is diet specific, with individuals in a higher resource environment having a greater level of gene down-regulation. Whilst at a population level using selection experiments and whole genome re-sequencing we identify putative mechanisms of resistance that vary between nutritional environments. Genome re-sequencing of evolved hosts show that resistance mechanisms are, again, highly polygenic. It also suggests that the underlying genetic architecture may differ depending on the nutritional environment.

I also present evidence that the resource environment of a host may influence the likelihood of a viral pathogen undergoing a host shift into a novel host.

These results suggest that immune responses are not purely driven by a viral challenge, but likely to involve active modulation of immune regulation by a host, as a function of the resource availability they have. Thus, as a whole, my results emphasise the importance of nutritional resources on the outcome of host parasite interactions and the subsequent evolution of resistance.

The evolution of extreme fertility defied ancestral gonadotropin mediated brain-reproduction tradeoff

Authors: Robinson Gene[3], Bloch Guy[1], Herb Brian, Shpigler Hagai[2] and Band Mark, [1]"Department of Ecology, Evolution and Behavior, The Alexander Silberman Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel, [2]Department of Ecology, Evolution and Behavior, The Alexander Silberman Institute of Life Sciences, The Hebrew University of Jerusalem, Israel, [3]United States

Abstract: Gonadotropic hormones coordinate processes in diverse tissues regulating animal reproductive physiology and behavior. Juvenile hormone (JH) is the ancient and most common gonadotropin in insects, but not in advanced eusocial honey bees and ants. To probe the evolutionary basis of this change, we combined endocrine manipulations, transcriptomics, and behavioral analyses to study JH regulated processes in a bumble bee showing an intermediate level of sociliality. We found that in the fat body, more JH-regulated genes were upregulated and enriched for metabolic and biosynthetic pathways. This transcriptomic pattern is consistent with earlier evidence that JH is the major gonadotropin in the bumble bee. In the brain, most JH-regulated genes were downregulated and enriched for protein turnover pathways. Brain ribosomal protein gene expression was similarly downregulated in dominant workers, which naturally have high JH titers. In other species, similar downregulation of protein turnover is found in aging brains or under stress, and is associated with compromised long-term memory and health. These findings suggest a previously unknown gonadotropin-mediated tradeoff. We did not find a similar downregulation of protein turnover pathways in the brain of honey bees in which JH is not a gonadotropin but rather regulates division of labor. These differences between JH effets in the bumble bee and in the advanced eusocial honey bee suggest that the evolution of advanced eusociality was associated with modifications in hormonal signaling supporting extended and extremely high fertility while reducing the ancient costs of high gonadotropin titers to the brain.

Leaf-cutting ants learn from their efforts: foragers recall olfactory memories to avoid plants they previously experienced as hard to cut

Authors: Roces Flavio[1], Leberecht Bo[1], Bollazzi Martin[2] and Garcia Mateo[2], [1]Department of Behavioral Physiology and Sociobiology, Biocenter, University of Würzburg, Germany, [2]Entomology Unit, Department of Plant Protection, Agronomy Faculty, University of the Republic, Montevideo, Uruguay

Abstract: Leaf-cutting ants reject previously-accepted plants if they prove to be unsuitable for their symbiotic fungus, a phenomenon that involves olfactory avoidance learning. We asked whether olfactory memory also underlies the avoidance of suitable plants that were previously experienced as hard to cut. Would ants associate an odor with a high cutting effort and would the odor be sufficient to recall such a negative association, leading to subsequent plant avoidance? In the laboratory, naïve workers of the leaf-cutting ant Acromyrmex lundii were initially tested for their spontaneous preferences for different odors in a binary-choice olfactometer. Then, colonies were offered pseudo-leaves (of inert material) of two different toughness, i.e., easily and hard to cut, scented with specific odors, to allow workers to gain experience with them over three days. One day later, putative experience-dependent changes in odor preferences were quantified both as individual responses using the binary-choice assay, and as a colony-wide foraging response when the two odors were offered on soft material, to reveal odor-guided preferences irrespective of the mechanical properties of the material actually cut. After their experience with the two scented materials of different toughness, single workers developed a marked learned preference for the odor associated with the soft material, and colonies foraged more material scented with the odor paired with the low cutting effort. Additional evidence for the learned avoidance of odors that are only associated with the increased cutting effort was indirectly obtained in an experiment that involved no cutting effort at all, by offering scented, yet transportable discs of tough and thin leaves over three days. Ants showed no change in their spontaneous odor preference after their foraging experience with the scented discs that required no cutting behavior to be transported, which is consistent with the idea that ant workers learn to olfactorily recognize, and to avoid, only those leaves they previously experienced as hard to cut.

Aedes and Climate Change – mechanisms, predictions and uncertainties

Authors: Rocklöv Joacim, Section of Sustainable Health, Department of Public Health and Clinical Medicine, Umeå University, Sweden

Abstract: This review focuses on the latest research on the linkages between Aedes aegypti and Aedes albopictus and climate change. It synthesizes literature on the influence of changes in climate on vector-related factors, including potential changes in geographical ranges, abundance, and time trends. The importance of other drivers is also discussed. Literature on the vectoral capacity for selected Arboviruses is further synthesized and discussed with respect to the same.

The presentation further elaborates on results from studies involving predictions and projections using scenarios of future change in climate. The potential impact of climate change is looked at both in isolation and in combination with socio-economic factors, such as mobility and development. The synthesis further contrasts modelling scenarios based on different pathways for future changes in atmospheric CO2 concentration.

In the review, findings are contrasted between mechanistic and process-based models, with a discussion of the implications of associations from fitted observational data. Finally, the study concludes by highlighting knowledge gaps, and limitations of the current state-of-the-art on research of Aedes mosquitoes and climate change. It stresses the need for specific research to better understand the relationship between changes in climate, socio-economic development, and the proliferation of vectors and their respective abilities to transmit virus as a function of changes in local climate conditions.

Feeding behaviors of Yamatotettix flavovittatus Matsumura (Hemiptera: Cicadellidae) a vector of sugarcane white leaf phytoplasma using electrical penetration graphs (EPGs)

Authors: Roddee Jariya[2], Tongkaw Jirachatr[2], Thepjit Kannika[2] and Hanboonsong Yupa[1], [2]Institute of Agricultural Technology, Suranaree University of Technology, Thailand

Abstract: The leafhopper, Yamatotettix flavovittatus Matsumura (Hemiptera: Cicadellidae), is an efficient vector of sugarcane white leaf phytoplasma. Acquisition and inoculation of phytoplasma occur sometime during the process of stylet penetration into the sugarcane plant. That process is most rigorously studied via electrical penetration graph (EPG) monitoring of insect feeding. The probing behavior of the Y. flavovittatus was studied with an electrical penetration graph (EPG-DC system) technique. EPG waveforms were described based on amplitude, frequency, voltage level, and electrical origin of the observed traces during stylet penetration into sugarcane plant tissues. Additionally, through a histological study using leaf cross-sections revealing, the observed locations of the stylet tips in the plant tissue were compared to EPG probing waveforms, salivary sheath locations. This study provides part of the crucial biological meanings that define the waveforms of each new insect species recorded by EPG. The behavioral activities were also inferred based on waveform similarities in relation to other leafhoppers. By analyzing 10-h EPGs of adult females five waveforms were described: NP, A, B, C, and D. Non-penetration, NP was non-probing when the stylets did not penetrate; waveform A occurred at the beginning of stylet penetration. This waveform was detected with stylet penetration into the epidermal cells; waveform B was correlated with stylet penetration into the parenchyma and mesophyll cells; waveform C was correlated to salivation; and waveform D was correlated with ingestion, which was the longest activity observed. This detailed understanding of the stylet penetration behaviors of Y. flavovittatus is an important step toward identifying the instant of phytoplasma inoculation which, in turn, will be applied to studies of disease epidemiology and development of host plant resistance.

Community-level change in insect abundance and biomass over 50 years in a northern forest

Authors: Rodenhouse Nicholas[2] and Holmes Richard[1], [1]Dartmouth College, [2]Wellesley College, United States

Abstract: Long-term community-level study of insects is rarely embedded within an ecosystem study, but this context can provide the data needed to assess drivers of change. Monitoring and experimental study of insects and birds began in 1969 at the Hubbard Brook Experimental Forest, New Hampshire, USA, and continues. Caterpillar and flying insect abundance were monitored using visual surveys and Malaise traps, respectively, from late May to early August. Results showed that caterpillar abundance fell by half, due to the loss of outbreak peaks after the 1980s. Coleoptera captured per 24-hr declined 60%, but pulsed inputs of coarse woody debris were associated with Coleoptera increases that each lasted a decade. Trichoptera and Plecoptera showed a convex pattern of change related to minimum stream flow and stream water pH. Abundance of all flying insect taxa did not decrease, largely because Diptera showed no trend and comprised on average 61% of individuals captured. Total biomass of all taxa measured at low, mid and high elevation, 1996-2018, declined significantly but only at high elevation. We will show how these dramatic changes in the structure and dynamics of the forest insect community can be linked to climate change and forest disturbance.

An Iron Fist in a Velvet Glove: Unraveling the systematics and Müllerian mysteries of the Australian Velvet ants (Hymenoptera: Mutillidae)

Authors: Rodriguez Juanita[1], Giannotta Madalene[2], [1]Australian National Insect Collection-CSIRO, Canberra, ACT, Australia, [2]Division of Ecology and Evolution, Research School of Biology, and Centre for Biodiversity Analysis, Australian National University, Acton, ACT, Australia

Abstract: The Mutillidae (Velvet ants) is a cosmopolitan family of aposematically coloured parasitoid wasps known to form Müllerian mimicry complexes. Recent studies on the North American mutillid fauna have revealed mimicry rings, within which, multiple species that share highly discernible colour patterns are bound by discrete geographical ranges. This is concordant with the assumption that all unpalatable species within an area will adverge on an effective warning signal. Pilot studies at the Australian National Insect Collection, which assessed more than 5,000 Australian mutillid specimens (females only), identified four colouration complexes indicative of Müllerian mimicry. Unlike that of the North American system, each putative mimicry ring exhibited widespread, sympatric distributions that were not geographically delimited. If Müllerian mimicry is occurring, the high geographic overlap may be explained by a single origin of colour pattern or by convergent evolution, however, without a robust taxonomic framework, these hypotheses cannot be tested. Currently, no molecular phylogeny exists for the Australian Mutillidae and species/generic boundaries are poorly defined - a result of highly pronounced sexual dimorphism and morphological similarities. Using a comprehensive morphological and Ultra Conserved Element (UCE) dataset, this project aims to study the evolution of mutillid colouration patterns by testing the phylogenetic relatedness of all 260 described Australian species, along with 300 additional Australian morpho-types. Finding non-monophyletic mimetic taxa will negate the hypothesis that species have evolved from a common ancestor with subsequent dispersals across the Australian continent. However, finding polyphyletic taxa would do little to explain why multiple aposematic signals are being conserved in sympatric populations. One possible explanation is that niche partitioning within particular geographic regions may be maintaining the putative mimetic diversity. The present study further aims to test if mimicry rings are associated with particular habitats/microhabitats by linking environmental and ecological data with fine-scale distribution data that is mapped on to the inferred phylogeny. Via the reconstruction of the first-ever molecular phylogeny for the Australian Mutillidae, the present study will provide a framework for unraveling the evolutionary origins and relationships of this poorly studied parasitoid family. Furthermore, the study will begin to develop an understanding of the genetic basis, and mechanisms, shaping the phenotypic diversity and mimicry of Australian mutillids.

The first described pergid fossil with implications on the evolution and biogeography of Pergidae

Authors: Rodriguez Juanita[2], Macdonald John[1] and Frese Michael[3], [2]Australian National Insect Collection-CSIRO, Canberra, ACT, Australia, [1]Australian Museum, Sydney, Australia, [3]University of Canberra, Canberra, ACT, Australia

Abstract: The evolution of adaptive traits such as resistance to plant toxins in herbivores is often obscured by the absence of accurate phylogenetic dating mainly caused by lack of well-preserved fossil specimens. In Southern hemisphere groups, such as Pergid sawflies, this problem is exacerbated by the sparsity of the fossil record in the Southern latitudes. No Pergidae fossils had been discovered so far. Using morphological and molecular data we aim to determine the phylogenetic placement of anewly discovered Pergidae fossil from the Talbragar fossil beds, and use it for divergence time estimation of the pergid phylogeny and determine implications on the evolution of toxicity resistance in early Hymenoptera. We analysed a combined morphological and molecular dataset using a phylogenetic Bayesian framework. The phylogenetic results suggest that the fossil sawfly belongs to the clade formed by Acordulecerinae (including Phylacteophaginae) and Perginae. Within this clade it issister to Phylacteophaginae, which is an exclusively Australian group. This relationship was recovered with a low posterior probability, which impedes placing the fossil at the subfamily level. Our results suggest that spitfire sawflies (Pergidae) originated in the UpperCretaceous (ca 101 Ma) and not in the Late Jurassic, as previously proposed. This suggests that the presence of the family in South America and Australia is probably a result of both vicariance through the late break-up of Gondwana and connectivity through Antarctica. Divergence time and host plantshows that Pergidae switched to the use of Myrtaceae at least four times intependently throughout the evolutionaryhistory of the group. The first switchtook place in the Upper Cretaceous, close to 80Ma, which coincides with the origin of crow-group Myrtaceae. Other switches took place in the Eocene, closer to the age of Eucalypts. This is the first fossil Pergidae, whose discovery has implications for the historical biogeography of Pergidae and the evolution of early Hymenoptera.

Phytoplasma infection influences cranberry interactions with insect herbivores

Authors: Rodriguez-Saona Cesar[2], De Moraes Consuelo[1], Polaschock James[3], Mescher Mark[1] and Pradit Nakorn[2], [1]ETH Zurich, Switzerland, [2]Rutgers University, United States, [3]USDA-ARS, United States

Abstract: Phytoplasma infection causes false blossom disease in cranberries, which is vectored by the blunt-nosed leafhopper (Limotettix vaccinii). We explored how phytoplasma infection of cranberries affects L. vaccinii and three non-vector Lepidopteran herbivores: spotted fireworm (Choristoneura parallela), Sparganothis fruitworm (Sparganothis sulfureana), and gypsy moth (Lymantria dispar). Additionally, we compared levels of nutrients, phenolics, and phytohormones, as well as volatile emissions and transcriptome profiles between infected and uninfected plants. Our oviposition data showed a preference of L. vaccinii for uninfected plants, whereas our attraction data showed no preference between infected and uninfected plants. While slower development on phytoplasma-infected cranberry plants led to larger L. vaccinii adult size, there was no evidence for any beneficial effects of infection on other performance parameters. Larvae of all three non-vector species grew 2–3 times bigger, and damaged 1.5–3.5 times more leaves, when feeding on infected plants; larval survival of one of them was also ~1.5 times higher on infected plants. Levels of ten nutrients, including nitrogen, were higher in infected plants, while levels of defensive proanthocyanidins were reduced by 20–40% compared to uninfected plants. At the molecular level, phytoplasma infection increased the expression of genes associated with nutrient metabolism, while suppressing genes associated with defensive pathways. While uninfected plants emitted higher amounts of volatiles than infected plants, we observed no effect of infection on phytohormone levels. In conclusion, phytoplasma infection through changes in phytochemistry and gene expression enhanced host-quality of cranberries to non-vector herbivores, although the benefits on its vector are less clear.

Guttation: A nutrient-rich natural food source for insects

Authors: Rodriguez-Saona Cesar[3], Urbaneja Bernat Pablo[2], Tena Alejandro[1] and Gonzalez-cabrera Joel[4], [1]Instituto Valenciano de Investigaciones Agrarias, Spain, [2]Rutgers University, New Brunswick, New Jersey, United States, [3]Rutgers University, United States, [4]University of Valencia, Spain

Abstract: Guttation is the appearance in plants of xylem drops at the tips or edges of their leaves. These fluids are usually rich in sugars and amino acids. Although guttation fluids are reported from many plant species, little is known on their effects on insects, particularly agricultural pests. In the present study, we hypothesized that guttation fluids produced by highbush blueberry (Vaccinium corymbosum; Ericaceae) provide a suitable food source for the survival of insect pests. To test this hypothesis, we determined the effects of guttation on the adult longevity of a frugivorous pest, spotted wing drosophila (Drosophila suzukii) and two beneficial insects, the wasp Aphidius ervi and the predator Chrysoperla rufilabris. Newly emerged adults were fed daily either: 1) guttation from blueberry leaves, 2) sugar solution (i.e., sucrose, as positive control), 3) protein, 4) sugar plus protein and 5) water (as negative control) under controlled laboratory conditions. Adult longevity and other fitness parameters were measured for these insects compared among the five treatments. Preliminary results indicate that insect survival is enhanced when feeding on guttation fluids. These results will be discussed in relation to the composition of the guttation fluid. This study documents for the first time the potential effects of guttation on this invasive pest and beneficial insects in an agro-ecosystem.

Developmental plasticity in spruce budworm and the importance of intraspecific variability

Authors: Roe Amanda[1], Wardlaw Ashlyn[1], Candau Jean-Noel[1] and Perrault Kerry[1], [1]Natural Resources Canada, Canadian Forest Service, Great Lakes Forestry Centre, Canada

Abstract: Spruce budworm (SBW) is a familiar native insect that is responsible for extensive defoliation throughout the North American boreal forest. SBW experiences cyclical population outbreaks and predicting SBW population dynamics is crucial for effective management. Much of our understanding of SBW biology was based on insects reared in the Insect Production and Quarantine facility at the Great Lakes Forestry Centre, so there are concerns that these insects may not reflect the true range of variability expressed in wild populations. We now have five colonies established from wild populations from across the range of SBW. We've documented surprising variability within the wild populations, contradicting long held assumptions of the growth and development of SBW. These traits can significantly impact our developmental models and may help explain known disconnects between predicted and observed SBW population dynamics.

Novel Textile for the Protection of Agricultural Crops

Authors: Roe R. Michael[1], Cave Grayson[3], West Andre[4], Koene Bryan[2], Benjamin Beck J.[2], Zhu Jiwei[3] and McCord Marian[3], [1]Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, [2]Luna Innovations, United States, [3]North Carolina State University, United States, [4]Wilson College of Textiles, North Carolina State University, United States

Abstract: With an increasing world population, climate change and increased insect resistance to pesticides, a different way of thinking is needed to produce food in the future with no pesticides. Our research team has been investigating applications in the material sciences for insect and weed control and to improve plant growth even in challenging temperature conditions and water availability. We are reporting here a reusable, novel knitted textile structure, named Plant Armor, that is surprisingly open for maximum air-light-water penetration, excludes insects and weeds, and significantly increases the rate of plant growth. The technology is not based on size exclusion like typical insect barriers but creates a tortuous path. In Petri dish, choice bioassays, 50% of adult Franklinellia fusca moved across Plant Armor to a cabbage leaf in 3 h versus 10 min for Proteknet, a commercially available crop cover standard used in our studies. For similar studies with Heliocoverpa zea neonates, the time for 50% penetration for Proteknet was 2.5 h with only 10% penetration after 24 h for Plant Armor. In small cage, worst-case-scenerio bioassays where 25 H. zea neonates were applied topically to Plant Armor covered individual cabbage plants, there was no penetration after 10 days. In a separate cage, where the larvae were applied directly to the cabbage, 90% of the plant was consumed. In separate small field plots for Plant Armor versus Proteknet and where the cabbage was covered or not covered for 3 mos, there was clear phytophagy on the uncovered plants while the covered plants had no damage for both textiles. Weeds were totally excluded by both textiles. Surprisingly, the plant size based on wet and dry weight was 2-3 time greater for the cabbage covered with Plant Amor than in the other treatments where the plant weights were similar. This enhanced growth for Plant Armor covered plants was also found in green house studies with tomatoes and by independent on farm trials. Sunlight transmission was essentially 100% for Proteknet and 75% for Plant Armor. Water vapor transmission, air penetration, water penetration, Martindale abrasion, temperature and humidity for Plant Armor versus Proteknet will be presented
along with bioassay and physical research data on Plant Armor Gen II. We will also show the use of
Plant Armor in the winter in Raleigh, North Carolina (USA).

Sprayable, Mechanical Insecticides for Vector Control and Agriculture: The Future is Now

Authors: Roe R. Michael[3], S. Apperson Charles[6], Stewart David[4], Agossa F.[1], Marcel Deguenon J.[6], Chen Kaiying[2], Akogbeto M.[1], McCord Marian[5] and Azondekon R.[1], [1]Centre de Recherche Entomologique de Cotonou (CREC), Cotonou, Benin, [2]Department of Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, [3]Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, [4]Imerys, San Jose, CA, United States, [5]North Carolina State University, United States

Abstract: Research was conducted on the use of industrial minerals as a wettable powder and residual spray for adult mosquito control, use on other vector important arthropods, and use in agriculture. The work included investigating different mineral types on a variety of substrates, under different environmental conditions, under lab and field conditions, and as an alternative to chemical insecticides or in combination for dual modes of action. Our original work with amorphous silica led to the discovery of a more efficacious insecticide made from volcanic rock. In field trials in Benin, Africa in WHO approved huts and with WHO approved testing procedures, our new mechanical insecticide produced from volcanic rock was more effective and more persistent than chemical insecticides used for indoor residual sprays. Phase III field trials in Africa are in process. Field trials will also be presented for insect control in row crops. We will discuss mode of action, impact on host seeking for vector important arthropods, and its enhanced activity for insecticide resistant mosquitoes. Introduction of a new commercial product for mosquito control is planned in Africa and select countries in Central and South America by our commercial partner. Additional uses are under investigation.

WholeGarment® Knitting of Military Clothing with Bite Protection against Mosquitoes and Other Arthropods

Authors: Roe R. Michael[2], West Andre[5], S. Apperson Charles[3], Kirkwood Elizabeth[3], DenHartog Emiel[4], Luan Kun[1] and McCord Marian[3], [1]Department of Forest Biomaterials, College of Natural Resources, North Carolina State University, United States, [2]Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, [3]North Carolina State University, United States, [4]Wilson College of Textiles, North Carolina State University, United States, [5]Wilson College of Textiles, North Carolina State University, United States

Abstract: In the current work, we are undertaking a research and development effort that demonstrates the benefits and capabilities of applying Wholegarment® knitting technologies to the production of bite-resistant U.S. Army knitted garments for both non-combat and combat wear.

Vector-borne diseases have had a devastating impact on the readiness of combat troops. Due to their increased exposure through training and operations outdoors, deployed military personnel are often at greater risk of receiving arthropod bites than common populations. Presently, the military uses chemical treatments (primarily permethrin) to prevent exposure to vector-borne diseases. The chemical bonding on knitted fabric is not as successful as with wovens and under normal operational conditions, these measures often result in incomplete protection. Mosquito resistance to existing pyrethroid chemistries is problematic in some areas of military operations. In addition, military personnel are concerned that exposure to pyrethroid treatments have adverse effects on their health or that of their family members. Therefore, vector control and personal protection strategies are still of critical importance in ensuring the operational readiness of armed forces. There is an urgent need to develop an alternative effective bite-resistant system, which is more effective against insecticide-resistant mosquitoes and other arthropods, reducing the potential hazard for human health. This technology is also transferable to the private sector.

Conventional approaches to creating a textile barrier to human-vector contact rely on creating impenetrable fabric structures that have reduced air and moisture permeability, and therefore, negatively impact thermophysiological comfort. As such, their applications are quite limited in practical garments. In previous NSRDEC funded research, we developed comfortable and insecticide-free bite-resistant spacer fabrics for incorporation into a military clothing system. We use multilayer spacer fabrics that are designed to minimize thermal burden while providing bite protection. One example contains 3 main constituents: 1) a bottom layer that provides tactile comfort and moisture-wicking; 2) a top layer that is open enough for breathability (air, moisture, heat transfer) and includes our patent-pending bite-resistant structure; and 3) a middle layer that provides appropriate separation of the bottom and top layers and provides additional resistance to biting.

Physical exclusion as a cultural management practice for SWD: effects on fruit infestation, yield, and microclimate conditions

Authors: Rogers Mary[3], Petran Andrew[1], Hodge Claire[3], Burkness Eric[2], Gullickson Matthew[3] and Hutchison William[2], [1]Twin City Berry Co, United States, [2]University of Minnesota, United States, [3]University of Minnesota Department of Horticultural Science, United States

Abstract: Small-scale, diversified and organic growers depend on cultural pest management tools to preserve crop yield and quality and to meet consumer demand for reduced pesticide residues. Growers in the U.S. are increasingly using controlled environment and high tunnel production to expand the growing season and for crop protection. Physical exclusion is one of the few cultural management practices that can effectively reduce fruit infestation by SWD, allowing for a reduction in pesticide application. In the Midwest U.S., primocane-bearing raspberries are particularly susceptible to SWD infestation due to berry physiology and phenology. Fine mesh netting is required in order to effectively exclude SWD. Use of this netting in poly-covered tunnels can impact the microclimate of tunnels and exclude pollinators, consequently affecting berry yield and quality. This presentation will highlight data collected over a four-year period (2016-2019) on the effects of physical exclusion on fruit infestation, microclimate conditions, and berry yield and quality from primocane-bearing raspberries in Minnesota. Our results show that if used early in the growing season, fine mesh netting can effectively be used to protect fruit from SWD infestation. This is primarily due to the effects of physical exclusion itself and not mediated by microclimate effects. If flies successfully colonize tunnels, these habitats can become protective to flies and infestation can rapidly build within the tunnel environment. The tunnel environment typically results in higher raspberry fruit yield and quality compared to open field plots. Additionally, our results indicate that introducing bumblebee pollinators in our tunnels does not impact raspberry yield or quality and deploying baited traps for adults within tunnels has no impact on fruit infestation by SWD.

How And Why Herbivores Should Respond To Concentrated Resources

Authors: Roitberg Bernard, Simon Fraser University, Canada

Abstract: The resource concentration hypothesis posits that sites with denser plantings will harbour more herbivores per plant. This hypothesis has been the basis of many experimental tests and theoretical explorations. Here, I take a slightly different tact and ask how the rate of accumulation changes as a function of (i) the evolutionary history of the herbivore in question with regard to its historical host plant landscapes and (ii) the focal experimental landscape. I use conditional semivariograms or structure functions (Mangel and Adler 1994; Roitberg and Gillespie 2014) to describe the world of the herbivore from its point of view to explain why it might remain or move within or among plants or clusters of host plants in order to maximize lifetime reproductive success, in different environments (e.g. various planting densities). This approach marries, life history theory, landscape ecology and plant herbivore theory. I discuss implications for agriculture.

Are Insects Declining?

Authors: Romanowski Hannah[2], Shortall Chris[2], Blumgart Dan[1], [1]Rothamsted Research, Lancaster University, United Kingdom, [2]Rothamsted Research, United Kingdom

Abstract: The Rothamsted Insect Survey (RIS) has been monitoring insects since 1964 using a network of suction traps and light traps; the former collects medium-sized migrating insects at a height of 12.2 m and the latter is designed to catch moths of all sizes using a tungsten filament bulb. These two networks represent the most comprehensive standardised long-term terrestrial data on insects in the World. A RIS study of insect biomass, led by Shortall et al (2009) found that declines in biomass had occurred at one of four sites investigated but this downward trend was primarily driven by a decline in abundance of a relatively heavy fever fly. Aphids on the other hand, were shown to have shown little sign of change in annual totals over the last 50 years despite significant changes to their phenology which was shown to be driven by climate and adaptions in life cycle traits (Bell et al. 2015). Conversely, moths have seen some dramatic declines in numbers alongside a shift in their phenology. Kelvin Conrad and colleagues flagged up two-thirds of the 337 species studied declined over the 35 yr study and 21% of the species declined more than 30% 10 yr-1. But, moth declines were worse in southern Britain, with a 40% decrease in total abundance, while there was no overall change in northern Britain which has been offset by increases. These and other studies highlight that standardised long term data is best placed to answer questions concerning declines that are often nuanced in their support of trends. However, combining long term data from many sources and studies, it is unquestionable that some insects are declining at a rapid rate and changes in policy and conservation practice are needed.

Genetic structure of cereal aphids in England using genomic approaches

Authors: Romanowski Hannah[1], Morales-Hojas Ramiro[1], Greenslade Alex[1], Alvira Fernando[1], Alderson Lynda[1], Hall Mike[1] and Kruger Tracey[1], [1]Rothamsted Research, United Kingdom

Abstract: Cereal aphids are among the most economically relevant pest species in the UK. They can reduce crop yield by direct feeding but are also vectors of the barley yellow dwarf virus (BYDV). Their abundance has been monitored in the UK for over 50 years by the Rothamsted Insect Survey, which holds the longest running dataset of insect populations. Analyses of this dataset shows a long-term stability of aphid population size despite climate change. However, little is known about their population dynamics from the genetic perspective. Studying the population genetics of these pests is fundamental to determine the geographic distribution of the genetic diversity, the patterns of gene flow and dispersal, and identify potential barriers to their movement. Here, we present results of population genetic analyses of two cereal aphids in England using genome-wide molecular markers. We compare the structure of Rhopalosiphum padi and Sitobion avenae and investigate the gene flow patterns across England to understand their dispersal and discuss the potential natural barriers to their long-distance migration. We have also investigated the temporal evolution of R. padi populations and the gene flow patterns by examining the genetic differentiation in historic times using Rothamsted Insect Survey's archive of samples. We also present an improved genome of R. padi assembled using a hybrid approach with long reads obtained with ONT MinION.

The effect of land-use type on long-term trends of British moths

Authors: Romanowski Hannah[4], Blumgart Dan[3], Botham Marc[1] and Menendez Rosa[2], [1]Centre for Ecology and Hydrology, United Kingdom, [2]Lancaster University, United Kingdom, [4]Rothamsted Research, United Kingdom, [3]Rothamsted Research, Lancaster University, United Kingdom

Abstract: The Rothamsted Insect Survey is the most extensive, standardised long-term terrestrial insect dataset in the world. A network of light-traps across the UK has been running since the 1960s to the present day and has recorded over 700 species of macro-moths. The total abundance of moths in the network has been in decline since records began, with the most severe declines occurring in the south-east of the country and to species which feed on shrubs and low-growing plants. Habitat loss through agricultural intensification is widely thought to be the main driver of decline but strong evidence for this is lacking. Using data from over 500 trapping locations from 1968 to 2016, we show that, contrary to expectations, declines in moth populations have been most severe in the least agriculturally intensified areas, especially broadleaf woodlands, and the lowest rate of decline has occurred in arable land and improved grassland. Moth abundance in woodlands and other semi-natural habitats was much higher than in agricultural settings at the beginning of the time series, so the relative decline in abundance is more dramatic in semi-natural areas than in agricultural areas where abundance was relatively low to begin with. The mechanisms behind these findings are unclear, but it is evident that drivers other than agricultural intensification need to be more seriously considered.

Understanding the origins and spread of resistant-breaking biotypes in aphids

Authors: Romanowski Hannah[1], Morales-Hojas Ramiro[1], Garrett Dion[1], Teakle Graham[2] and Collier Rosemary[2], [1]Rothamsted Research, United Kingdom, [2]University of Warwick, United Kingdom

Abstract: Climate change is driving the phenology of aphids earlier, compromising crop production because younger plants are being targeted earlier in the season. During colonisation and subsequent feeding, young plants are more susceptible to virus transmission and high levels of infestation can cause stunted growth, leading to supermarket rejections.

The currant-lettuce aphid, Nasonovia ribisnigri, is the most damaging species of aphid on outdoor lettuce and is responsible for large economic losses. The use of insecticides and host-resistant lettuce cultivars were previously the best method to reduce aphid outbreaks. However, insecticide-resistant biotypes and others that break host-plant resistance (resistant-breaking (Rb)) have recently been found in the UK. In the absence of lettuce cultivars with a new resistance mechanism, N. ribisnigri infestations will likely escalate. It is known that the resistant lettuce cultivar is underpinned by one gene (Nasonovia-resistant gene – Nr), yet little is known about how the aphid can overcome this single gene resistance in the host.

This sequencing project used N. ribisnigri, as a model to examine and explore potential insect resistance mechanisms to the Nr¬¬-gene resistance in the host plant. The first reference genome of N. ribisnigri has been constructed using Illumina (PE 150) and MinION sequence data obtained from both susceptible and resistance-breaking (Rb) biotypes. Whole genome analysis has been conducted to obtain gene model predictions, genome comparisons of other closely related species and produce gene phylogenies.

In addition, by obtaining near-complete genomes of both susceptible and resistance-breaking biotypes of N. ribisnigri, it is hoped that potential candidate regions which confer resistance could be identified. This in turn can be used to study the evolution and spread of resistance throughout the UK and infer migration distances using the Rothamsted Research Insect Survey suction trap network archive over the past 15 years. It is envisaged that this research could be applied to other species models and act as platform to investigate alternative control strategies such as the development of other resistant cultivars.

Gene drive technology (aka scary mutant insects) in the media

Authors: Ronai Isobel, The university of Sydney, Australia

Abstract: Science communication is vital for new technologies as it can inform the community about current developments, risk assessments and regulations. The newest genetic engineering technology for insects is gene drive (uses gene editing to trick the typical rules of inheritance). Gene drive research is progressing at a rapid pace, for example, the Target Malaria research consortium is currently testing a mosquito gene drive under field realistic conditions in the laboratory. This technology is of huge public interest and will never be permitted to be deployed in the field without community support. I recently contributed to a 'Position Statement on the Importance of Continued Innovation in Gene Drive Technology' for the Entomological Society of America. This policy statement details how and why continued research into gene drives is of the utmost importance. To publicise the findings of the Position Statement to a wider audience, such as community stakeholders and lawmakers, I proposed to write an article for the online media outlet The Conversation (over 38 million article views per month). The article titled 'Gene drives in insects hold lots of promise' has thousands of more readers than the original Position Statement, which is linked in the article. I outline the process for publishing an article in The Conversation. Overall, I reflect on my experiences of effectively partnering with the media to communicate my own research to a wider audience, which is particularly helpful for early career researchers.

Aversion of the invasive Asian longhorned tick to the white-footed mouse, the dominant reservoir of tick-borne pathogens in the United States

Authors: Ronai Isobel[2], M. Tufts Danielle[1] and A. Diuk-Wasser Maria[1], [1]Columbia University, United States, [2]University of Sydney, Australia,

Abstract: The Asian longhorned tick (Haemaphysalis longicornis) was reported for the first time in the United States of America in 2017 and has now spread across 12 states. The potential of this invasive tick vector to transmit pathogens will be determined through its association to native hosts, such as the white-footed mouse (Peromyscus leucopus) which is the primary reservoir for the causative agent of Lyme disease (Borrelia burgdorferi) and other zoonotic pathogens. We placed larval H. longicornis on P. leucopus, 65% of the larvae (n = 40) moved off the host within a short period of time and none engorged. In contrast, larval black-legged ticks (Ixodes scapularis) did not move from where they were placed in the ear of the mouse. We then conducted a laboratory behavioural assay to assess the interaction of H. longicornis with the hair of potential mammalian host species in the United States of America. H. longicornis larvae were less likely to enter the hair zone of P. leucopus and humans compared to the hair of domestic cats, domestic dogs, and white-tailed deer. Our study identifies a tick-host hair interaction behaviour, which can be quantified in a laboratory assay to predict tick-host associations and provides insights into how ticks select a host.

The effect of caging and banking on queen ovaries

Authors: Ronai Isobel[3], Aamidor Sarah E[1], Oldroyd Benjamin[3], Antonio Mendes Cardoso Júnior Carlos[2], Evenhuis Christian[4] and Cole Louise[4], [1]Behavior and Genetics of Social Insects Laboratory, The University of Sydney, Australia, [2]Department of Cell and Molecular Biology and Biopathogenic Agents, Ribeirão Preto School of Medicine, University of São Paulo, Brazil, [3]University of Sydney, Australia, [4]University of Technology Sydney, Australia

Abstract: In the honey bee (Apis mellifera), queen and worker casts originate from identical genetic template but develop into uniquely different phenotypes. A mature queen lays up to 2000 eggs per day continuously throughout her life in contrast to the non-reproductive workers that are sterile in the presence of the queen. However, periodically queens stop laying eggs, for example during swarming and winter. Although facultative sterility in workers has been widely investigated not much is known about the mechanism by which queens can stop laying. Commercial bee keeping requires the transportation of queens for sale by shipment of individual queens transported in cages for up to 10 days. During this time queens do not lay eggs until reintroduction to the new colony. Here we investigated the mechanism by which queens cease to lay eggs by testing whether genes related to programed cell death are involved in the regulation of queen reproductive physiology and the morphological changes during this time. In this study we used confocal microscopy to investigate the structural changes occurring when a queen is prevented to lay. We show that already after 4 days of caging queen ovaries start to deteriorate along the ovarioles, ovariole length decreases and mature eggs are compressed at the oviduct. We show for the first time a clear morphological response occurring as a result of this environmental constraint. These observations have commercial implications for agriculture and a better understanding of honey bee health.

Stranger things in honey bees (Apis mellifera): gynandromorphy and androgenesis

Authors: Ronai Isobel[2], Aamidor Sarah E[1], Oldroyd Benjamin[2] and Yagound Boris[1], [1]Behavior and Genetics of Social Insects Laboratory, The University of Sydney, Australia, [2]University of Sydney, Australia

Abstract: Hymenoptera (bees, ants and wasps) are haplodiploid: females are diploid while males are haploid. The cytogenetic mechanisms underlying haplodiploidy enables peculiar phenomena such as thelytoky (female cloning), androgenesis (male cloning) and gynandromorphs (sex mosaics). We sampled 11 sister gynandromorph honey bee (Apis mellifera) workers and assessed parentage and sex of various tissue. Most bees were gynandromorphs with up to three paternal origins. Remarkably, one was phenotypically female, but with no maternal alleles. It was created from the fusion of two sperm nuclei (i.e. androgenesis). This is the first reported case in Hymenoptera of sperm fusion resulting in a female. We also found queen-like characteristics in some gynandromorphs indicating a breakdown in the pathways of caste determination. Overall, our results show that when gynandromorphy occurs, unusual biological phenomena can also arise. These phenomena shed light on the evolution of some of the more bizarre social systems and cast differentiation.

The potato psyllid, Bactericera cockerelli (Sulc): history and evolution of management strategies in western United States

Authors: Rondon Silvia I, Oregon State University, Hermiston Agricultural Research and Extension Center, Hermiston, OR USA, United States

Abstract: The potato psyllid, Bactericera cockerelli (Sulc) (Hemiptera: Triozidae) is a major pest of solanaceous crops that causes damage to crop plants by direct feeding (‘causing “psyllid yellows’) and by transmitting the bacterial pathogen Candidatus Liberibacter psyllaurous (a.k.a. Ca. L. solanacearum) that causes ‘Zebra Chip’. In the western United States (US), where close to 54% of the total US production of potatoes is produced, zebra chip was reported for the first time in 2011. Our industry was unprepared for such arrival. Since then, many studies have been conducted to understand vector and pathogen geographical distribution, prediction models, basic biology and ecological studies, and management control. Studies in the past 8-years have documented substantial genetic variability in this invasive species, including several haplotypes of the vector and bio-types of the bacterium, overwintering capability in non potato plants and weeds, population dynamics and timing of potato psyllids arrival in commercial fields that has helped us tailored better control options. This presentation seeks to provide a comprehensive update to B. cockerelli life history, relationship to the pathogen, and the current status of management strategies against B. cockerelli in the U.S.

Candidate chemosensory genes identified in antennae of Harmonia axyridis (Coleoptera: Coccinellidae)

Authors: Rondoni Gabriele[2], Roman Alessandro[1], Meslin Camille[3], Montagné Nicolas[4], Conti Eric[5] and Jacquin-Joly Emmanuelle[3], [1]DSA3, University of Perugia, Perugia, Italy / University of Exeter, Penryn, UK, [2]DSA3, University of Perugia, Italy, [3]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [4]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [5]University of Perugia, Italy

Abstract: The harlequin ladybird, Harmonia axyridis (Pallas) (Coleoptera: Coccinellidae) is an important natural enemy of several herbivore pests, but at the same time, due to its very invasive behaviour, it may negatively affect other predatory species through, e.g., intraguild predation and indirect competition. Like other ladybirds, H. axyridis uses antennae to detect chemical cues relevant for courtship, mating and for locating food sources and suitable oviposition habitats. Understanding the molecular basis of chemosensory reception in H. axyridis could provide relevant information for field application, e.g., to increase its ability to suppress herbivore pests or, conversely, to reduce its populations whenever the ladybird is recognized as a threat to local biodiversity. Using NextSeq 550 Illumina sequencing, we assembled the antennal transcriptome of Harmonia axyridis males and females and described the expressed chemosensory genes. We annotated candidate chemosensory sequences encoding 26 odorant receptors (ORs) (including the coreceptor, Orco), 17 gustatory receptors (GRs), 27 ionotropic receptors (IRs), 31 odorant-binding proteins (OBPs), 12 chemosensory proteins (CSPs), and 4 sensory neuron membrane proteins (SNMPs). Phylogenetic analyses with sequences of other beetle species allowed to assign candidate H. axyridis chemosensory genes to known groups already described for Coleoptera. Differential expression analysis revealed low variability between males and females, potentially mirroring the absence of relevant sexual dimorphism in antennal morphology. However, significant differences were detected in the expression of three chemosensory genes, namely two male-biased odorant-binding proteins and one male-biased odorant receptor, suggesting their possible involvement in pheromone detection.

Effect of microplastics on the oviposition behaviour of a herbivorous pest in a soil-plant system

Authors: Rondoni Gabriele[2], Agnelli Alberto[1], Chierici Elena[2], Conti Eric[3] and Massaccesi Luisa[1], [1]Department of Agricultural Food and Environmental Sciences - University of Perugia, Italy, [2]DSA3, University of Perugia, Italy, [3]University of Perugia, Italy

Abstract: Pollution by microplastics, i.e. 1 µm - 5 mm plastic particles, is recognized as an emerging issue of global interest. To date, most of the research on microplastics has focused on the evaluation of health risks associated with contaminated food and seafood, or on the environmental effects in aquatic ecosystems. Recent investigations revealed that remarkable levels of microplastics can be found also in natural and cultivated soils. Concerning agricultural soils, major incomes are represented by the deposition and infiltration of particles from the surrounding environment or by direct contamination from particles derived from mulching films or irrigation tubes. Microplastics may negatively interfere with the soil microorganism and invertebrate biodiversity and with the related biological processes. Notably, it has been demonstrated that microplastics can also affect plant's development, e.g. reducing aboveground and belowground biomass. Surprisingly, there is a poor understanding of how microplastics can influence the interactions between members of the different trophic levels.

Here, we aimed at investigating whether high-density polyethylene (HDPE) microplastics in the substrate affects the emission of volatile compounds from a soil-plant system, thus possibly interfering with the oviposition behaviour of a herbivorous insect. As a model system, we used economically important crop pests, i.e. fungus gnats (Diptera: Sciaridae), and lentil (Lens culinaris) as the host plant. Fungus gnats use olfaction to identify odours from the environment and to locate a suitable habitat for oviposition.

Using one-way olfactometer, we recorded the female's residence time (the time spent in the sector closer to the stimulus) when exposed to odours from plants subjected to different combinations of the following treatments: 1) 0% and 5% of HDPE soil concentration; 2) well-watered or moderate water-stressed plants; 3) 1-day or 7-day duration of the plants' treatments.

Females were similarly attracted by plants maintained 1 day in the presence or absence of microplastics. Conversely, females' attraction was significantly reduced when exposed to plants maintained 7 days with 5% HDPE compared to 0% HDPE. Moderate water stress in 5% HDPE plants did not significantly affect the attractiveness to females compared to well-watered 5% HDPE plants. Conversely, water stress reduced the attractiveness of 0% HDPE plants to a level similar to 5% HDPE plants.

We demonstrated that the presence of microplastics induced changes in the volatile emission from the soil-plant system. These changes might interfere with the plant-herbivore infochemical communication and the effect is similar to that induced by moderate water stress. The possible mechanisms involved are under investigations and include changes of the soil physical properties and soil microbial activity.

Evolution of gall wasps: a phylogenomic analysis

Authors: Ronquist Fredrik[3], Hearn Jack[1], Nieves Aldrey José Luis[2], Branca Antoine[4], Gobbo Erik[3] and Stone Graham[5], [1]Liverpool School of Tropical Medicine, [2]Museo Nacional de Ciencias Naturales, [3]Swedish Museum of Natural History, Sweden, [4]Université Paris-Saclay, [5]University of Edinburgh, United Kingdom

Abstract: The phylogeny of gall wasps (Cynipidae) and their parasitic relatives has attracted considerable attention in recent years. The family is now widely recognized to fall into twelve natural lineages, designated tribes, but the relationships among them have remained elusive. This has stymied any progress in understanding how cynipid gall inducers evolved from insect parasitoids, and what role inquilines (species that develop inside the galls of other species) might have played in this transition. A recent analysis of ultraconserved elements (UCEs) represents the first attempt at resolving these questions using phylogenomics. Here, we present the first analysis of gall-wasp relationships based on protein-coding sequences from genome and transcriptome assemblies. To address potential problems due to model misfit, we focus on models that accommodate site-specific amino-acid profiles and that are less sensitive to long-branch attraction than standard models. Our results show that the Cynipidae as previously circumscribed are not monophyletic. Specifically, the Paraulacini and a clade formed by Diplolepidini + Pediaspidini both fall outside of a core clade (Cynipidae sensu stricto), which is more closely related to Figitidae. This result is robust to the exclusion of long-branch taxa that could potentially mislead the analysis, and it is consistent with the previous UCE analysis. Given this, we propose that the Cynipidae be divided into three families: the Paraulacidae, Diplolepididae and Cynipidae (s. str.). Our results suggest that the Eschatocerini are the sister group of the remaining Cynipidae (s. str.). Within Cynipidae s. str., our results are consistent with the UCE analysis but place two additional tribes: (1) the Aylacini (s. str.), which are more closely related to the oak gall wasps (Cynipini) and some of their inquilines (Ceroptresini) than to the other herb gallers (Aulacideini and Phanacidini); and (2) the Qwaqwaiini, which are likely the sister group to Synergini (s. str.) + Rhoophilini. Many alternative scenarios for the evolution of cynipid life histories are compatible with the relationships suggested by our analysis, but all of them display an astonishing level of complexity with multiple shifts between parasitoids, inquilines and gall inducers. Linking the different types of life-history transitions to specific genomic signatures may be one of the best ways of differentiating among these alternative scenarios. Our study represents the first step towards enabling such analyses.

From Inquilines to Gall Inducers: Genomic Signature of a Life-style Transition in Synergus Gall Wasps

Authors: Ronquist Fredrik[5], Abe Yoshihisa[1], Ide Tatsuya[3], Gobbo Erik[5], Wheat Christopher[4], Stone Graham[6], Hearn Jack[2] and Lartillot Nicolas[7], [1]Kyushu University, Japan, [2]Liverpool School of Tropical Medicine, United Kingdom, [3]NMNS, Tokyo, Japan, [4]Stockholm University, Department of Zoology, Sweden, [5]Swedish Museum of Natural History, Sweden, [6]University of Edinburgh, United Kingdom, [7]University of Lyon, France

Abstract: Gall wasps (Hymenoptera, family Cynipidae) induce impressively complex galls on oaks, roses and other plants, but the mechanism of gall induction is still unknown. Here we take a comparative genomic approach to revealing the genetic basis of gall induction. We focus on a clade of cynipids, the genus Synergus, whose members are inquilines, which cause the development of nutritive tissues inside galls initiated by other species, but cannot initiate galls themselves. Recently, it has been shown that one Synergus species, S. itoensis, has evolved the ability to induce its own gall from an inquiline ancestry. We compared the genome of S. itoensis to that of three related Synergus inquilines to identify genomic changes associated with the origin of de novo gall induction. We used a novel Bayesian selection analysis, which accounts for branch-specific and gene-specific selection effects, to search for signatures of selection in 7,600 single-copy orthologous genes shared by the four Synergus species. We found that the terminal branch leading to S. itoensis had more genes (Positive Signature Genes, PSGs) showing a signature of positive selection, as identified by a significantly elevated dN/dS ratio, than the other terminal branches in the tree. Similarly, the S. itoensis branch also had more genes with lower dN/dS ratio (Negative Signature Genes, NSGs). Gene set enrichment analysis showed that the PSG set of S. itoensis, unlike the PSG sets for the inquiline Synergus species, is enriched in several types of biological process Gene Ontology terms, the most prominent of which is “Ovarian Follicle Cell Development” (GO:0030707). Our results indicate that the origin of gall induction is associated with distinct genomic changes, and provide a good starting point for further characterization of the genes involved.

Optimizing amplicon-based metabarcoding in inventorying insect communities

Authors: Ronquist Fredrik[3], Iwaszkiewicz-Eggebrecht Elzbieta[3], Miraldo Andreia[1], Marquina Daniel[2], [1]Department of Bioinformatics and Genetics Swedish Museum of Natural History Stockholm, Sweden, [2]Department of Bioinformatics and Genetics, Swedish Museum of Natural History Stockholm, Sweden, [3]Natural History Museum Stockholm, Sweden

Abstract: Genetic methods are bound to revolutionize studies of insect communities but these approaches are still in their infancy. Results obtained so far need to be interpreted with caution, accounting for biases and errors, and further method refinement is a priority. As part of an ambitious comparative study of the insect faunas of Sweden and Madagascar and their associated microbiomes, the Insect Biome Atlas project, our lab has recently been testing and optimizing several aspects of amplicon-based metabarcoding protocols for sampling insect communities. We summarize our findings with respect to optimal markers and primers, and compare communities detected in Malaise trap samples and soil samples from the same locality. We also analyze the differences between the signal retrieved from preservative ethanol versus tissue homogenate from the same Malaise trap sample. Finally, we compare the effectiveness of mild lysis protocols versus tissue homogenization in retrieving the species diversity and abundance in mock communities and in real Malaise trap samples.

Can we expect to use a single generic trap deployed at potential ports-of-entry for early detection of exotic cerambycids, bark and ambrosia beetles, and buprestids?

Authors: Roques Alain, INRAE, Zoologie Forestière Orléans, France

Abstract: Globalization is leading to an exponential increase in the introduction of non-native insects into other continents without any saturation being observed. Most of these species are phytophagous insects associated with woody plants, probably in connection with the explosion of the global ornamental trade. A growing number of the newcomers are said to be emerging because previously unknown as invaders elsewhere, or considered harmless in their areas of origin. As such, these species were not regulated before their arrival in Europe, The definition of tools allowing an early, generic detection at arrival is therefore essential. Because pheromone components are often conserved at world level among related species in Cerambycidae, successive tests in France allowed to design a blend involving 8 pheromone components as a lure with generic attractiveness, allowing to detect "unkown" species arriving from other continents. In 2018 and 2019 black multifunnel traps baited with this blend, complemented with ethanol and a-pinene, captured a total of 126 native cerambycid species in French forests, which represented 52% of the country's fauna. At potential points-of-entry, captures with the same trapping design concerned 38 cerambycid species including 8 non-native ones, two of which having never been reported in Europe, yet. These trapping designs also allowed to detect non-native bark and ambrosia beetles (Xylosandrus spp.) and platypodids (Euplatypus spp.) in forests and ports. However, these black traps caught very few buprestids whereas such species may also constitute serious threats to forests. Therefore, we compared the attractiveness of green and black multifunnel traps baited with the same 8-component blend complemented with ethanol and [-] a-pinene. The green traps effectively captured 25 species of buprestids of which 15 Agrilus spp. but the number of cerambycid species, as well as the number of individuals, significantly decreased with regard to the trappings by black traps. We would probably need to deploy traps of different colours, and baited with different lure combinations to detect both cerambycids, bark and ambrosia beetles and buprestids at ports of entry.

Using multi-pheromone blends as a tool for early detection of non-native cerambycid species at arrival on other continents: results of a worldwide trapping program

Authors: Roques Alain[2], Ren Lily[1], Auger-Rozenberg Marie-Anne[3], Yuan Yuan[1], Shi Juan[1] and Sun Jiang-Hua[4], [1]BFU & IFOPE, [2]INRAE, [3]INRAE, URZF, Orleans, France, [4]IOZ- CAS

Abstract: Globalization is resulting in an exponential increase in the introduction of non-native insects into other continents, of which a growing proportion are emerging species, yet never found outside their native range. Being capable of detecting such species at arrival at ports of entry before they establish in non-native countries is an urgent challenge. Large progresses in cerambycid pheromone chemistry revealed that sex- and aggregation-sex pheromones are rather well conserved at world level. A blend combining 8 pheromones showed a large generic attractiveness in France, with 130 cerambycid species of different subfamilies trapped. These results led to propose the development during 2019- 2021 of a joint trapping program between Europe and China using this multi-pheromone blend with the rationale: if a species is trapped in numbers in its native continent, higher is the probability of catching it at arrival on a non-native continent. The trappings were carried out in 13 European countries and 13 provinces of China. They allowed to catch 75 species at least in China and 173 in Europe, including 9 species trapped in both regions of which invaders in Europe. Attempts to generalize at world level such trappings using the same generic blend are in progress.

Specific problems of IPM in the case of maize leaf weevil (Tanymecus dilaticollis Gyll.) In Romania, ways and methods of limiting the economic impact on farmers

Authors: Rosca Ioan[1], Chiriloaie Andrei[1] and Fatu Viorel[1], [1]Research Development Institute for Plant Protection, Romania

Abstract: From 2014 to 2022, Romania granted exemptions for the use of neonicotinoids in seed treatment, because there are no effective technical alternatives to control the Tanymecus dilaticollis Gyll. which is considered the most important pest of corn, causing considerable damage and on sunflower and in the area of corn cultivation, in Romania especially in the south, east and southeast, being a limiting factor of these crops in the southeast of Romania, the favorable biological requirements of the pest, corresponding entirely to this area, there are no viable alternatives for replacing the seed treatment with other methods of pest control within the IPM. The main causes that contribute to this situation are presented, including the implications of the fact that the EFSA did not require the PLH Committee to provide standards for assessing the effectiveness of a pesticide specific to maize corn leaf beetle (this is done by "similar" standards to completely different pests by biology and mode of attack). Being proposed and justified the study of the value of the pressure of water vapor deficit in the atmosphere (VPD) calculated using the equations developed by Syswin Solutions company for assessing the risk of pest attack in maize and sunflower crops.

Does increasing field size worsen pest problems? A test in commercial citrus production

Authors: Rosenheim Jay[1] and Cass Bodil[1], [1]University of California, Davis, United States

Abstract: Agroecology theory suggests that the loss of diversity associated with crop monocultures worsens pest problems, and that the larger the monocultures, the worse the problems. This is, however, difficult to test experimentally, because most research farms are too small to replicate different field size treatments at spatial scales that are meaningful for commercial agricultural production. Here we use a database of pest densities in commercial citrus production in California's San Joaquin Valley to look for associations between field size and pest densities. We use data gathered by independent pest management consultants, who monitor a community of arthropod pests, including herbivorous mites and insects (including the citrus thrips, fork-tailed bush katydid, citrus red mite, California red scale, citricola scale, cottony cushion scale), as well as a single beneficial mite, Euseius. Although different species reveal different relationships between field size and mean pest density, we find no broad support for the idea that larger monocultures are associated with worse pest problems. We discuss the implications for agroecology theory.

Introduction to the round table "How to work on lever combination to control pests"

Authors: Rosiès Blandine, INRAE (French National Research Institute for Agriculture, Food and Environment), France

Abstract: This talk is an introduction to the round table we propose in the second hour of this symposium. The theme addressed by the round table is "How to work on lever combination to control pests". In the frame of the API-Tree project we have been working on single levers of action as well as on the design of combinations of practices alternative to chemicals to control apple pests.
Three proposals presenting different options to work on lever combinations will be briefly (3-5') developed in the following hour. Between each argument an open discussion with the room will be proposed. This round table will be concluded by an invited testimony, who will share his/her feedback and the message that's he/she is bringing home.
First proposal offers the system approach as the optimal to work on lever combinations, and argues for experimental evaluation between the levers to assess interactions, overlap and compatibility between levers of action against pests.
Second proposal proposes modelling can better capture the complexities and identify knowledge gaps.
Third proposal is that the design of such integrated systems and their dissemination require various types of knowledge, from basic, to applied and empirical knowledge, thus involving a range of stakeholders in a participatory approach to tailor agroecological orchards.

Insights into morphological disparity of Palaeodictyopterida from the late Carboniferous of Piesberg

Authors: Rosová Kateřina[2] and Prokop Jakub[1], [2]Faculty of Science, Charles University, Czech Republic, [1]Czech Republic

Abstract: New palaeodictyopterid insects from the famous Moscovian (Pennsylvanian) locality of Piesberg quarry near Osnabrück (Lower Saxony, Germany) reveal spectacular disparity in the patterns of the wing venation. So far, the still active site provided over 1400 specimens of insects giving us an exceptional view of the insect diversity in the Moscovian, in some instances with exceptional preservation uncovering microstructural details. Significant part of the insect diversity at Piesberg belongs to the superorder Palaeodictyopterida, with so far recorded 10 families and 15 genera known from this locality. Our findings extended the enormous morphological disparity in the wing venation of orders Diaphanopterodea, Megasecoptera and Palaeodictyoptera during this time section and also provided links to other Pennsylvanian deposits in Europe and North America.

K.R. gratefully acknowledges the support of her research by the project "Grant Schemes at CU" (reg. no. CZ.02.2.69/0.0/0.0/19_073/0016935).

An overview of how phylogenomics changed our view of the lepidopteran tree of life and which sections of the tree remain unresolved

Authors: Rota Jadranka, Biological Museum, Department of Biology, Lund University, Sweden

Abstract: In this presentation I provide an overview of the advances made in our understanding of the lepidopteran tree of life and which parts of the tree remain unresolved.

The unresolved phylogenomic tree of butterflies and moths (Lepidoptera): Assessing the potential causes and consequences

Authors: Rota Jadranka, Biological Museum, Department of Biology, Lund University, Sweden

Abstract: Next-generation sequencing technologies have revolutionized the field of molecular phylogenetics and we are now in the era of phylogenomics. Lepidoptera – butterflies and moths – are one of the largest animal groups on the planet and they represent the largest radiation of herbivorous insects. In the past decade a number of phylogenomics studies focusing on the order Lepidoptera have been published, advancing our efforts to resolve the lepidopteran tree of life. In this presentation, I will provide an overview of how our understanding of the lepidopteran phylogenetic relationships has changed because of the wealth of data coming from transcriptomes and genomes, which parts of the tree remain unresolved, and the potential reasons for difficulties in resolving the relationships among the lepidopteran superfamilies.

The Spotted Lanternfly (Lycorma delicatula): A Highly Under-rated but Predictable Global Invasive Threat?

Authors: Roush Richard, Department of Entomology College of Agricultural Sciences Pennsylvania State University, United States

Abstract: The rapid expansion of the Spotted Lanternfly (SLF) across Korea (from 2006) and the northeastern USA, its impact on grape vineyards, and difficulty of management highlight its threat to other countries. Nymphs and adults feed on a wide range of host plants. Adult females routinely lay eggs in rocks and dead wood. The first record in the USA was in September 2014, about 100 km NW of Philadelphia, arriving on stone imports and/or their wood packaging materials from China. The SLF is now widely distributed across southeastern Pennsylvania and into at least 3 neighboring states (New Jersey, Delaware and Virginia). Despite intensive and costly management efforts, at least one vineyard has already been killed by SLF feeding, and others have been unable to yield crops. The financial impact on industries such as nurseries, Christmas tree growers and hardwood producers and especially vineyards already exceeds US$50 million annually in Pennsylvania alone. Expansion across Pennsylvania is predicted to cost at least $325 million in damages and 2,800 jobs. The US and Pennsylvania Departments of Agriculture have already spent more than $30 million attempting to suppress SLF populations and contain their spread. The preferred host of SLF, Ailanthus altissima, which has been a key factor in its rapid expansion, is reputed to be a noxious/invasive weed in Australia, New Zealand, South Africa, many countries of central, eastern and southern Europe, and also introduced to Argentina, suggesting that all of these regions are at risk from this insect. Despite intensive research, no effective pheromones or feeding attractants have been found. The public has been heavily engaged to take advantage of one of the SLF's few weaknesses, its distinctive appearance, to help identify and map infestations. Public reports of SLF by phone or website have exceeded 90,000 in 2019 alone, with 640 outside the initial quarantine zone. Novel control and detection strategies are being tested in Pennsylvania, including the use of insecticidal nets on tall objects, which are very attractive to SLF, and sniffer dogs. Dispersal of adults is greater than expected from observations in Korea. To protect grape vineyards, control must apparently be applied against nymphs for at least 500 meters from the vineyard.

Gene regulatory elements and networks provide an insight into direct and indirect negative regulation by the ecdysone cascade

Authors: Roy Sourav[5], Saha Tusar T[1], Banerjee Roumik[1], Aksoy Emre[3], Kulkarni Aditi[5], Ha Jisu[2], Raikhel Alexander[4], [1]Birla Institute of Technology and Sciences, [2]Lieber Institute of Brain Development, [3]University of California Riverside, [4]University of California Riverside, United States, [5]University of Texas at El Paso

Abstract: Introduction: Hematophagous female Aedes aegypti mosquitoes transmit pathogens for devastating viral diseases like Dengue, Yellow fever, and Zika, while blood-feeding. Being anautogenous, these mosquitoes require a blood meal for vitellogenesis - the process of yolk formation, during the maturation of eggs. Upon blood feeding, a steroid hormone, 20-hydroxyecdysone (20E), turns on the reproductive program during which thousands of genes are differentially expressed. Using transcriptomic data, we have previously detected four distinct and sequential gene expression patterns along with major regulators for each pattern, in the post blood meal (PBM), reproductive period. Pathways related to 20E-mediated gene activation are well known. However, the mechanism of repressive action by this hormone remains poorly understood.

Method: Bioinformatics combined with molecular biology techniques helped us identify the mechanisms of 20E-dependent direct and indirect transcriptional repression by the ecdysone receptor (EcR). To decipher how complex transcription networks, govern differentially expressed genes, during the vitellogenic period, we used genomics and bioinformatics tools to search for the promoters of co-regulated gene sets. Identified putative transcription factor binding sites (TFBSs) and their corresponding transcription factors (TFs), were used to build putative regulatory networks. RNAi-mediated depletion of selected TFs, ChIP, luciferase assays, and qRT-PCR of the target genes, were used for evaluation of the functionality of some of these putative TFs within the networks.

Results: Eighty-nine putative transcription factor binding sites (TFBSs) on the cis-regulatory regions of more than 1,400 differentially expressed genes, were identified. Putative transcription factors that may bind to these TFBSs were identified and used for the construction of temporally coordinated regulatory networks. Molecular biology techniques helped us uncover mechanisms of direct and indirect negative transcriptional regulation by the steroid hormone 20-hydroxyecdysone (20E) through the ecdysone receptor (EcR). Genes within the two groups - early genes and late mid-genes, with distinctly different expression profiles show lower expression at the high titers of 20E. Transcriptional repression of early genes is indirect and involves the classic 20E pathway with ecdysone-induced protein E74 functioning as a repressor. On the other hand, Late mid-genes are repressed directly by EcR, which recognizes and binds a previously unreported DNA element (EcREr), different from those utilized in the 20E-mediated gene activation, within the regulatory regions of its target genes and initiates chromatin condensation by recruiting a corepressor, Mi2.

Discussion: We have characterized two negative regulatory pathways for the liganded EcR, during the 20E-driven reproduction of the female Ae. aegypti, which advances our understanding of the 20E-EcR mediated complex repression mechanisms and could lead to improved vector control approaches.

Fire – to the rescue! Dry heathland burning has positive impact on Orthoptera diversity.

Authors: Rozenfelde Rūta, University of Latvia, Latvia

Abstract: European dry heaths have unfavourable conservation status in European boreal region and is at risk of disappearing regionally. In Latvia dry heathlands can only exist in areas where continuous disturbance is present. Since 2009 controlled burning has been applied as a habitat management practice to preserve the heathlands of protected landscape area „Ādaži". It is necessary to estimate the contribution this practice has on maintaining and improving the diversity of habitat-characteristic and rare species. The goal of this study was to learn how controlled burning influence Orthoptera species diversity. Respectively, quantitative Orthoptera occurrence data was obtained from both burned and unburned heathlands, using pitfall traps exposed in 20 sample sites over a period of one month. Projective vegetation, litter and bare ground cover was estimated, and vegetation height was measured for interpretation. We found that heathland burning had positive effect on Orthoptera species composition and diversity. Majority of the Orthoptera species were characteristic to heathlands. The diversity and occurrence of Orthoptera was positively correlated with vegetation diversity, bare ground and grass cover, and negatively with the cover of heath Calluna vulgaris. From the findings we conclude that controlled burning in dry heathlands is an effective method for Orthoptera conservation.

Effect of constant temperatures on Culicoides sonorensis midge physiology and vesicular stomatitis virus infection

Authors: Rozo Lopez Paula[1], Barbara Drolet[2], Park Yoonseong[1], [1]Kansas State University, [2]United States Department of Agriculture

Abstract: Culicoides biting midges are nuisance pests of livestock and well-known vectors of veterinary arboviruses, such as vesicular stomatitis virus (VSV). Female midges ingest viruses when feeding on blood to obtain protein for egg-laying. After ingesting a VSV-infected blood meal, the environmental temperature of the resting location mediates the rates at which blood is digested, eggs are laid, and virus particles are replicated inside the midge. VSV transmission will occur if the timing of virus amplification aligns with the next feeding–egg-laying cycle. We evaluated the impact of constant environmental temperatures on midge physiology (lifespan and reproduction), vector competence for VSV (infection and dissemination), and thermal resting preference. Our results indicate that after ingesting a blood meal, most midges prefer to rest in areas that fall within their preferred physiological range regardless of the temperatures at which they were being maintained. These preferred temperatures maximized their survival, the number of egg-laying cycles, and the likelihood of VSV transmission. Our temperature approach shows that in the Culicoides–VSV system, the preferred resting temperature selected by blood-fed midges is beneficial for both insect and virus transmission.

Venereal transmission of a Culicoides-borne arbovirus: Vesicular stomatitis virus

Authors: Rozo Lopez Paula[1], Drolet Barbara[2], [1]Kansas State University, [2]United States Department of Agriculture, Agricultural Research Service, Arthropod-Borne Animal Diseases Research Unit, Manhattan, KS, United States

Abstract: Culicoides sonorensis biting midges are well-known agricultural pests and arbovirus vectors in the USA. Natural reservoir questions remain for arboviruses that persist between vector seasons in the absence of infected animals. One such arbovirus is the rhabdovirus, vesicular stomatitis virus (VSV). This virus has a complex epidemiology with a broad range of vertebrate hosts, multiple routes of transmission, and an extensive diversity of suspected and incriminated vector species. Examining potential non-conventional routes for vector transmission, such as venereal transmission between midges, might help explain viral maintenance during inter-epidemic periods and times of adverse conditions for horizontal (bite) transmission. Under laboratory conditions, venereal transmission was demonstrated by plaque assay and real time qRT-PCR from infected females to uninfected males, and from infected males to uninfected females. Relevant anatomical sites for virus location resulting in transmission through copulation were identified by immunohistochemical staining. Our research results indicate C. sonorensis midges are capable of efficient venereal VSV transmission which may inform ecological, temporal, and spatial aspects of inter-epidemic arbovirus epidemiology.

A story on how milkweed plants defend against seed predators

Authors: Rubiano-Buitrago Paola[1], Pradhan Shrikant[1], Paetz Christian[1] and Rowland Hannah[1], [1]Max Planck Institute for Chemical Ecology, Germany

Abstract: Plants in the genus Asclepias produce cardenolides as a defence against herbivory. Cardenolides are a diverse group of compounds derived from triterpenoids and have a specific physiological target, the transmembrane protein Na+, K+–ATPase (NKA). Cardenolides are toxic because they bind to the extracellular surface of the NKA and disable passage of Na+ and K+ across the membrane. This disrupts electrochemical gradients causing many physiological systems to become dysregulated. Although the NKA is highly conserved among animals, independent evolution of NKA insensitivity to cardenolides has occurred in six taxonomic orders of insects and Asclepias are host plants for numerous insect species which in turn use cardenolides as their own chemical defence against their predators, e.g. milkweed bugs (family Lygeadeae), monarch butterflies (Danaus plexippus), aphids (Aphis nerii), and others. In this talk I present results of the isolation and identification of cardenolides from seeds of Asclepias curassavica, including the description of four new cardenolides, and the toxicity of individual cardenolides to the specialist herbivore the large milkweed bug Oncopeltus fasciatus. I describe the concentration and diversity cardenolides in seeds and the comparative inhibitory activity of the major cardenolides to three organisms, a sensitive vertebrate (Sus domesticus), a non-adapted insect (Drosophila melanogaster) and the specialist herbivore O. fasciatus. My results add to the understanding of how plants respond to specialist herbivores and opens the door to understanding how the arms race between plants and herbivores results in chemical diversity.

Can nanopore sequencing provide a cost- and time-effective solution for identifying quarantine-actionable arthropods?

Authors: Rugman-Jones Paul, University of California Riverside, United States

Abstract: Each year, thousands of arthropod specimens are found in cargo shipments and personal baggage entering or leaving the U.S. Many cannot be easily identified to species using morphological techniques and the relevant authorities typically adopt a “guilty unless proven innocent” attitude. This can trigger a host of possible quarantine measures, many of which may have been avoided had an accurate species level identification been available. DNA sequencing offers a fast and precise alternative for species identification, but until very recently, equipment costs and logistical requirements for laboratory space made it an impracticable option. However, the recent introduction of a highly portable and highly affordable DNA-sequencer, Oxford Nanopore Technologies’ MinION®, has renewed interest in the use of DNA sequences to provide a quick, accurate, cost-effective means of identifying difficult taxa to species. As a test of the MinION’s potential, I will present findings from a “proof-of-concept” project that focuses on a critical need to increase the speed, accuracy, and precision, of mite identification, to safeguard the citrus, stone fruit, and avocado industries in California.

Plant growth promoting bacteria (PGPBs) as bioinsecticides

Authors: Ruiu Luca, Dipartimento di Agraria University of Sassari, Italy

Abstract: The industrial interest in plant growth promoting bacteria (PGPBs) is significantly growing as a result of the discovery of new properties of certain microbes in benefiting agricultural crops. While several rhizobial species have been widely exploited for their ability to optimizing plant use of environmental resources, now the focus is shifted to species that are additionally capable of improving plant health and conferring resistance to abiotic stress and deleterious biotic agents. In some cases, PGPB species may directly act against plant pathogens and parasites through a variety of mechanisms including competition, protective biofilm formation, and the release of bioactive compounds. The use of this type of bacteria is in line with the principles of eco-sustainability and integrated pest management, including the reduction of employing chemical pesticides. Several strains of Bacillus, Paenibacillus, Brevibacillus, Pseudomonas, Serratia, Burkholderia, and Streptomyces species have been the subject of specific studies in this direction, and under evaluation for further development for their use in biological control. Accordingly, specific case studies are presented and discussed, including the entomopathogenic bacteria Brevibacillus laterosporus and Pseudomonas protegens.

Ability of recombinant Bacillus subtilis 26DCryChS line to induce defensive response of wheat to greenbug aphid Schizaphis graminum and bird cherry-oat aphid Rhopalosiphum padi feeding.

Authors: Rumyantsev Sergey[1], Blagova Daria[1], Burkhanova Guzel[1], Maksimov Igor[1], Veselova Svetlana[1] and Alekseev Valentin[1], [1]Institute of Biochemistry and Genetics of the Ufa Federal Research Center of the Russian Academy of Sciences, Russia

Abstract: Obtaining of biological control agents based on recombinant lines of endophytic bacteria of the genus Bacillus which combine fungicidal and insecticidal activities is one of the most effective technique in protecting plants from pests and diseases.

In our laboratory, we obtained the new recombinant line Bacillus subtilis 26DCryChS containing the Btcry1Ia gene from Bacillus thuringiensis B-5351. It retained endophyticity and the ability to synthesize lipopeptide surfactin, and also acquired the ability to produce Cry1Ia protein. We observed insecticidal effect against Schizaphis graminum Rond. and bird cherry-oat Rhopalosiphum padi L. aphids of lipopeptide rich fraction of the culture filtrate of B. subtilis 26D strain and B. subtilis 26DCryChS line. The introduction of the Btcry1Ia gene into the genome of the B. subtilis 26D strain increase the aphicidal activity of B. subtilis 26DCryChS line. It was found that in wheat plants which were colonized by S. graminum and R. padi, bacterial strains under investigation triggered induced systemic resistance (ISR). ISR was characterized by an increase in the content of hydrogen peroxide, a decrease in activity of catalase, and an increase in activity of peroxidases and proteinase inhibitors in wheat plants occupied by aphids.

The advantage of the B. subtilis 26DCryChS recombinant line was stimulation of the transcriptional activity of both salicylate (SA) and jasmonate (JA) - dependent genes, while the source strain B. subtilis 26D activated genes which are regulated via SA pathways, and the donor strain B. thuringiensis B-5351 activated JA dependent genes. The recombinant B. subtilis 26DCryChS line can be proposed as a solution for the development of modern biocontrol agents.

Inheritance and fitness cost of clothianidin resistance in the brown planthopper, Nilaparvata lugens

Authors: Ruoheng Jin[2], Li Jianhong[2], Wan Hu[1], Kaikai Mao[2], Pengfei Xu[2], [1]College of Plant Science and Technology, Huazhong Agricultural University, Wuhan, PR China, China, [2]Huazhong Agricultural University, China, [3]Huazhong Agricultural University, China

Abstract: The brown planthopper (BPH), Nilaparvata lugens (Stål), one of the most important pests on rice crops and has developed resistance to many insecticides including clothianidin, a kind of neonicotinoid insecticides. Here, a laboratory selected clothianidin resistant strain and a susceptible strain were used to investigate the genetic basis and the fitness cost of clothianidin resistance in N. lugens. The clothianidin resistant N. lugens strain with 173.36-fold resistance was selected in laboratory. Data from the F1 reciprocal crosses between clothianidin-resistant and -susceptible strains indicated that resistance might be autosomal and incompletely dominance. Chi-square analyses of self-bred and backcross progenies suggested the resistance was controlled by multi-gene. The resistant strain had a relative fitness of 0.78 with the increased adult pre-oviposition period and the decreased total fecundity. The mRNA expression level of NlVg in the resistant strain was significantly downregulated compared to the susceptible strain. Clothianidin resistance in N. lugens was shown to have an autosomal and incompletely dominance mode of inheritance. The development of resistance may have a significant fitness cost for the resistant population including the decreased fecundity. Downregulation of NlVg may contributed to the reduced fecundity in the resistance. Current study provides valuable information for the establishment of resistance management strategies to delay the resistance of clothianidin in N. lugens in the field.

Predator biomass distribution and biological pest control services in agricultural landscapes

Authors: Rusch Adrien, INRA, UMR SAVE - Villenave d’Ornon, France

Abstract: Biological control of pests by their natural enemies is a crucial ecosystem service supporting agricultural production. It has been demonstrated that landscape heterogeneity or organic farming promote biological pest control services but the relationship between predator community composition and predation rates of pests remains poorly investigated.. A deeper understanding of the processes shaping interaction strength in agroecosystems is therefore needed if we are to accurately predict biological pest control services. The large body of literature studying the relationships between biodiversity and ecosystem functioning indicates that there is a positive non-linear relationship between taxonomic richness of a given community and ecosystem functioning. However, recent studies have demonstrated that other aspects of community structure such as community composition or functional diversity are important providing major insights on processes shaping emergent functions from species assemblages. If all species contribute equally to a given ecosystem function, the overall numerical abundance of individuals might best explain the level of functioning than any other characteristics of the community incorporating evenness of species distribution or functional traits. However, if a trait is strongly related to an ecosystem function then the moments of trait-abundance distribution (i.e., mean, variance, skewness and kurtosis) in the community might best explain ecosystem functioning while shedding light on the ecological mechanisms explaining these relationships (e.g., sampling effect, complementarity, asymmetric competition). Here, using large empirical datasets replicated at landscape scales, we examined how predator abundance, taxonomic richness as well as the mean, variance, skewness and kurtosis of predator biomass distribution affect pest predation rates in an agroecosystems. We particularly hypothesized that landscape heterogeneity and organic farming would enhance abundance and taxonomic diversity of predators but that parameters describing predator biomass distribution would better explain biological pest control services than metrics only based on abundance or taxonomic diversity. Our results supported our hypothesis and we demonstrated that predator biomass distribution is a key trait to explain the level of biological control. We found that the skewness of biomass distribution of predators was the most important parameter positively affecting the level of pest predation. Indeed, when the proportion of large biomass predator increases in the community, the level of pest predation decreases suggesting negative interactions between predators such as intraguild predation or behavioural interactions. This study demonstrated that considering functional trait composition of communities provides a mechanistic understanding of the processes shaping the strength of trophic interactions in terrestrial ecosystems.

Black soldier fly (Hermetia illucens L.) reared on coffee by-products enriched with microalgae

Authors: Ruschioni Sara[3], Riolo Paola[3], Truzzi Cristina[2], Olivotto Ike[2], Zarantoniello Matteo[2], Loreto Nino[1] and Isidoro Nunzio[1], [1]Department of Agricultural, Food and Environmental Sciences - Università Politecnica delle Marche, Italy, [2]Department of Life and Environmental Sciences - Università Politecnica delle Marche, Italy, [3]Università Politecnica delle Marche, Italy

Abstract: Nine billion people are expected on Earth by 2050 with an increase in global feed and food demand. Furthermore, a rise in waste and by-products are also expected. Insects reared on by-products represent a good example of bio-converting organisms for the production of feed and food in a circular economy view. In addition, farming of insects is sustainable in terms of land use, water consumption and CO2 production. Among several insect species, the black soldier fly, Hermetia illucens, has a promising role for both bioconversion and aquafeed production. The aim of the present study was to compare the influence of different rearing substrates on H. illucens larvae fed on a by-product of the coffee industry (coffee silverskin) enriched with different inclusions of two microalgae: Schizochytrium sp. and Isochrysis galbana. At this purpose, eight different diets based on coffee silverskin enriched with 5, 10, 20 and 25% of Schizochytrium sp. and I. galbana respectively, and a control diet composed by 100% coffee silverskin were tested. Larval mortality rate, larval development time and prepupal weights were recorded for each diet treatment. Moreover, the growth rate, the efficiency of conversion of digested food, the feed conversion rate, the efficiency of conversion of ingested food, and the waste reduction index were determined. No significant differences among diets were recorded for the larval mortality rate. Whereas, the larval development time and the prepupal weight were strongly affected by dietary treatment: higher inclusions of both microalgae resulted in shorter larval development time; and higher inclusions of Schizochytrium sp. resulted in higher prepupal weights. Moreover, the higher growth rates were recorded for larvae fed on higher inclusions of Schizochytrium sp.. Better values of the efficiency of conversion of digested food, feed conversion rate, and efficiency of conversion of ingested food, were recorded on higher inclusions of both microalgae. Finally, the waste reduction index showed significantly higher value on diet enriched with 10% of Schizochytrium sp. In conclusion, this study showed that higher inclusion of Schizochytrium sp. in the diet resulted in the best larval performances.

Sound emitted by honey bees as non-invasive monitoring methods in a beehive

Authors: Ruschioni Sara[3], Riolo Paola[3], Terenzi Alessandro[2], Isidoro Nunzio[1] and Cecchi Stefania[2], [1]Department of Agricultural, Food and Environmental Sciences - Università Politecnica delle Marche, Italy, [2]Department of Information Engineering - Università Politecnica delle Marche, Italy, [3]Università Politecnica delle Marche, Italy

Abstract: Honey bees are very useful insects since they are able to produce honey, beeswax, royal jelly and propolis and, most important, they play a key role in the service of pollination allowing the proliferation of both cultivated and spontaneous flora. In the last decades, an increasing of bee mortality has been recorded, with ecological and economic consequences. The causes can be found in the Colony Collapse Disorder which is a situation characterized by a sudden disappearance of honeybees from the hive. Actually, the decline of honey bee colonies is the result of multiple source of stress, that act independently, in combination, or synergistically to impact the honey bees health. In this scenario, it is clear the necessity of an intensive monitoring activity in order to better understand the problems which are seriously affecting the health of honey bees. Nowadays, different monitoring methods are studied to try to solve the problem. Among them, the sound emitted inside a beehive could be one of the key parameters for a non-invasive monitoring able to determine the family condition. Sound signal modulates many colony behaviors. There is a strict correlation between the frequencies and the amplitudes of honey bee hive sounds and the prevision of events. Different sounds are used by the honey bees to communicate within the colony, in order to give notice of the presence/absence of the queen, the presence of a young queen, the swarming, the presence of smoke in the environment, and of other events. The sound is generated through vibro-acoustic signal production. Honey bees produce these sounds by gross body movements, wing movements, high-frequency muscle contractions without wing movements, and pressure of the thorax against the substrates or against another bee. Therefore, an accurate interpretation of these sounds could help to identify specific situations within the hive. In this work, a multi-sensor platform capable of real-time monitoring beehives condition has been used. The system has been developed to record the sounds emitted by the bees in the hives, and to measure parameters such as temperature, humidity, CO2, weight and weather conditions. Moreover, we applied advanced digital signal processing techniques to recognize different states in a beehive using as input audio data of beehives collected from the NU-Hive project. The proposed work aims at analyzing the bees sound introducing new advanced algorithms to determine and identify several situations, like swarming period, the absence of queen bee, and presence of smoke in the environment. Taking into consideration a real scenario, several experiments have been performed focusing on particular events to highlight the potentiality of the proposed approach. Several experimental results have been collected from a real field deployment, proving the effectiveness of the proposed approach in identifying specific situations.

Precibarial valve of Cicadella viridis (Hemiptera: Cicadellidae): a potential vector of Xylella fastidiosa

Authors: Ruschioni Sara[2], Riolo Paola[2], Salvi Alessandro[1], Corsi Lorenzo[1] and Isidoro Nunzio[1], [1]Department of Agricultural, Food and Environmental Sciences - Università Politecnica delle Marche, Italy, [2]Università Politecnica delle Marche, Italy

Abstract: Xylella fastidiosa is a xylem-inhabiting, vector borne, gram-negative bacterium that infects numerous plant species. This pathogen is transmitted by xylem sap-feeding insects of the order Hemiptera, sub-order Auchenorrhyncha. These insects have a sucking mouthparts with which they are able to reach the xylem of their host plants. After the acquisition from the xylem of the source plants, the bacterium attaches to the precibarium and multiplies in it without circulation in the hemolymph. With the exception of Philaenus spumarius L. (Aphrophoridae), identified as a vector of X. fastidiosa in California and in Apulia, the American vector species are absent in Europe. In America the most important vectors of X. fastidiosa are insects belonging to the family of Cicadellidae, subfamily Cicadellinae, but in Europe only a few species of sharpshooters are present, among which Cicadella viridis (L.) (Cicadellidae). This leafhopper is widespread in the Europe, and it is considered a X. fastidiosa putative vector. There is a good amount of available knowledge on the ecology and phenology of C. viridis, but some morphological information on its feeding structures are lacking. The precibarial valve plays an important role in sap ingestion. Therefore, considering the importance of this structure in the transmission of the bacterium, we used light and electron microscopy to study the morphology of the precibarial valve of C. viridis. Up to now, the valve of Cicadellidae was described as a bulbous tip attached to the proximal side of a pit, that when opens fits into a groove at the anterior end of the basin. The use of cross-sections, compared to images taken with the electron microscope, allows us to describe a different structure. In our observations, the precibarial valve of C. viridis appears as a complex structure, with a bell-like invagination located in the middle of the epipharynx, linked to a flap-like structure that pivot on it, attached to a muscle originating on the clypellus. This structure is similar of what we observed in our previous work on P. spumarius, in which the valve opens by dilator muscles and closes through cuticular and fluid tensions, the latter leading to morphological changes to the plane of the valve based on sap flow. X. fastidiosa presents little species specificity within xylem-feeding specialists. This characteristic suggest that foregut morphological traits determine the efficiency of bacterial transmission. For this reason, the morphological similarity to P. spumarius together with its wide distribution, and its polyphagia supports the hypothesis that C. viridis can be seriously considered a potential vector of X. fastidiosa.

Rearing mealworm larvae on substrates contaminated by foodborn pathogens

Authors: Ruschioni Sara[1], Riolo Paola[1] and Corsi Lorenzo[1], [1]Università Politecnica delle Marche, Italy

Abstract: Tenebrio molitor larvae were reared on organic wheat middling, spiked with Escherichia coli and Staphylococcus aureus at three contamination levels (1, 5, and 7 Log colony forming units per gram).

Chemical control of hala scale, Thysanococcus pandani, and its current geographic distribution on the Hawaiian Islands.

Authors: Russo Mason[1], Cheng Zhiqiang[1], Lutgen Hannah[1] and Waisen Phillip[1], [1]University of Hawaii at Manoa, United States

Abstract: The hala scale, Thysanococcus pandani, was first detected in Hana, Maui in 1995. The primary host plant for T. pandani is the hala tree, Pandanus tectorius, which is found in coastal areas of the Hawaiian Islands and frequently planted as a landscape tree. P. tectorius trees are very significant to Hawaiian culture as they were part of the original canoe plants brought by Polynesian voyagers across the Pacific. Since its initial introduction in Maui, it is now widespread on Maui and Molokai, and is established on limited locations on Oahu. In April and May 2021, a statewide survey was conducted to evaluate its current distribution with an emphasis on Kauai, Hawaii Island, and Lanai. The Lanai population that was previously detected has been eradicated. There was no hala scale detected on Kauai and Hawaii Island at the available survey sites. Chemical control methods were also evaluated to determine if any treatments could be effective for reducing or eliminating hala scale in landscape settings. An open-field potted plant experiment was conducted testing the efficacy of various foliar insecticides on T. pandani infested plants. Our results so far indicate that flupyradifurone and buprofezin reduced the overall infestation levels and improved the visual appearance of the infested plants. This research provides potential control methods against hala scale, and the latest distribution of the pest statewide.

Effects of fungicide on Bombus vosnesenskii microcolony performance and microbiome composition

Authors: Rutkowski Danielle[2], Vannette Rachel[2], Litsey Eliza[1] and Maalouf Isabelle[1], [1]Department of Entomology and Nematology, University of California Davis, United States, [2]Department of Entomology and Nematology, University of California Davis, United States

Abstract: Introduction and Methods
The bacterial microbiome of bees is responsible for numerous nutritional and immune-related functions, but whether the fungi that inhabit bees and their colonies influence bee health is poorly understood. Among bees, bumble bees exhibit particularly well-characterized associations with fungi. Queens often host fungal propagules during overwintering, and worker attraction to yeast volatiles has been documented in multiple floral systems. To test the hypothesis that fungi in the microbiome are important to worker survival and health, we performed an experiment using a native bumble bee species (Bombus vosnesenskii). Fungicide was used to reduce fungal growth and to determine the importance of fungi to bee health. We exposed microcolonies of worker bumble bees to the fungicide propiconazole in their nectar supply and then gave them the opportunity to regain fungi by allowing them to feed on nectar containing fungi isolated from B. vosnesenskii queens, in a factorial design. We measured bee survival, foraging preference, nectar consumption, and microbiome composition.

Results and Discussion
We found no differences in worker foraging preferences, but bees exposed to fungicide consumed more fungi-rich nectar than bees not previously exposed to fungicide. Bee survival was negatively affected by fungicide exposure, but if bees subsequently fed on fungi-rich nectar, survival did not differ from bees in the control group which was not exposed to fungicide. Amplicon sequencing will examine changes in the fungal and bacterial composition of worker microbiomes. These results suggest that the fungal microbiome of bees influences survival, and that workers may reacquire microbes from the environment under some conditions. More research is required to elucidate the mechanisms, but these results suggest that agricultural application of fungicides may have direct negative consequences on bumble bee health and fitness.

A novel insecticidal molecule extracted from Alpinia galanga to control a pest insect, Spodoptera frugiperda

Authors: Ruttanaphan Torranis[1], Le Goff Gaelle[2], [1]Kasetsart University, Thailand, [2]Institut national de la recherche agronomique, France

Abstract: Spodoptera frugiperda, a highly polyphagous insect pest from America, has recently invaded and widely spread throughout Africa and Asia. Effective and environmentally safe tools are needed for successful pest management of this invasive species. Natural molecules extracted from plants offer this possibility. Our study aimed to determine the insecticidal efficacy of a new molecule extracted from Alpinia galanga rhizome, the 1'S-1'-Acetoxychavicol acetate (ACA). The toxicity of ACA was assessed by topical application on early third-instar larvae of S. frugiperda. Results showed that ACA caused significant larval growth inhibition and larval developmental abnormalities. In order to further explore the effects of this molecule, experiments have been performed at the cellular level using Sf9 model cells. ACA exhibited higher toxicity on Sf9 cells as compared to azadirachtin and was 38-fold less toxic on HepG2 cells. Inhibition of cell proliferation was observed at sublethal concentrations of ACA and was associated with cellular morphological changes and nuclear condensation. In addition, ACA induced caspase-3 activity. RT-qPCR experiments reveal that ACA induces the expression of several caspase genes. This first study on the effects of ACA on S. frugiperda larvae and cells provides evidence that ACA may have potential as a botanical insecticide for the control of S. frugiperda.

The evolution of bite force in insects

Authors: Rühr Peter[1] and Blanke Alexander[1], [1]Bonn University

Abstract: In vertebrates, bite force can be correlated to the ecological demands of animals but is often phylogenetically structured as well. In insects, bite force data is extremely scarce and it is unknown if similar patterns of bite force evolution occur in this megadiverse clade. Here, we present an analysis of bite force values and bite curve progression shapes of individual bites of more than 600 insect species across 111 families and 13 orders. We found an allometric relationship between bite force and head volume (both log10-transformed: $R^2 = 0.67$, $p < 0.001$). Blomberg's K indicated no phylogenetic structuring of size-corrected maximum bite force in insects ($p = 0.18$), but Pagel's lambda implied that the evolution of bite force follows phylogeny to some extent ($\lambda = 0.66$, $p < 0.001$). The variation of bite force across insects was also only weakly explained by feeding mode and general head phenotype (both $R^2 < 0.1$), while flight ability had no effect. We also found weak phylogenetic signal in models describing the bite curve shapes ($K = 0.091$, $p = 0.02$; $\lambda = 0.34$, $p < 0.001$), but statistical parametric mapping of the bite curve shapes revealed well-defined differences between hemimetabolous and holometabolous orders.

Silicon integrates into phytohormonal signalling to enable targeted plant defence against insect herbivores

Authors: Ryalls James[1], Johnson Scott[3], Frew Adam[2], Hall Casey[4] and Hartley Susan[5], [1]Centre for Agri-Environmental Research, School of Agriculture, Policy and Development, University of Reading, United Kingdom, [2]Charles Sturt University, Faculty of Science, Wagga Wagga, Australia, [3]Hawkesbury Institute for the Environment, Western Sydney University, Australia, [4]Hawkesbury Institute for the Environment, Western Sydney University, Australia, [5]York Environment and Sustainability Institute, Department of Biology, University of York, United Kingdom

Abstract: Plants and herbivorous insects are amongst the most abundance multicellular organisms on the planet. Moreover, the two have been locked in an evolutionary arms race for over 300 million years. Plants deploy an array of defences which deter feeding or otherwise cause harm to herbivores and herbivores, in turn, develop counter-adaptations to evade their effects. Many plants, especially the grasses, acquire large amounts of silicon (Si) which can be used for herbivore defence. Silicification of plant tissues makes them physically stronger, more difficult manipulate and reduces the nutritional quality of foliage. It is unclear how Si-based defences relate to other anti-herbivore defences. Most anti-herbivore defences are under the control of the jasmonic acid (JA) pathway which is triggered following herbivore attack. Using the model grass Brachypodium distachyon, we demonstrate that chewing herbivores induce Si uptake. Similar results using methyl jasmonate suggest that induction of the JA pathway drives Si uptake. Chewers were negatively affected when feeding on plants with Si (+Si plants) which also possessed higher densities of leaf macro-hairs. Removal of these macro-hairs restored chewer performance. Crucially, attack by chewing herbivores triggered a much weaker JA response in +Si plants compared to plants without Si. Sap-feeding herbivores, in contrast, did not induce Si uptake or trigger the JA pathway and were unaffected by Si. We hypothesise that certain grasses use Si physical defences constitutively or in response to either chewing herbivory or triggering of the JA pathway, in lieu of other metabolically costly secondary metabolites. Dampened JA responses may be sufficient to stimulate Si uptake and deposition, which is irreversible, without requiring levels of JA activity needed for continued synthesis of secondary metabolites.

New insights into chromosome and genome evolution in mosquitoes revealed by improved genome assembly of the West Nile virus Culex quinquefasciatus

Authors: Ryazansky Sergei S.[3], Sharakhova Maria[2], Naumenko Anastasia N.[2], Lukyanchikova Varvara[5], Masri Reem A.[2], Brusentsov Ilya I.[4], Karagodin Dmitriy A.[4] and Tu Zhijian[1], [1]Department of Biochemistry, Virginia Polytechnic and State University, Blacksburg, United States,

[3]Department of Molecular Genetics, Institute of Molecular Genetics, Moscow, Russia, [4]Federal Research Center, Institute of Cytology and Genetics, Novosibirsk, Russia, [5]Novosibirsk State University, Novosibirsk, Russia

Abstract: Mosquitoes of two subfamilies Anophelinae and Culicinae have different genome sizes and chromosome arrangements. However, the details of these differences are not completely understood. In this study, chromosome and genome evolution in mosquitoes was investigated using chromosome-scale assemblies for four species from the major branches of the mosquito evolution, including recently reported Cx. quinquefasciatus genome. The quality of this genome was improved using advanced genome technologies. In addition to the previously detected chromosomal rearrangements, a pericentric inversion in sex-determining homomorphic chromosome 1 between the two species was identified. Comparison of the rate of the chromosomal evolution in different species indicated that the sex-determining chromosome 1 has significantly higher rate of evolution in Cx. quinquefasciatus but not in Ae. aegypti. Our study supports the previous observations that genome evolution in Culicinae mosquitoes is associated with significant expansion of transposable elements in their genome. Concentrated only in the pericentromeric and some internal regions in the genomes of Anopheles species, they spread along the arms toward the telomeres in Cx. quinquefasciatus and became evenly distributed in the Ae. aegypti genome. We thank Culex quinquefasciatus genome consortium for providing an improved version of the genome and NIH for funding (R21 AI156280).

Quantifying insect biodiversity using distributed optical sensors

Authors: Rydhmer Klas, Copenhagen University, Sweden

Abstract: We have developed a method to quantify the biodiversity of a optically recorded dataset and correlated it with ground truthing methods. Using newly developed optical sensors, recording the back-scattered signal from any insects that flies trough its measurement volume we have recorded labelled data from ca 100 insect species. Using this dataset, we have developed a biodiversity index, to be used as a proxy for the species richness in conventional monitoring methods. The method is based on applying a clustering algorithm on a low-dimensional representation and counting the number of found clusters. In order to validate our method, we have collected field data from 5 locations from March to November.

Winners and losers of a boreal pollinator community reflect climate and land use changes

Authors: Rytteri Susu[1], Suuronen Anna[1], Heliölä Janne[1], Isaac Nick[3], Kouki Jari[4], Kuussaari Mikko[1], Martikainen Petri[4], Paukkunen Juho[2], Sihvonen Pasi[2] and Pöyry Juha[1], [1]Finnish Environment Institute SYKE, Finland, [2]Finnish Museum of Natural History, Finland, [3]UK Centre for Ecology & Hydrology, [4]University of Eastern Finland

Abstract: Changes in pollinator assemblages have been reported widely, raising the concern of potential reductions of pollination services. Much of the current knowledge is based on well-studied pollinator groups in temperate, agriculture-dominated regions. Thus, we largely lack the understanding of the generalisability of this knowledge to different geographic regions and taxonomic groups. Here, we present how species traits affect the occupancy trends of 28 bumblebees, 108 solitary bees, 145 hoverflies, and 19 longhorn beetles across a 1100-km latitudinal gradient across the boreal zone in Finland. Time series (1980-2019; except for wild bees 1930-2019) analysed with occupancy models consist of museum and distributional records. The occupancy of bumblebees and longhorn beetles changed more often than that of solitary bees and hoverflies. Among bumblebees, the numbers of decreasing species were higher than those of increasing species. In other taxonomic groups, the proportions of decreasing and increasing species varied more between different time periods. Southern distribution was related to increasing occupancy in all pollinator groups, while none of the northern species increased. Other traits associated with occupancy trends varied among taxonomic groups and time periods. The changes of boreal pollinator community reflect the expected outcomes of changes in climate and habitat availability.

Adaptations of olfactory circuits in the honeybee – function and evolution

Authors: Rössler Wolfgang, Department of Behavioural Physiology and Sociobiology (Zoology II), Biozentrum, University of Wuerzburg, Germany

Abstract: Honeybees, like many other social Hymenoptera, heavily rely on olfaction mediated by thousands of olfactory sensory neurons housed in various types of olfactory sensilla on the antenna. How the diverse world of odorants is encoded in the brain to finally result in adaptive behavior is a highly active area of research across many species of insects and vertebrates. I will focus on adaptations at three processing levels of the honeybee olfactory system – from the antennal sensilla to olfactory glomeruli, the odor processing units in the antennal lobe, to memory circuits in high-order integration centers in the mushroom bodies and their output to the protocerebrum. One striking feature of the honeybee olfactory system is a dual (medial and lateral) pathway of projection neurons connecting two distinct layers of antennal-lobe glomeruli with many thousands of large input synapses in the mushroom-body calyx. I will highlight the odorant coding properties and high potential of this dual pathway for processing complex odorant mixtures and discuss the evolution of this highly sophisticated olfactory circuitry within the Hymenoptera.

Developmental and adult neuronal plasticity of olfactory and visual synaptic microcircuits in the mushroom-body calyx of social Hymenoptera

Authors: Rössler Wolfgang[1], Groh Claudia[1], [1]Department of Behavioral Physiology and Sociobiology (Zoology II), Biozentrum, University of Würzburg, Germany

Abstract: Mushroom bodies (MBs) are prominent neuropils in the insect brain that perform high-level sensory integration and the organization of complex behaviors involving learning, the formation of associative memories, and spatial orientation. In social Hymenoptera, the MBs receive multimodal (olfactory and visual) input from cholinergic projection neurons (PNs) relayed to numerous MB intrinsic neurons (Kenyon cells, KCs) within morphologically elaborate (doubled and cup-shaped) MB calyxes. PNs synapse on KCs forming large identifiable synaptic complexes called microglomeruli (MG). The talk will first highlight a remarkable structural plasticity of MG associated with postembryonic brood care during pupal development in nectar-feeding ants and honeybees. We investigated that thermoregulatory rhythmic nursing behavior mediated by Camponotus mus workers on the developing pupae leads to an increase in MG density and total MG numbers in the olfactory lip region of the young adult MB calyx. Similar results were found in honeybee workers where the synaptic organization in the young adult olfactory lip is affected by slight deviations within and beyond the natural range of a constant pupal rearing temperature experienced in the brood area. The difference across the two species indicates that the favorable temperature range and the optimal temperature regime are species-specific within social Hymenoptera. The brood-temperature mediated differences in initial MG numbers in the MB calyx may have important consequences for behavior at later stages of adulthood. The second part of the talk will highlight aspects of cellular and subcellular processes that shape olfactory and visual MG in the calyx during adult maturation in Camponotus rufipes ants and honeybees. During the natural transition from nursing to foraging an overall reduction of MG is accompanied by a significant increase in postsynaptic contacts of KC dendritic spines. As a result, we infer that dendritic spines are key candidates to the reorganization of MG that occur during the age-related transition between nurse and forager. Our results suggest that the different levels of structural neuronal plasticity in olfactory and visual microcircuits play important roles in the regulation of social organization in Hymenopteran societies.

Distributed plasticity in ant visual pathways following associative and non-associative visual experiences

Authors: Rössler Wolfgang[1], Yilmaz Ayse[2] and Spaethe Johannes[1], [1]Department of Behavioural Physiology and Sociobiology (Zoology II), Biozentrum, University of Wuerzburg, Germany, [2]Department of Biology, Lund University, Sweden

Abstract: Camponotus ants possess a highly plastic visual system that comprises both “experience-independent” and “experience-dependent” components (Yilmaz et al., 2016). Our findings on plasticity in retinal opsin gene expression and optic centers suggest two independent processes—an age-related and light-induced neuronal plasticity. We suggest that both sources of plasticity in the visual system represent important components promoting optimal timing of the interior–forager transition and flexibility of age-related division of labor: the peripheral and central neuronal system must cope with new challenges such as visual orientation, long distance navigation, and learning and memory of the visual information to locate rich food sources.

Recently, we showed that C. blandus workers are able to learn the association of color information and a reward, independent of intensity differences, and form complex color memories based upon experience (Yilmaz et al., 2017). This enabled us to link associative color learning performance with structural neuronal plasticity in defined neuropils – the optic lobes (OLs), mushroom body (MB) input (collar) and output (vertical lobe) regions, central complex (CX) and anterior optic tubercle (AOTU) – aiming at identifying whether associative colour experiences are reflected in plasticity of underlying neuronal circuits. The result clearly showed that the OLs, AOTU, and CX respond with plastic changes after colour learning and long-term memory formation, suggesting a complex neuronal network in color processing (Yilmaz et al., 2019). Such a colour-processing network probably represents an efficient design promoting fast and accurate decisions during orientation and navigation.

Insights into genetics of Trissolcus japonicus populations accidentally introduced into North America and Europe

Authors: Sabbatini Peverieri Giuseppino[3], Abram Paul[1], Haye Tim[2], Hoelmer Kim A.[5], Talamas Elijah[4] and Guermache Fatiha[6], [1]Agriculture and Agri-Food Canada, Canada, [2]CABI, Delémont, Switzerland, [3]Council for Agricultural Research and Economics-Research Centre for Plant Protection and Certification, Italy, [4]Florida Department of Agriculture and Consumer Service, United States, [5]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States, [6]USDA-ARS-European Biological Control Laboratory, France

Abstract: Adventive populations of the Asian egg parasitoid Trissolcus japonicus (Ashmead) (Hymenoptera: Scelionidae), the most promising agent for classical biological control of Halyomorpha halys, were first detected in the northeastern USA in 2014 and in the northwestern USA in 2015, and have since been reported in a total of 12 states. Although the actual pathway of entry for T. japonicus in North America remains unknown, it is presumed to have entered with parasitized host egg masses or as hitchhiking adult wasps. More recently, adventive populations were found in northern Italy and southern Switzerland in 2017 and 2018 and in British Columbia, Canada, in 2018. In northern Italy the spread of H. halys has also provided an invasion opportunity for another egg parasitoid, Trissolcus mitsukurii (Ashmead) (Hymenoptera: Scelionidae). Results from a phylogeographic study based on the mitochondrial barcoding region of the cytochrome oxidase subunit 1 revealed that all adventive populations of T. japonicus found to date belong to the same maternal T. japoncus lineage that is widely distributed in China, Japan and South Korea. The T. mitsukurii specimens recovered in Italy harbored one unique barcode haplotype which does not match any of the haplotypes evidenced so far in Asia. We developed a panel of 24 polymorphic microsatellites based on representative T. japonicus populations throughout the native range, and we used a population genetics approach to study the genetic structure and the differentiation of T. japonicus populations and to understand the origin(s) and dynamics of the spread of the adventive populations. The detection of additional genetic structure within this maternal lineage shows that these microsatellites can detect differentiation at a local scale. Our analyses indicated the existence of three genetically differentiated population clusters in the USA and one in Europe. Preliminary analysis supports the scenario of multiple invasions in USA, most likely from China, but also shows that the rapid population expansion observed in the USA retains genetic diversity within the US populations of T. japonicus, in contrast to the quarantine laboratory colonies of T. japonicus which have been maintained in the U.S. for host range evaluation. Although our comparative analyses are ongoing, the results to date provide the first clues about mechanisms contributing to adaptation and success of these adventive T. japonicus populations.

The use of Long-Lasting Insecticide-treated Nets to control the Japanese beetle Popillia japonica: a laboratory and field evaluation

Authors: Sabbatini Peverieri Giuseppino[1], Paoli Francesco[1], Marianelli Leonardo[1], Barzanti Gian Paolo[1], Roversi Pio Federico[1], Cavagna Beniamino[3], Benvenuti Claudia[1], Giacometto Emanuela[2], Bosio Giovanni[10], Torrini Giulia[1], Mazza Giuseppe[1] and Ciampitti Mariangela[3], [1]CREA - Council for Agricultural Research and Economics, Research Centre for Plant Protection and Certification, Italy, [2]Regione Piemonte - Settore Fitosanitario e servizi tecnico-scientifici, Italy, [3]Servizio Fitosanitario, Regione Lombardia, Milano, Italy, [4]Settore Fitosanitario, Regione Piemonte, Torino, Italy,

Abstract: The Japanese beetle Popillia japonica Newman is a quarantine insect pest that recently invaded northern Italy, between Piedmont and Lombardy regions. This was the first record of this pest in mainland Europe. From its discovery on, the invaded territory is getting wider, reaching in 2019 more than 6,000 square Km in Italy. In the meanwhile, findings of adults of P. japonica occurred also in Switzerland in 2017. Due to its high polyphagy and the ability to rapidly spread into new areas, this insect is considered a serious threat to agriculture. Confirming the foregoing, it is noteworthy that the new EU regulations have inserted the Japanese beetle within the EU list of priority pests. In the last decades, several trials on biological control of the Japanese beetle by entomopathogenic nematodes and fungi have been carried out with variable efficacy. However, the necessity of an integrated pest management approach to improve its control has arisen. Long-lasting insecticide-treated nets (LLINs) are a technology recently evaluated for the control of other agricultural pests with an attract-and-kill strategy. Here, we present results from laboratory evaluation of two different LLINs, Storanet (BASFTM) and ZeroFly (VestergaardTM), against P. japonica adults. Both were effective in killing the beetles; however, some differences emerged if different exposure times were compared: ZeroFly always gave 100% mortality in tests from 5-sec to 30-min exposure; Storanet showed 100% mortality only with 30-min exposure and going down to 99%–89% mortality for 15-min to 5-sec exposure. Furthermore, in order to define the possibility of the field use of such LLINs, we present the result of field experimentation in which attract-and-kill devices made by LLIN with a pheromone were left exposed outside for the entire flight period of P. japonica, which is roughly from June to September. Results showed that the full effectiveness of the LLIN is maintained for first-month exposure. After that time, the effectiveness appears to progressively decline. However, increasing natural mortality of Japanese beetles late in the growing season may compensate for decreased effectiveness of the LLIN in August and September. In conclusion, the utility of LLINs for the control of the Japanese beetle is discussed.

Trissolcus japonicus in Italy: physiological host range and egg morphology analysis provide a predictive approach to risk analysis

Authors: Sabbatini Peverieri Giuseppino[1], Paoli Francesco[1], Marianelli Leonardo[1], Roversi Pio Federico[1], Giovannini Lucrezia[1], Hoelmer Kim A.[2], Mazza Giuseppe[1], Dapporto Leonardo[3] and Boncompagni Luca[3], [1]CREA - Council for Agricultural Research and Economics – Research Centre for Plant Protection and Certification, Italy, [2]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States, [3]University of Florence, Italy

Abstract: Halyomorpha halys is an invasive Asian species, causing severe damage to field crops, vegetables and fruits. This species is currently widespread in Italy and in many other countries worldwide. To date, pest control is realized by chemicals, but for a long-term solution classical biological control will be fundamental in pest managing. Trissolcus japonicus is an Asian egg parasitoid wasp considered to be the most important natural enemy of H. halys. However, its potential introduction to new regions for classical biological programs requires that non-target risk assessment studies be conducted.

The aim of this study was to evaluate the reproductive success (physiological host range) of five day old T. japonicus females in short (2h) and long (24h) exposure time in no-choice tests, using a single hemipteran egg as the test unit (instead an egg mass) of H. halys (the target species) and of other 15 native non-target Hemipterans: Raphigaster nebulosa, Palomena prasina, Acrosternum heegeri, Carpocoris purpureipennis, Carpocoris mediterraneus, Piezodorus lituratus, Dolycoris baccarum, Staria lunata, Eurydema ventralis, Peribalus strictus, Nezara viridula, Sciocoris sideritis, Coreus marginatus, Gonocerus juniperii, Rhynocoris iracundus. Moreover, we also tried to identify the possible association between morphological features of host eggs and parasitization success of T. japonicus to produce a predictive model of attack success. In addition, to verify the effect on female fecundity developed in different host species, the egg load in the ovaries of females emerged from H. halys and D. baccarum were assessed.

Our results showed that H. halys, Ra. nebulosa and Pa. prasina were the species with the highest percentages of parasitization success: 100%, 97% and 96% respectively. Lesser accepted species were Ca. purpuripennis, A. heegeri, Ca. mediterraneus, and D. baccarum (58%, 52% 46%, 11% respectively), while Pi. lituratus and Pe. strictus had low parasitization rates (3%, 5% respectively). The other species tested, i.e. Sc. sidertis, E. ventralis, St. lunata, N. viridula, the two coreids Co. marginatus and G. juniperi and the reduviid Rh. iracundus were never parasitized.

We provided evidence that using single eggs in short time exposure tests is a valid alternative in the first step of a non-target analysis, thus saving considerable time and resources. Moreover, this new approach can be also useful with rare species or those with a low rearing success in the lab. Analysis of egg morphology and parasitization success revealed that the shape and the volume of the pentatomid host eggs are features correlated with the host acceptance rate: Pa. prasina and Ra. nebulosa have eggs similar in shape and size to H. halys and displayed similar parasitization rates. Egg size also influenced the development of T. japonicus, since smaller females obtained from D. baccarum exhibited a lower egg load in the ovaries while the females from H. halys had a higher egg load

Prey DNA digestion data and their implications for carabid trophic networks and biocontrol potential

Authors: Sacco-Martret de Préville Ambre[1], Staudacher Karin[3], Traugott Michael[3], Plantegenest Manuel[2] and Canard Elsa[1], [1]INRAE, UMR IGEPP, [2]L'Institut Agro, UMR IGEPP, [3]Mountain Agriculture Research Unit, Institute of Ecology, University of Innsbruck

Abstract: Molecular analysis has been a major step in lifting the veil on the structure of food webs and in gaining insights on biocontrol potential of predators. However, one substantial flaw of molecular analysis is their qualitative nature. Indeed, differential digestive rates bias both the estimate of the relative frequency of prey in a predator diet, but also the relative contribution of different predators in the consumption of a prey. To correct for this bias, the detection time of the prey DNA in the predator gut must be considered. The purpose of our study was to assess the differential digestive rates for different prey items in the diet of a range of carabid species occurring in agroecosystems. In a previous study, diet of several carabid species was assessed through a multiplex PCR diagnostic. Feeding experiments were carried out on the same carabid species. Detection times for prey DNA were assessed using the same multiplex at several time intervals after feeding. Detection times varied depending on prey group and carabid size. Finally, we applied a detection time-based weighting to the dietary data obtained in the field and observed the resulting changes in the prediction of carabid community diets and their biocontrol potential.

A single principle for male sex determination in major agricultural pests (Tephritidae): Maleness-on-the-Y (MoY), its evolutionary conservation and its usage for future genetic control.

Authors: Saccone Giuseppe, Department of Biology, University of Naples “Federico II”, Napoli, Italy, Italy

Abstract: The dipteran Tephritidae family includes dozens of major agricultural pest species, including the mediterranean fruitfly Ceratitis capitata (medfly), in which genetic control of sex determination has been previously studied using Drosophila melanogaster as reference to clone orthologous genes. New generation sequencing technologies and development of novel bioinformatic tools made possible to isolate novel genes of medfly on the basis of their sex-linked location and sex-specific embryonic expression. The identification of the Y-linked male determining gene of medfly, Maleness-on-the-Y (MoY), led to discover that it is widely conserved in many other species of this family, spanning 100 million of years of evolution. This evolutionary stability of a sex determining primary signal is shared for example with Drosophilidae species in which X-signaling system is widely conserved but contrast with the rapid evolvability of other sex primary signals observed even with the same species, such as the case of Musca domestica. Present challenges and on-going work are understanding MoY molecular mechanism of action in repressing the downstream female determining transformer gene and MoY biotech usage to harness innovative genetic control strategies for Tephritidae invasive species, such as the oriental fruitfly pest Bactrocera dorsalis which recently started to be sporadically detected in south Italy and poses new risks for European countries.

Plasticity of olfactory circuits in Drosophila

Authors: Sachse Silke, Dept Evol Neuroethol Max Planck Inst Chem Ecol Jena, Germany

Abstract: Most animals rely on their olfactory system to accomplish behavioral tasks that guarantee their survival and reproduction. Since the odor space consists of an enormous, nearly infinite number of possible stimuli, olfactory systems require special strategies to perceive, identify and evaluate the highly diverse odor information from the environment. The vinegar fly Drosophila melanogaster represents a premier model system for studying olfactory processing mechanisms since it exhibits a stereotyped architecture which is similar to its mammalian counterpart, but is less complex and highly tractable as well as susceptible to genetic manipulations. By exploiting these genetic techniques and linking them to neurophysiological, molecular and behavioral methods, my group is dissecting the neural circuits that are involved in coding, processing and perception of odors.

The structure and function of the olfactory system of Drosophila is well characterized. However, little is known about whether and to which extent individual experience is modulating the olfactory circuitry. We therefore aim at elucidating plastic changes at the morphological, functional and behavioral level. Our previous studies have shown that the first olfactory neuropil, the antennal lobe, reveals a unique connectivity of input and output neurons for each individual glomerulus, which is correlated to behavioral relevance. Using tracing methods, neuronal reconstructions, functional two-photon calcium imaging and behavioral assays to monitor odor-guided behavior, we investigate the influence of experience and learning to specific odors after long-term exposure. The talk will summarize our recent insight into the plastic changes of the olfactory circuitry.

Oranges and apples? Plant responses to insect herbivores of distinct feeding guilds

Authors: Sadeh Asaf[2], Coll Moshe[5], Gershenzon Jonathan[4], Reichelt Michael[4], Eldar-Liebreich Michal[3], Ibdah Mwafaq[1] and Yahyaa Yahyaa[1], [1]Agricultural Research Organization, Neve Ya'ar Research Center, Israel, [2]Department of Natural Resources Agricultural Research Organization, Volcani Center, Israel, [3]Department of Natural Resources Agricultural Research Organization, Volcani Center. Department of Entomology, Hebrew University of Jerusalem, Israel, [4]Max Planck Institute for Chemical Ecology, Department of Biochemistry, Jena, Germany, [5]The Hebrew University of Jerusalem, Israel

Abstract: Plants face a diversity of biotic challenges in the field, including a broad range of arthropod herbivores. To understand plant responses to multiple herbivory challenges, chemical and molecular ecologists generally focus only on their proximate mechanisms, employing arbitrary herbivore loads in factorial presence-absence treatments of two species, or additive density designs. These experiments do not disentangle specific responses of plants to herbivore species from responses to the overall herbivore pressures that they experience.

We suggest a conceptual methodological approach for determining functionally equivalent loads of each herbivore species, exerting on the plant similar herbivore pressures, which can be measured using a common currency (e.g. a proxy for plant fitness or yield). We present an example, calibrating equivalent loads of leaf-chewing caterpillars and phloem-sucking aphids for similar damage to cabbage seedlings, coupled with the quantification of plant hormone and volatile responses.

Seedling vegetative growth decreased linearly with the loads of each herbivore species, producing a one-to-one equivalence mapping between herbivore loads. This mapping covered all of the implemented range of caterpillar loads, and most of the implemented aphid loads. Consequently, across these ranges, differences between plant chemical responses to the herbivores could be attributed to the identities of the herbivore species.

This calibration approach offers to remove the common confound of unstandardized herbivore pressures in multiple herbivory experiments, and can foster a more refined understanding of plant responses to the diversity of herbivores encountered in nature.

Impervious Surface Enhances Winter Survival of Evergreen Bagworm

Authors: Sadof Clifford[2] and Dawadi Sujan[1], [1]Department of Entomology Purdue University, United States, [2]Purdue University, United States

Abstract: Extreme cold weather events, not average temperatures limit winter survival of the evergreen bagworm (Thyridopteryx ephemeraeformis Haworth) (Lepidoptera: Psychidae), a generalist defoliator that causes extensive defoliation of urban landscapes. We sought to determine if microclimate warming associated with impervious landscape surfaces could act as a buffer and protect these insects during periods of cold weather. Northern Indiana is near the northern limit of bagworm distribution and routinely experiences temperatures that are cold enough (-18.1 °C for 24 h) to kill bagworms. During the winters of 2018 and 2019 we identified sites in Northern Indiana with latitudes ranging from 39.93 N to 41.47 N whose coldest day in the winter had a maximum temperature that ranged between -22.2 and -17.2 °C. We tested the hypothesis that impervious surface within 20 m of each host plant could keep bagworms warm enough during cold periods to improve bagworm survival. A total of 1303 bagworms were collected from 72 sites whose warmest temperature in on the coldest day in 2018 ranged between -20 and -17.2 °C. Similarly, we collected 952 bagworms from and 47 sites whose warmest temperature on the coldest day of 2019 ranged between – 22.2 and -17.2 °C. The percentage of impervious surface within a 20 m radius of each host tree was estimated by pace to plant technique. During both years, the survival of eggs and larval hatch was positively correlated increased with impervious surface area around the host trees. We conclude that in urban areas impervious surfaces around host trees can create a buffer zone where marginally hardy species like bagworm can easily survive regional temperatures that can kill bagworms. Limits of this effect have yet to be determined.

Biological Control of Weeds in Thailand: 1974 - 2014

Authors: Saengyot Samaporn, Plant Protection Program, Faculty of Agricultural Production, MaeJo University, Chiang Mai, Thailand

Abstract: A short historical and global overview of biological control of weeds was provided and a review was made to cover the activities and accomplishments on both augmentative and classical biological control of weeds in Thailand from 1974 to 2014 covering a period of approximately 40 years. It covered pertinent and relevant details on eight target weed species on their origin and resident endemic natural enemies employed in augmentative biological control programs, and nine target weed species on their origin and exotic natural enemies introduced from countries of weed original habitats employed in classical biological control programs. The successes were qualitatively evaluated as being partial, substantial and complete. The utilization of some biological control agents from Thailand in the Southeast Asian region and elsewhere was also given.

Chemical interactions between the phytophagous ladybird Chnootriba elaterii (Coleoptera, Coccinellidae) and Cucurbitaceae

Authors: Saitta Valerio[2], Piersanti Silvana[1], Rebora Manuela[1] and Salerno Gianandrea[2], [1]Perugia University, Dipartimento di Chimica, Biologia e Biotecnologie, [2]Perugia University, Dipartimento di Scienze Agrarie, Alimentari e Ambientali, Italy

Abstract: Among Coccinellidae, Epilachninae are phytophagous ladybirds feeding on various plants species and representing serious pests for Cucurbitaceae, Fabaceae and Solanaceae crops. Research focusing on chemical ecology in phytophagous ladybird beetles is still scanty, especially regarding the interaction with Cucurbitaceae. The aim of the present work is to describe for the first time the olfactory sensilla on the antennae of the phytophagous ladybird Chnootriba elaterii (Chevrolat) under scanning electron microscopy, and to evaluate the antennal response to volatiles through electroantennographycal investigations using VOCs from Cucurbitaceae crops (Citrullus lanatus, Cucumis melo, Cucumis sativus, Cucurbita pepo, Cucurbita moschata, Lagenaria siceraria, Luffa cylindrical) and wild species (Ecballium elaterium). Moreover, two-choice feeding tests (evaluation of damaged leaf area) were performed to understand the insect preference among the same plant species. The suitability of the plant species to the ladybird was determined evaluating the development time of larvae and pupae and the total damaged leaf area during the development on the different host plants. The present research can be considered a first step in developing sustainable semiochemical-based control strategies for melon ladybirds in crops.

Pollination by sucking insects reproducing on inflorescences in Macaranga spp. (Euphorbiaceae)

Authors: Sakai Shoko[3], Kamata Ittetsu[1] and Inui Yoko[2], [1]Center for Ecological Research, Kyoto University, Japan, [2]Department of Arts and Sciences, Osaka Kyoiku University, Japan, [3]Kyoto University, Japan

Abstract: Nearly 90 % of flowering plants have been estimated to be pollinated by animals. Since the reproductive success of animal-pollinated plants depends on the number of visitors, plants have evolved various floral traits to attract pollinators. On the other hand, a few plant groups have adopted a strategy to attract small numbers of visitors and breed them on inflorescence to increase pollen dispersal. The most studied example is Ficus spp. (Moraceae), in which daughters of the founder female fig-wasp disperse pollen. It is different from other similar systems such as yucca-yucca moth in that the flower or inflorescence phenology is precisely tuned so that the emergence of offspring matches with the timing of pollen release of the inflorescence.

The dioecious tree genus Macaranga (Euphorbiaceae) is distributed in tropical to subtropical regions. Some Macaranga species are pollinated by sucking insects (thrips or flower bugs) reproducing on the inflorescences. The pollinator insects feed on both nectar and small insects on the host plants.

In this study, we investigate if the reproduction of the pollinators benefits the host plant in Macaranga tanaius on Amami Island, Japan. We found that many larvae of the pollinator Orius atratus (Anthocoridae) on male and female inflorescences before anthesis. Both larvae and adults significantly increased their numbers towards the peak of flowering, especially on male trees. Both dry weights and stable isotope ratio of nitrogen also increased with time.

The results indicate that the reproduction of O. atratus increases the number of pollinators and enhances pollen dispersal. Though many plant groups are known to provide breeding sites to pollinators as a reword, pollinator offspring emerged from flowers or inflorescence well after the anthesis and rarely contribute pollination. M. tanarius, on the other hand, start attracting and breeding pollinators well before anthesis and use offspring to disperse their pollen effectively. On the other hand, it is not clear why pollinator flower bugs have to move between plants though the host plant provides them with food and breeding sites.

A previous study based on a molecular phylogeny indicates that brood-site pollination has evolved more than once in Macaranga. In these plants, bugs (Hemiptera) and thrips (Thysanoptera) have been reported as pollinators. Nectar is packed in the ball- or hair-shaped nectary on the bracteoles, so nectar may be only accessible to piercing-sucking insects. It is an important research topic for future studies what was the key characteristics that have caused the repeated evolution of this unique pollination system.

Trap and release of pollinators in Aristrochia spp. mediated by morphological changes of epidermal cells

Authors: Sakai Shoko[1] and Junnan Li[1], [1]Kyoto University, Japan

Abstract: Recent studies have highlighted the importance of the traits of the flower epidermal cells in plant-pollinator interactions. However, temporal changes of the cells during flowering and its ecological significance largely remain unexplored. Here, we report morphological change of the epidermal cells in the protogynous trap flower of Aristolochia spp. (Aristolochiaceae). In the plant species, the inner surface of the calyx tube has the papillate microstructure at the initial female phase, while it disappears during the following male phase. To evaluate the correlation between the change and the trap function of the flower, we collected the flowers at different phases and counted the number of trapped pollinators. Furthermore, to examine if the presence or absence of the papillate microstructure affect the behavior of pollinators, a pollinator was introduced into calyx tubes with the nectary part had been cut off, and we checked if the pollinator could escape from the calyx tube. The results suggest that the microstructure controls the trap and release of the pollinators, and the morphological change of the epidermal cells plays a primary role in the trap pollination of the plant species.

Dissecting the molecular mechanism of taste sensation of blood in Aedes aeypgti

Authors: Sakuma Chisako[1], Kanuka Hirotaka[1], [1]Department of Tropical Medicine, Center for Medical Entomology, The Jikei University School of Medicine, Japan

Abstract: Exploring the molecular mechanism of blood sucking behavior of female mosquitoes is one of the critical steps to fight against vector-borne diseases such as dengue and malaria, since pathogens are transmitted when mosquitoes are gorging on blood. Especially, it is important to reveal the molecular mechanism of taste sensation of blood, since female mosquitoes need to discriminate blood from sugar to deliver each to the destination after sucking them by using the identical proboscis. It has been known that adenine nucleotides in blood serve as phagostimulants for blood sucking. Besides, the presence of chemoreceptive cells is suggested in labral apical sensilla and sensilla in cibarium (pre-oral mouth cavity). However, the molecular nature of chemoreceptors and corresponding primary neurons remains to be examined. To identify molecules regulating the taste sensation of blood, we employed two approaches. First, we focused on the gustatory receptor 5 (Gr5) of dengue and zika virus-vector mosquito (Aedes aegypti) that was already reported to be expressed higher in female labella than that of males. We generated Gr5 deficient mosquitoes by using CRISPR/Cas9 system. Deletion of Gr5 did not affect attraction to host, but affected the initiation of blood sucking, suggesting that Gr5 may contribute to the taste sensation of blood. Second, we performed RNAseq analysis and compared the expression pattern of genes in brains between pre- and post-blood/ATP suction. The expression level of innate immunity-related signaling molecules, chaperons, and microRNAs was changed immediately after engorgement. In addition, the expression level of transient receptor potential like (TRPL) whose function in taste sensation was reported in Drosophila was increased after taking either blood or ATP, suggesting that TRPL might be involved in taste sensation of blood. Furthermore, we identified a plant derived molecule that negatively affects blood sucking in Aedes mosquito: mosquitoes quit sucking ATP when this molecule was present, although they were still attracted to the target and performed probing. These results may provide not only new insights into the taste sensation of blood, but also intriguing ways for identifying molecules that control blood sucking behavior of mosquitoes.

Study of The effects of three Botanical Oils on Management of Onion Thrips, Thrips tabaci (Lind) (Thysanoptera: Thripidae) and Some ecological aspects, Gezira state, Sudan

Authors: Salah Faiza, U. of Gezira, Sudan

Abstract: Onion thrips (Thrips tabaci (Lindeman) is the most serious insect pest causing damage to the crop. This study aimed to evaluate the effects of some botanical oils including cotton, castor bean and bitter cucumber oils on thrips infesting onion. Field experiments were conducted at Gezira state during two winter seasons (2015/16-2016/17). Two experiments were conducted in the first season (2015/16) at the experimental farm of the University of Gezira and in the Gezira research Station Farm (GRSF) of the Agricultural Research Corporation (ARC). The third experiment was conducted in the second season (2016/17) for confirmatory studies at the (GRSF) in (ARC) and observation plot of 20 X 40 m2 was used to study the population dynamics of the thrips and natural enemies. The design of the experiments was randomized complete bloc(RCBD) with four replications. Cotton oil, castor bean oil and bitter cucumber oil were applied at a concentration of 2.5% in the first season (2015/16). In the second season 50% upper and lower concentration of castor oil and bitter cucumber oil were applied at the rates of (1.25%, 2.5% and 3.75%). The onion variety used was Saggai. The results indicated that all oil treatments were effective against the onion thrips compared to the untreated control. Significant differences at $P < 0.01$ in the mean number of insects were found. This study show that the bitter cucumber oil was the most effective in reducing the number of thrips compared to the other two oils as well as the control treatment. Large number of natural enemies of thrips were found in the (GRSF) of (ARC), while, Orius bug and jumbing spider were most available and by the end of the season these natural enemies had a role to decrease the number of onion thrips. No significant difference was observed between treatments in yield. This study recommends that, bitter cucumber crude oil at 1.25% concentrations can be used to reduce the number of onion thriups. .

The EU Bee Partnership

Authors: Salazar Andrés[1] and Simon-Delso Noa[2], [1]BeeLife European Beekeeping Coordination, Belgium, [2]BeeLife European Beekeeping Coordination; CARI (Apicultural Centre for Research and Information), Belgium

Abstract: The EU Bee Health Partnership, officially established in 2018, is a collaborative stakeholder group dynamized by the European Food Safety Authority (EFSA). It includes representatives from the beekeeping and farming sectors, NGOs, veterinarians, academia and industry. After a continuous collaboration, the partnership has concluded on the need to improve efforts for bee and pollinator data standardization and communication. To achieve data standardization, the EU Bee partnership and the Apimondia BeeXML working group are working to conclude the required standards for bee and pollinator data under the Extensible Markup Language (XML) language. On the other hand, working to further materialize data sharing and integration, BeeLife European Beekeeping Coordination is leading the development of an integrative tool for the analysis, visualization and communication of pollinator-related data, The Bee Hub. In the frame of the fast-track-to-innovation project, the Internet of Bees, a Proof of Concept of the Bee Hub is under initial construction. It aims to achieve a European (and potentially worldwide) open platform that includes any relevant data linked to pollinators, especially bees (but not necessarily restricted to bees). The objective is to build a communicative tool on the status of pollinators and pollination, both essential for food security and biodiversity. Throughout the collaborations established in the EU Bee Partnership, efforts to develop data standardization, integration and communication continue to advance. The final objective is to transform data into accessible and relevant information for stakeholders and authorities.

Did the climate changes and/or the mountains impacted the diversification process of an Andean Genus of Ladybird beetles (Coleoptera: Coccinellidae)?

Authors: Salazar Karen[2], Achaz Guillaume[1] and Nattier Romain[2], [1]Centre Interdisciplinaire de Recherche en Biologie, CIRB, UMR 7241, CNRS, Collège de France INSERM, Paris, France, [2]Institut Systématique Evolution Biodiversité (ISYEB) UMR 7205, Muséum national d'Histoire naturelle, Sorbonne Université, EPHE, CNRS, France

Abstract: The development of mountain belts favored a rise in biodiversity, as a result of high speciation and low extinction rates, and can be considered as species pumps that feed the rest of the continent. In South America, the Andes are a good example of interactions between mountain building and diversification processes that decisively affected present biodiversity patterns. Pleistocene glaciations are recognized as important promoters of population divergence and ultimately speciation. However, the role of these recent glaciations in speciation has also been largely debated and various studies demonstrated that several lineages diversified earlier during the Mio-Pliocene intense uplift period. The aim of the study is to test the respective contributions of Mio-Pliocene intense uplift period and Pleistocene glacial cycles on the diversification of the South American ladybird beetles Eriopis Mulsant. Mitogenomes were obtained by genome skimming approach from 35 dry specimens deposited in natural history collections and with collection data 1882-2005. These taxa were chosen to cover the whole geographical distribution of the genus. The 13 protein-coding genes and two ribosomal RNA genes were used to infer the phylogenetic tree using a Bayesian method. We established a dated phylogeny of the group using Relaxed-Clock Method.

How to find a missing gene: the case of IMD in Rhodnius prolixus

Authors: Salcedo Nicolas[1], Lowenberger Carl[1], [1]Simon Fraser University, Canada

Abstract: The immune deficiency pathway (IMD) is a major component of the innate immune system in arthropods. This pathway mediates the recognition, elimination, and tolerance of pathogens and symbionts. In the kissing bug Rhodnius prolixus, which transmit the human parasite Trypanosoma cruzi, many of the genes of the IMD pathway were not found in its genome; this pathway was therefore described as absent and nonfunctional. Subsequent characterization, however, revealed it was indeed functional towards pathogen infections. Most of the missing elements of the pathway were also described except for the IMD and Kenny genes. We present the methods and parameters we apply to find candidate orthologs and present a new candidate for the IMD gene. We used a combination of reciprocal BLAST searches, HMM protein profile searches, domains architecture, phylogenetic trees, and RNA-seq-driven gene annotation. The ultimate proof to validate candidate genes is their functional characterization. Our results highlight the use of multiple approaches to discover genes in non-model organism using information from taxonomically distant species.

Endogenous viral elements and their role in mosquito antiviral immunity

Authors: Saleh Maria Carla[3], Suzuki Yasutsugu[2], Fontaine Albin[2], CRIST Anna[2], Baidaliuk Artem[2], Blanc Hervé[2], Conclois Isabelle[2], Frangeul Lionel[2], Lambrechts Louis[2], Miesen Pascal[1], van Rij Ronald[1], Merkling Sarah[2] and Lequime Sebastian[2], [1]Department of Medical Microbiology, Radboud Institute for Molecular Life Sciences, Radboud University Medical Center, Nijmegen, Netherlands, [2]Insect-Virus Interactions Unit, Department of Virology, Institut Pasteur, UMR2000, CNRS, Paris, France, [3]Institut Pasteur Paris, France

Abstract: Endogenous viral elements (EVEs) are full or partial viral sequences integrated in host genomes. A large number of EVEs was bioinformatically identified in Aedes mosquito genomes, supporting the hypothesis that mosquito EVEs contribute to control exogenous infections by closely related viruses in nature. To experimentally test this hypothesis, we investigated the role of an EVE naturally found in Aedes aegypti populations and related to the widespread insect-specific virus cell-fusing agent virus (CFAV). Deep sequencing revealed that CFAV-EVE produced primary piRNAs in antisense orientation and targeted CFAV RNA in the naturally infected mosquitoes. Using CRISPR/Cas9 genome editing, we created an Ae. aegypti line lacking the CFAV-EVE. The absence of EVE resulted in increased CFAV replication in ovaries, possibly modulating vertical transmission of the virus. Viral replication was controlled by the interplay between viral and EVE RNAs via the piRNA pathway. Our results provide evidence that antiviral piRNAs are produced in the presence of a naturally occurring EVE and its cognate virus, demonstrating a functional link between EVEs and antiviral immunity in a natural insect-virus interaction.

Minimal fermentative metabolism fuels extracellular symbiont in leaf beetles

Authors: Salem Hassan, Mutualisms Research Group, Max Planck Institute for Developmental Biology, Germany

Abstract: While genome erosion is extensively studied in intracellular symbionts, the metabolic implications of reductive evolution in microbes subsisting extracellularly remain poorly understood. Stammera capleta—an extracellular symbiont in leaf beetles—possesses an extremely reduced genome (0.27 Mb), enabling the study of drastic reductive evolution in the absence of intracellularity. Here, we outline the genomic and transcriptomic profiles of Stammera and its host to elucidate host-symbiont metabolic interactions. Given the symbiont's substantial demands for nutrients and membrane components, the host's symbiotic organ shows repurposing of internal resources by upregulating nutrient transporters and cuticle-processing genes targeting epithelial chitin. The turn-over of foregut- lining chitin is a common process in insects and releases several nutrients such as N-acetylglucosamines that serve as precursors for microbial membrane biosynthesis, which is eroded in Stammera. Facilitated by this supplementation and its localization, Stammera exhibits a highly streamlined gene expression profile and a fermentation pathway for energy conversion, sharply contrasting the respiratory metabolism retained by most intracellular symbionts. Lactate fermentation has been discussed in the context of parasitic eukaryotes, but is unknown in insect symbionts with reduced genomes, likely because lactate accumulation would result in toxicity within host cells. In the case of Stammera, however, the extracellular localization supports the erosion to a sole fermentative metabolism by minimizing acid stress. Our results provide insights into a tightly regulated and metabolically integrated extracellular symbiosis, expanding our understanding of the minimal metabolism required to sustain life outside of a host cell.

Predation capacity and some biological features of Simosyrphus aegyptius (Wiedemann), 1830 (Diptera: Syrphidae) on Mealy plum aphid [Hyalopterus pruni (Geoffroy) (Hemiptera: Aphididae)

Authors: Salih Özgökçe Mehmet[1], Kara Hilmi[1] and Tekin Nuray[1], [1]Van Yuzuncu Yil University, Turkey

Abstract: Syrphids flies, also known as hover flies or flower flies, have two important ecological roles. When adults feed on nectar or pollen, many larvae are the most important predators of aphids and other pest species. Simosyrphus aegyptius (Wiedemann), 1830 (Diptera: Syrphidae), commonly found in aphid colonies, is common in subtropical and tropical regions of the world. In this study, predation capacity and life table of S. aegyptius on Mealy plum aphid [Hyalopterus pruni (Geoffroy) (Hemiptera: Aphididae)] were investgated. The study was carried out in 2017 in a climate room with 25 °C temperature, 60 ± 10 % relative humidity and 16: 8 hours of light: dark conditions. The raw data were analyzed based on the age-stage, two-sex life table. The preadult period of S. aegyptius was found 23.13 days and life table parameters were as follows: The intrinsic rate of increase (r), the finite rate of increase (?), the net reproduction rate (R0), and the mean generation time (T) of S. aegyptius were 0.103 day-1, 1.108 day-1, 15.00 eggs/generation and 26.37 days, respectively. Pre-adult predation rate was found as 820.21 preys/predator. The highest predation rate was observed in the 3rd larval stage as 545.64 preys/predator. This predation capacity is very high than many other aphid predators.

The eradication of the tsetse fly Glossina palpalis gambiensis from the Niayes of Senegal using an area-wide integrated pest management approach that includes the release of sterile males

Authors: Sall Baba[2], Bouyer Jeremy[1], Vreysen Marc[3] and Tall Seck Momar[4], [1]CIRAD, UMR ASTRE « Animals, health, Territories, Risks and Ecosystems, France, [2]Department of Veterinary Services of Senegal, Ministry of Livestock and Animal Production, Senegal, [3]Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, International Atomic Energy Agency, Austria, [4]National Laboratory of Livestock and Veterinary Research, Senegal

Abstract: The “Projet de lutte contre la mouche tsé-tsé et la trypanosomose dans les Niayes” targets a total area of 7,350 km2, of which 1,375 km2 were infested with Glossina palpalis gambiensis (Diptera: Glossinidae) which were solely responsible for the cyclical transmission of trypanosomes, the causative agents of African animal trypanosomosis (AAT). The tsetse population in the Niayes was completely isolated from the main tsetse belt in the south eastern part of the country, which prompted the Government of Senegal to select an eradication strategy of the vector and the disease, as the risk of re-invasion would be minimal or non-existing. The project was implemented in different phases, i.e. following a phased conditional approach, which consisted of (1) training and commitment of all stakeholders, (2) baseline data collection (BLDC) and feasibility studies, (3) pre-operational activities, and (4) operational activities. During the BLDC, entomological, parasitological, environmental and socio economic data were collected to assess tsetse distribution, population dynamics, trypanosomosis prevalence and distribution, potential environmental impact, and anticipated benefit-cost ratios. Activities during the pre-operational phase included the establishment of a colony of tsetse originating from the target area in Senegal, competiveness studies between the sterile flies and those from the target area, development of transport methods for long distance shipments of sterile male pupae, competitiveness of the sterile male flies after release in the target area, development of aerial release methods, including a new chilled adult release system, and development of a Maxent-based distribution model to guide the suppression, sterile male releases and the monitoring of the campaign. During the operational phase, the fly populations were suppressed using insecticide-impregnated traps (~3000), insecticide-treated cattle (~10,000 heads) and insecticide-impregnated fences around pig pens (~300 m). During the eradication phase, more than 5,000,000 sterile male tsetse flies have so far been released from the ground or by air. An extensive entomological monitoring system implemented in the 3 operational blocks indicated the following: no wild fly catches since August 2012 in block 1, while in block 2 et 3 the densities of the wild tsetse populations have been reduced by > 99% at the time of writing. SIT is still on going in those 2 blocks up to end of 2020 in order to ensure the eradication of tsetse in the area. Monitoring data of sentinel herds located inside and outside the tsetse-infested area indicated already a significant reduction of the AAT prevalence. The environmental monitoring demonstrated a very low impact of the project on non-target species, and the socio-economic study showed a high cost-effectiveness of the project.

The implementation approach of this project could serve as a model for future potential tsetse eradication campaigns in sub-Saharan Africa

Identification and Functional Characterization of Toxoneuron nigriceps Ovarian Proteins Involved in the Early Suppression of Host Immune Response

Authors: Salvia Rosanna[1], Scieuzo Carmen and Falabella Patrizia, [1]University of Basilicata, Italy

Abstract: Toxoneuron nigriceps (Viereck) (Hymenoptera, Braconidae) is an endophagous parasitoid of the larval stages of Heliothis virescens (Fabricius) (Lepidoptera, Noctuidae). During oviposition, T. nigriceps injects into the host body the egg, the venom, the calyx fluid, which contains a Polydnavirus (T. nigriceps BracoVirus: TnBV), and the Ovarian Proteins (OPs). OPs, originating from the ovarian calyx cells, are involved in the induction of precocious symptoms in the host immune system alteration. To functionally characterize the OPs, we carried out two approaches. Firstly, incubating hemocytes with OPs in toto, detecting several alterations on host cells: the OP injection induced an extensive oxidative stress and a disorganization of actin cytoskeleton. These alterations can explain the loss of haemocyte functionality (the reduction in encapsulation ability by the host) and the high-level of haemocyte mortality. Then, we evaluated the effect of HPLC fractions deriving from in toto OPs. Among the 28 analyzed fractions, two fractions caused a reduction in hemocyte viability and were tested to detect changes in hemocyte morphology and functionality. In accordance with previous results, obtained with in toto OPs, the two fractions caused severe oxidative stress, actin cytoskeleton disruption, loss of hemocyte encapsulation ability and high mortality rate. Moreover, a transcriptome and proteomic approach was applied to identify the proteins of the two fractions: eight proteins that might be involved in the observed host hemocyte changes were detected. Our findings will contribute to a better understanding of the ovarian components and their role in parasitic wasp strategy to escape the host immune responses.

Insects an innovative source of chitosan: possible applications

Authors: Salvia Rosanna[1], Triunfo Micaela[1], Guarnieri Anna, Ianniciello Dolores, Scieuzo Carmen[1], Zibek Susanne, Hahn Thomas and Falabella Patrizia, [1]University of Basilicata, Italy

Abstract: The polysaccharide chitin is one of the most abundant natural polymers and it is the major structural component of the arthropod exoskeleton and the cell wall of fungi and yeasts. Due to their properties, like biodegradability, bio-compatibility, non-toxicity, adsorption and antimicrobial activity, chitin and its main deacetylated derivative, chitosan, have a great economic value and they are molecules of great interest as new functional biomaterials, finding many applications in the industrial and biomedical field. The main commercial source of chitin and chitosan is crustaceans' exoskeleton. The extraction of chitin from insects, a promising alternative source, has received relatively little attention. Among insects, Hermetia illucens is a promising source of chitin. This insect is the subject of increasing research in the scientific world thanks to its ability to convert organic waste into larval biomass rich in proteins and lipids of high biological value.

Currently, the chitin contained in the exoskeleton of last instar larvae, pupae and adult flies constitutes a by-product of the bioconversion process aimed at the production of animal feed. All the available protocols for chitin and chitosan extraction from insects involve the use of chemicals, mainly acids for minerals removal, bases for both proteins hydrolyzation and chitin deacetylation, and various reagents for depigmentation. The present study focuses on chitin extraction, and its deacetylation into chitosan, from the exoskeleton of H. illucens at different developmental stages, in order to make the most of a resource not yet fully exploited. The obtained product will be investigated for different possible applications.

New insights into the main components of the venom of Torymus sinensis by a transcriptomic and proteomic approach

Authors: Salvia Rosanna[3], Falabella Patrizia[3], Scieuzo Carmen[3], Cozzolino Flora[2], Maria Monti[2], Heiko Vogel[1], Chiara Ferracini[4] and Alberto Alma[4], [1]Max Planck Institute for Chemical Ecology, [2]University Federico II of Napoli, [3]University of Basilicata, [4]University of Torino

Abstract: Venomics, the study of the entire pool of peptides and proteins of one specific venom, has acquired increasing importance as source of new bioactive molecules relevant in several fields, including agriculture, since they could constitute a weapon in the biological fight against parasitic crop species. In nature these harmful insects are kept under control by parasitoids. Torymus sinensis, the parasitoid of the chestnut gallogenic Cinipid Dryocosmus kuriphilus is the only effective means of Cinipid biological control. The knowledge of venom protein composition is extremely useful to identify new molecules that can be used as bioinsecticides in integrated pest management. We identified T. sinensis main venom components through a transcriptomic and proteomic approach. Transcriptomic data (high-throughput nucleic acid sequencing) provided an overall picture of the putative proteins in the venom gland and information on molecular functions, biological processes and putative cellular compartments. The proteomic analysis was carried out on venom components fractionated by SDS-PAGE and analyzed by mass spectrometry. Combination of proteomic and transcriptomic data allowed us to identify 185 putative proteins of T. sinensis venom. The characterization of these molecules will be essential to understand the role of venom in induction and regulation of the pathological syndrome in parasitized hosts.

Study of Chemoreception in Capnodis tenebrionis L. (Coleoptera, Buprestidae) as an innovative tool in biological control

Authors: Salvia Rosanna[1], Falabella Patrizia[1], Franco Antonio[1] and Scieuzo Carmen[1], [1]University of Basilicata

Abstract: Insects use chemoreception to interact with the environment through the perception of volatile organic compounds (VOCs) that is essential for their survival. Capnodis tenebrionis (Coleoptera, Buprestidae), a pest of Rosaceae family, is attracted by chemical signals emitted by plants. The control of this pest lacks monitoring strategies such as information on insect chemical ecology. The composition of perceived VOCs play an important role in determining the signal specificity for C. tenebrionis repulsion or attraction. To improve the understanding of how VOCs are perceived, putative soluble olfactory proteins involved in chemoreception have been identified from de novo transcriptomes of antennae and whole bodies of C. tenebrionis adult males and females. Transcriptome analysis led to the identification of a putative odorant binding protein (OBP) named CtenOBP7, similar in terms of amino acid sequence to Agrillus mali (Coleoptera: Buprestidae) OBP3, already functionally characterized. CtenOBP7 was cloned, expressed and purified. Interaction of recombinant CtenOBP7 with different plant VOCs was measured by fluorescence spectroscopy. This approach offers guidelines to understand the mechanisms involved in the interaction between plants and insects, in order to define new strategies to control the proliferation of this pest, starting from the study of insect olfactory perception at the molecular level.

Latitudinal pattern in predation, herbivore performance and herbivory in hostile and enemy free space

Authors: Sam Katerina[1], Mrazova Anna[1], Kollross Jan[1], Lenc Jan[1], Sam Legi[1], Tahadlova Marketa[1], Libra Martin[1], Weiss Matthias[1], Sreekar Rachakonda[1], Finnie Sam[1] and Fernandez Garzon Sara[1], [1](1) Biology Centre of Czech Academy of Sciences, Institute of Entomology, Ceske Budejovice (2) University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic

Abstract: It is well recognized that predators can enhance plant growth by reducing herbivore abundance. Yet the strength of such trophic cascades has been found to be quite variable both within and between communities. Moreover, effects of various taxa were usually summed within the effect of “predators” thus it remains unclear which predators and where might control trophic cascades. We hypothesise that birds, bats and ants are important predators of arthropods, which further affect plant growth. However, their relative importance may differ along large (latitudinal) gradients due to changes in their richness and abundance and productivity of the environment. For similar reasons, we also expect that the importance of predators differs in forest canopies and understories, as productivity and trophic levels are predicted to be higher in the canopies. To find out where top-down forces control food webs, we conducted predator exclosure experiments along latitudinal and vertical gradient(s). We excluded ants, birds, and/or bats separately and in combinations from saplings and from branches in forest canopies. We protect saplings by nets (against birds and/or bats) and by tangle foot (against ants). We manipulate the cages daily to separate the effect of birds and bats. We survey the effect of such treatment on insect communities and herbivorous damage every four months. We further analyse various plant defences, which are inevitably shaping the interactions via bottom up control. Finally, we run a global search for similar studies during which predators were excluded. We conducted a meta-analysis on them and compared the results with our field-based data. At several of our study sites, bats and ants do not seem to affect arthropod communities significantly. Birds seem to be the most important predators at many of our study sites. Their exclusion led to more than eight times higher herbivory. The results of meta-analysis provide somewhat different results, with ants being very important predators. We discuss potential problems with meta-analysis vs. our data and we argue that the strength of the top down control can’t be considered without the bottom up control. We conclude that stable arthropod populations are maintained by natural enemies of various importance along gradients. In some study systems, mesopredators (spiders) were released, lowering the effect of exclusion of the focal predator. Disruption of communities of natural enemies result into significantly increased abundances of insect, increased herbivorous damage and into changes in leaf traits.

Effect of landscape structure on the abundance and diversity of pollinators in pear crops

Authors: Sanchez Juan Antonio[2], Ibarra-Marinas Daniel[4], López-Gallego Elena[3], Sgolastra Fabio[6], Javier Ortíz-Sánchez Francisco[5], De Pedro Luis[1], Perera-Fernández Luis[3] and Pérez-Marcos María[3], [1]Department of Crop Protection, Biological Control and Ecosystem Services - Instituto Murciano de Investigación y Desarrollo Agrario y Alimentario, Spain, [2]Instituto Murciano de Investigación y Desarrollo Agrario y Medioambiental-IMIDA, Spain, [3]Murcia Institute of Agri-Food Research and Development, Spain, [4]Physical Geography Laboratory, University of Murcia, Spain, [5]Research group “Transferencia de I+D en el Área de Recursos Naturales”. University of Almería, Spain, [6]Università di Bologna, Dipartimento di Scienze e Tecnologie Agro-Alimentari, Italy

Abstract: Pollinators have suffered from the intensification of agricultural, especially because of the destruction of habitat. The structure of the environment, at both the landscape and plot scale, may influence the abundance and diversity of pollinating insects. The main objective of this work was to determine if wild vegetation and landscape fragmentation affected the biodiversity of pollinators in pear orchards. For this, 27 pear orchards surrounded by land with different levels of landscape fragmentation and surface of wild vegetation were selected. The structure of the landscape surrounding each orchard was characterized by quantifying the surface of semi-natural habitats (hedges, forests, thickets, etc.) within a diameter of 1,000 meters using geographic information systems. Moreover, a fragmentation index was calculated, considering: the number of fragments of natural vegetation, within the 1,000-meter buffer, and their surface area. For the sampling of pollinators, two 15-minute transects were carried in two consecutive weeks in each plantation during the flowering period of the crop in 2019. A total of 2,191 pollinating insects were observed visiting the pear flowers, of which 54% were bees (Apis mellifera and wild bees), 20% dipterans (Syrphidae and other Diptera), and 9% Coleoptera. No significant influence of the landscape fragmentation on the abundances of the different groups of pollinators was registered. However, there was a significant influence of the surface of wild vegetation on the abundances of the Syrphidae, Diptera and Coleoptera; all were more abundant with the highest vegetation densities. In contrast, although bees were more abundant in the plantations with the highest surface of surrounding wild vegetation, the effect of vegetation was found to be non-significant.

How cover crops influence the biodiversity of ground arthropods in pear orchards

Authors: Sanchez Juan Antonio[2], López-Gallego Elena[3], De Pedro Luis[1], Perera-Fernández Luis[3] and Pérez-Marcos María[3], [1]Department of Crop Protection, Biological Control and Ecosystem Services - Instituto Murciano de Investigación y Desarrollo Agrario y Alimentario, Spain, [2]Instituto Murciano de Investigación y Desarrollo Agrario y Medioambiental-IMIDA, Spain, [3]Murcia Institute of Agri-Food Research and Development, Spain

Abstract: The intensification of agriculture has led to the reduction of the diversity of arthropods in agroecosystems. This is also the case for soil arthropods due the intensive ploughing, the use of insecticides and the elimination of ground vegetation, among other factors. The aim of this work was to evaluate the effect of restoring cover crops in comparison with the conventional management. The work was carried out in a 6 ha pear orchard that was divided in three blocks where two plots of 1,600 m2 (5 rows of 100 trees) each were established at random; two treatments were assayed (i.e., restored cover and conventional management) in each block. A mix of seeds of 10 plant species was sown in the restored cover plots. Soil arthropods were sampled using pitfall traps (500 ml plastic containers, 8 cm in diameter) filled with water and propylene glycol during five different weeks in 2019. The percentage of cover was estimated for each sampling date. Cover crops had a great impact on the abundance and diversity of arthropods. Several families of spiders (Linyphiidae, Lycosidae), beetles (Carabidae, Scarabaeidae, Staphylinidae) and hymenopterans (Scelionidae) were significantly more abundant in the plots with the restored cover than in the conventional plots. In contrast, ants (Formicidae) and collembola had a significantly higher abundance in the conventional plots. Other families of spiders (Gnaphosidae, Zoradiidae), beetles (Tenebrionidae) true bugs (Lygaeidae) were not found to be significantly affected by the ground cover.

The risks and advantages of using predators that also feed on plants as biological pest control agents

Authors: Sanchez Juan Antonio[1], van Rijn Paul[3], Cassis Gerasimos[4] and Gillespie David[2], [1]Instituto Murciano de Investigación y Desarrollo Agrario y Medioambiental-IMIDA, Spain, [2]Pacific Agri-Food Research Centre, Agriculture and Agri-Food Canada, [3]University of Amsterdam, Netherlands, [4]University of New South Wales

Abstract: IOmnivorous mirids (Hemiptera: Miridae) is one of the most controversial generalist predators because they feed both on prey and plants. They are particular as biological pest control agents and a thorough knowledge of their feeding behaviour and the development of management strategies are needed to minimise the negative aspects of their phytophagous character while exploiting their predatory side. In this presentation we review the worldwide importance, risks, and management strategies of omnivorous mirids. The modelling of the zoophytophagous behaviour and population dynamics are some of the tools discussed to enhance biological pest control and to reduce environmental risks. Additionally, the phytophagous character of these insects offers an interesting opportunity to enhance pest control by managing plant diversity in agroecosystems. Nonetheless, the worldwide commercialization of mirids as biological pest control agents, especially when the species is exotic to the area, entrails environmental risks that have to be taken into account. Mirids released in crops may colonize natural habitats and produce a double negative environmental impact. By one hand, exotic mirids may get established and damage wild plants; by the other, they may interfere with the communities of native arthropods.

Deep into the south, the evolutionary history of a widely distributed leaf-cutting ant

Authors: Sánchez Restrepo Andrés[3], Calcaterra Luis[2] and Confalonieri Viviana[1], [1]Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires (UBA), [2]Fundación para el Estudio de Especies Invasivas (FuEDEI), [3]Fundación para el Estudio de Especies Invasivas (FuEDEI), Hurlingham, Ar, Argentina

Abstract: The southern cone of South America has gone through a great number of complex geoclimatic events that triggered diverse evolutionary process. Leaf-cutting ants, belonging to the genera Acromyrmex, Amoimyrmex and Atta, characterize by using freshly cut fragments of leaves and flowers as substrate for the growing of fungus of which they feed. The southern black ant, Acromyrmex lobicornis, an economically important leaf-cutting ant species pest in vineyards and forest plantations, is widely distributed in this region. Distribution analyses reveal that this species has two main occurrence areas: one goes through the Arid diagonal of the Monte desert ecoregion in Argentina until Bolivia, and the other goes from central Uruguay up to Rio Grande do Sul state, in Brazil. Both areas are connected by isolated populations distributed along central section of the Espinal ecoregion in Argentina. In this study we analyze the evolutionary history of this ant in a phylogeographic context, using mitochondrial and nuclear markers, in order to determine its historical demographic and dispersion processes. In contrast to previous hypotheses, this study suggests that A. lobicornis would have been originated in the northernmost section of Monte desert in La Rioja province (putative origin center harboring the highest genetic diversity) in Argentina, then spread into south and north along the Arid diagonal, and into the east through the Espinal until savannas in central Uruguay and southern Brazil. Interestingly, the nesting behavior changes in the more arid regions from nest with big domes to nest without it. The Espinal would have played an important role as bridge that maintains genetic flow between eastern and western populations of this ant. Understanding the evolutionary history of the southern black ant will provide insights into the evolutionary history of leaf-cutting ants in southern South America and the role of historical geoclimatic processes in their diversification.

Exploring the Role of Relish on Antimicrobial Peptide Expressions (AMPs) Upon Nematode-Bacteria Complex Challenge in the Nipa Palm Hispid Beetle, Octodonta nipae Maulik (Coleoptera: Chrysomelidae

Authors: Sanda Nafiu[1], Sani Wudil Baba[1] and Youming Hou[2], [1]Department of Crop Protection, Faculty of Agriculture, Bayero University, Kano, Nigeria, [2]Department of Plant Protection, State Key Laboratory of Ecological Pest Control for Fujian and Taiwan Crops, Fujian Agriculture and Forestry University, Fuzhou

Abstract: The humoral immune responses of the nipa palm hispid beetle Octodonta nipae involves the inducible expression of the genes coding for antimicrobial peptides (AMPs) which are mediated by immune deficiency signaling pathways. In insects, the nuclear factor-kB (NF-kB) transcription factor, Relish, has been shown to regulate AMP gene expressions upon microbial infections. Here, we dissect the expression patterns of some AMPs in O. nipae during infections by entomopathogenic nematodes (EPNs) and their symbionts, before and after Relish knock down. Our results indicate that, prior to gene silencing, the AMPs attacin C1, attacin C2, and defensin 2B were especially expressed to great extents in the insects challenged with the nematodes Steinernema carpocapsae and Heterorhabditis bacteriophora as well as with their respective symbionts Xenorhabdus nematophila and Photorhabdus luminescens. The study also established the partial sequence of OnRelish/NF-kB p110 subunit in O. nipae, with an open reading frame coding for a protein with 102 amino acid residues. A typical Death domain-containing protein was detected (as seen in Drosophila) at the C-terminus of the protein. Phylogenetic analysis revealed that in O. nipae, Relish is clustered with registered Relish/NF-kB p110 proteins from other species of insect especially Leptinotarsa decemlineata from the same order Coleoptera. Injection of OnRelish dsRNA remarkably brought down the expression of OnRelish and also reduced the magnitude of transcription of attacin C1 and defensin 2B upon S. carpocapsae and H. bacteriophora and their symbionts infections. Altogether, our data unveil the expression pattern of OnRelish as well as that of some AMP genes it influences during immune responses of O. nipae against EPNs and their symbionts.

#SciComm in the classroom: practicum of public engagement with science

Authors: Sandall Emily L.[2], M Sakamoto Joyce[1] and López-Uribe Margarita[1], [1]Department of Entomology, Pennsylvania State University, University Park, PA, United States, [2]Frost Entomological Museum, Department of Entomology, Pennsylvania State University, University Park, PA, United States

Abstract: Quality entomological outreach requires both knowledge of the topic and engagement of the public. We partnered these two goals through a collegiate level experiential course to lead entomology students to find effective communication strategies for a range of audiences. Through our outreach and science communication course, we provided entomology students opportunities to (1) devise lessons plans for outreach events, (2) give and receive peer feedback about their materials and methods, (3) present outreach to different audiences, and (4) reflect on what worked and could be improved. The design and implementation of the course 'Public Engagement of Science' provided lessons for both instructors and student leaders.

Complementary interactions of native and introduced natural enemies of codling moth in New Zealand

Authors: Sandanayaka Manoharie[5], Wallace David[4], Charles John[1], Colhoun Kate[2], Cole Lyn[3] and Davis Vicky[1], [1]The New Zealand Institute for Plant & Food Research Limited, Mt Albert Research Centre, Better Border Biosecurity, New Zealand, [2]The New Zealand Institute for Plant and Food Research Limited, Clyde Research Centre, Alexandra, New Zealand, [3]The New Zealand Institute for Plant and Food Research Limited, Hawke's Bay Research Centre, Havelock North, New Zealand, [4]The New Zealand Institute for Plant and Food Research Limited, Motueka Research Centre, Motueka, New Zealand, [5]The New Zealand Institute for Plant and Food Research Limited, Mt Albert Research Centre, Auckland New Zealand, New Zealand

Abstract: Codling moth (Cydia pomonella) (CM) is a key pest of pipfruit in New Zealand. Cooler areas of New Zealand, have one generation of CM each year, while they go through two generations in warmer areas. Only two native predators are recorded and no native parasitoids of CM are found in New Zealand. Five parasitoid species introduced during the last ten decades have established in some regions, contributing to reducing CM populations. The establishment of CM parasitoid species was monitored in four main apple growing regions in New Zealand (Hawke's Bay, Nelson, Central Otago and Waikato) using corrugated cardboard bands (10-cm wide empty bands to trap wild CM larvae and 2-cm wide bands with sentinel CM larvae). Liotryphon caudatus (Hymenoptera: Ichneumonidae, released in 1906) was found in Hawke's Bay and Waikato, not in the South Island regions. Ascogaster quadridentata (Hymenoptera: Braconidae, released in the 1930s), Glabridorsum stokesii (Hymenoptera: Ichneumonidae, released in 1967), Dibrachys microgastri (Hymenoptera: Chalcidoidea: Pteromalidae, an accidental arrival) and Mastrus ridens (Hymenoptera: Ichneumonidae, released in 2012–2016) were found in both the North and South islands. The relative proportions of parasitoid species caught in different regions indicate the success of their establishment and interactions between the natural enemies of CM.

Hyperparasitoids drive host-parasitoid dynamics and structure

Authors: Sanders Dirk[1] and van Veen Frank[2], [1]Environment and Sustainability Institute, University of Exeter, United Kingdom, [2]University of Exeter, United Kingdom

Abstract: Hyperparasitoids are often seen covering a single fourth trophic level in plant-aphid -parasitoid-hyperparasitoid networks and have been predicted to either reduce the efficiency of primary parasitoids controlling aphid population or stabilise host-parasitoids dynamics and increase long term aphid top-down control. Here we show that hyperparasitoids span at least two trophic levels and that some species are extremely efficient in using their resource allowing for cryptic higher trophic levels. We further demonstrate that hyperparasitism rate increases over the season for a group of very generalist hyperparasitoid species while a more specialised group peaks earlier because they are attacked by the generalists. Experimental and long-term food web data show that hyperparasitoids reduce the control of aphid populations through primary parasitoids and can lead to the functional extinction of primary parasitoids. This places hyperparasitoids in a key position driving the structure and dynamics of host- parasitoids networks.

Spatio-temporal dynamics of Drosophila suzukii populations: A landscape perspective

Authors: Santoiemma Giacomo[1], Marini Lorenzo[1], Tonina Lorenzo[1] and Mori Nicola[2], [1]Department of Agronomy, Food, Natural Resources, Animals and the Environment. University of Padua, Italy, [2]University of Verona

Abstract: Landscape processes play a fundamental role in pest population dynamics. In particular, natural and semi-natural habitats, despite delivering important ecosystem services, can also support insect pest populations by providing refuge during pesticide applications, suitable overwintering sites and availability of alternative host plants. This work aimed at investigating the relationship between the distribution and damage of Drosophila suzukii, an invasive polyphagous pest, and landscape processes at multiple spatial scales. D. suzukii recently invaded Europe causing considerable economic damage on several thin-skinned fruits. The management of this pest is particularly complex due to its high dispersal potential, mobility and polyphagy. First, we studied the influence of landscape complexity on D. suzukii distribution and crop damage. During the growing season, semi-natural habitats enhanced population density and damage in cherry orchards. In particular, orchards within forested-dominated landscape appeared to be more susceptible to D. suzukii attacks. Second, we examined at large geographical scale the temporal dynamics and synchronization of D. suzukii activity along steep elevational gradients in Alpine environments. Due to the high dispersal potential and mobility, the insect revealed an extremely high synchronization of population fluctuations across different locations and elevations. Considering the emerging problems linked to the invasion of D. suzukii across several temperate countries, our work emphasized the need to incorporate landscape processes to understand the spatio-temporal dynamics of pest populations across complex landscapes

Phylogenomics and diversification of Ichneumonidae

Authors: Santos Bernardo, Muséum National d'Histoire Naturelle, United States

Abstract: Ichneumonid parasitic wasps comprise one of the largest insect lineages, but the lack of a comprehensive phylogeny currently hinders our understanding of their diversification process. In a collaborative, multi-institutional effort, we generated UCE data for 800+ species from all ichneumonid subfamilies. This enabled us to obtain a powerful phylogenetic framework for the family as a whole, as well as to pursue fine-scale investigations within specific ichneumonid taxa. In spite of this massive dataset, uncertainties remain and the placement of some groups is contingent on specific dataset formatting. Even with this limitation, our phylogeny allowed for the reconstruction of biological traits and unprecedented insight on the diversification process of this hyperdiverse wasp family.

Whole genome sequencing and the phylogenetic distribution of viral domestication events in ichneumonid parasitic wasps

Authors: Santos Bernardo[3], Volkoff Anne-Nathalie[1], Legeai Fabrice[2] and Robin Stephanie[2], [1]DGIMI, INRAE, University of Montpellier, France, [2]IGEPP, Agrocampus Ouest, INRAE, Université de Rennes 1, France, [3]Muséum National d'Histoire Naturelle

Abstract: One of the most staggering adaptations associated with parasitism is the use of endogenous viruses by parasitoid wasps. Until recently, our poor understanding of ichneumonid genomes prevented the investigation of the mechanistic and evolutionary aspects of this wasp-virus interaction. In this talk, we will discuss how recent advances in whole genome sequencing are allowing the mapping of endogenous viral elements found in wasps of the family Ichneumonidae, both in terms of the genomic architecture of this integration and the phylogenetic distribution of viral domestication events across various lineages. These advances have been accomplished both through complete assemblies with long scaffold sizes and by low coverage genome sequencing. We will present the results of a broad-scale screening of the family Ichneumonidae for endogenous viral elements and what these results reveal about the evolutionary pathways that led to viral domestication in ichneumonid wasps.

Broad-complex expression in the post-embryonic development of Apis mellifera

Authors: Santos Carolina, Federal University of Vicosa, Brazil

Abstract: Insects development is regulated by conserved pathways that were rewired in the course of evolution. Juvenile hormone (JH) and ecdysteroids (20E) are the main hormonal players in the morphogenetic events that direct the correct development. Although these pathways have been extensively studied, some of its molecular mechanisms are still unknown. Broad-complex (Br-C) is a transcriptional factor co-regulated by both JH and 20E. It is mainly related with pupal morphogenesis in holometabolous insects and with wing pad growth and development in hemimetabolous. Here I investigated the expression of Br-C during the post-embryonic development of the honey bee, Apis mellifera, and its possible role in the caste determination. The levels of Br-C varied during the development, with transcripts being detected in the fat body, head and imaginal discs of the fourth and early fifth instar larvae. The identified isoforms of Br-C presented differential expression among the tissues and ages analyzed. Considering the variation of JH hormones titers during caste development, and the well-known interaction of its direct response gene, Kr-h1, with Br-C in other insects, the relationship between these two transcription factors will be also be explored. Some remarks will be presented about a possible broader function of Br-C in development.

Financial Support: Department of General Biology, Federal University of Viçosa.

Detection of DNA modifications in eusocial bees

Authors: Sargent Chloe[3], Davies T.G. Emyr[2], Hardy Ian C.W. [1], Chakrabarti Lisa[4] and Stoger Reinhard [3], [1]Department of Agricultural Sciences, University of Helsinki, [2]Department of Biointeractions and Crop Protection, Rothamsted Research, [3]School of Biosciences, University of Nottingham, [4]School of Veterinary Medicine and Science, University of Nottingham

Abstract: Different castes of a eusocial bee species share identical genomes. Yet castes display marked differences in morphology, behaviour, longevity, and reproductive phenotypes.

These differences are generally driven by environmental signals and thought to be mediated by epigenetic mechanisms, including DNA methylation.

While nutrition, particularly during development, is a key signal that can shift developmental trajectories, other environmental exposures, including pesticides may also influence the epigenetic landscape and caste phenotypes. Recent evidence suggests that DNA methylation is not as responsible for the link between environment and gene expression as previously thought. That is, gene body methylation patterns are colony-specific and not driven by social or environmental factors but rather inherited.

Nevertheless, DNA methylation appears to be a vital process for development and caste determination. We aim to further elucidate the distribution of DNA methylation patterns within different caste genomes in eusocial bees using a variety of different approaches, including Oxford Nanopore sequencing. Here we report on procedures and preliminary results of our effort to map and catalogue different types of DNA modifications in brain and flight muscle of honeybees and bumblebees. Ultimately, this work will allow us to elucidate how environmental and anthropogenic stressors may impact epigenetic programming of these bees.

The transmission of Candidatus Liberibacter solanacearum by the carrot psyllid is mediated by cellular actin filaments

Authors: Sarkar Poulami[1], Lebedev Galina[1], Ghanim Murad[1] and Kontsedalov Svetlana[1], [1]Department of Entomology The Volcani Center Rishon LeZion, Israel

Abstract: Candidatus Liberibacter solanacearum (CLso) is associated with carrot yellowing disease in Israel and is transmitted by the carrot psyllid, Bactericera trigonica. Understanding the molecular interactions between CLso and its psyllid vector is imperative for disrupting CLso transmission. Intracellular pathogens often exploit the host cellular mechanisms to facilitate their entry, replication, survival, and transmission. The host cell cytoskeleton, in particular, is a well-known target exploited by vector-borne pathogenic bacteria and viruses, for inter and intracellular trafficking within the insect. Furthermore, many insect pathogens use actin-based assembly and polymerization to promote their invasion, enabling cellular infection, colonization, and translocation from the gut lumen to the hemolymph. However, hijacking the actin cytoskeleton requires the pathogens to deploy proteins that interact with actin or mimic proteins that regulate or mediate its polymerization. In this study, we analyzed the Arp2/3 complex in the carrot psyllid, which mediates actin polymerization and elucidated its role in liberibacter propagation and transmission. A recent transcriptomic study on the carrot psyllid upon CLso infection showed upregulation of ArpC2 and ArpC5 (components of the Arp2/3 complex) along with RhoGAP21 and Cdc42, all of which are involved in cell invasion and vesicular trafficking. FISH and co-immunolocalization experiments revealed the co-localization of CLso with the ArpC2 protein along the actin filaments throughout the psyllid midgut. Silencing ArpC2, by feeding psyllids with dsRNA delivered through plants, drastically reduced the F-actin formation, disrupted the usual localization pattern of CLso and increased its accumulation in the midgut. Transmission tests conducted with psyllids after ArpC2 silencing resulted in a 78% decrease in the disease transmission as compared to the control. The silencing of additional proteins involved in the regulation of F-actin formation such as Arp5, RhoGAP21, and Cdc42 resulted in similar results after ArpC2 silencing, suggesting that Liberibacter pathogenesis and transmission is Arp2/3 complex-dependent. These results further suggest that silencing those actin-related proteins significantly reduce CLso translocation from the midgut to the hemolymph and subsequently reduce pathogen transmission to plants.

Diet and dietary experience alters biocontrol potential of native transverse ladybird beetle for tomato potato psyllid in Australia

Authors: Sarkar Shovon Chandra[1], Milroy Stephen Paul[1] and Xu Wei[2], [1]Food Futures Institute, Murdoch University, WA 6150, Australia, [2]Food Futures Institute, Murdoch University, Australia

Abstract: Tomato potato psyllid (TPP) is a major threat to Solanaceae crops worldwide. Impact is due to feeding activity and the transmission of the bacterium that causes the zebra chip disease in potato. TPP was first found in Australia in 2017. In identify suitable candidate organisms for biocontrol of TPP, we evaluated the effects of diet and dietary experience on Coccinella transversalis (transverse ladybird beetle). To evaluate the effect of diet, an age-stage, two-sex life table was used to calculate the ladybird's development and reproduction on invasive TPP. The impact of previous experience with the prey species on the ladybird's predation on TPP was assessed. Results showed that C. transversalis could successfully develop and reproduce when feeding on TPP. Early life experience of C. transversalis with TPP as a prey species improved preference and switching activity toward TPP. This was presumably due to altered prey recognition when offered combinations of prey. This may lead to more immediate control of the target pest in the field. This study provides the basis for developing an augmentative release strategy of C. transversalis for management of invasive TPP in Australia.

Mid-Summer Peach and Apple Fruits are the Better Food Sources for the Development and Fecundity of Grapholita molesta (Lepidoptera: Tortricidae)

Authors: Sarker Souvic[1], Lim Un Taek[1], [1]Andong National University, South Korea,

Abstract: Host plants are an important factor that determines the population dynamics of herbivorous insects. The phenology of host plants may affect the performance of Grapholita molesta (Busck) in the development and the fecundity that have rarely been examined. Previously, we evaluated diet suitability of immature peach, plum, and apple fruits collected in early-summer (2.3, 2.7, and 3.4 cm in diameter, respectively) and found that immature plum and apple fruits are better food source for G. molesta. In this study, we evaluated immature fruits of peach, plum, and apple fruits collected in mid-summer (3.1, 4.1, and 3.9 cm in diameter, respectively). Higher choice rate of first instar larva was found in peach (66.7%) compare to plum (16.7%) or apple (16.7%). However, pupal weight was less in peach (12.4 mg) and plum (10.8) than in apple (14.7 mg) although fecundity was higher in peach (202.0) than plum (144.0). Peach fruit had highest sugar content and was 1.64 and 1.53 times harder than plum and apple, respectively. The intrinsic rate of increase was 1.3 times higher on peach and apple than plum. Therefore, peach and apple fruit would be better food source for G. molesta than plum during mid-summer.

Rearing Method of Tyrophagus putrescentiae (Sarcoptiformes: Acaridae)

Authors: Sarker Souvic[1], Lim Un Taek[1], Baek Jong Hwi[1], Eun Jang La[1], Arefur Rahman Md.[1] and Hyeok Kwon Min[1], [1]Andong National University, South Korea

Abstract: Tyrophagus putrescentiae (Schrank) is a pest of stored products, but a good prey source for various predaceous mites. The purpose of this study was to develop easy and economical mass rearing method of T. putrescentiae for being used as prey source to rear predaceous mites. We designed plastic jar (800 ml) of which opening is covered with filter paper filled with rice bran as an inexpensive food source and rice husk for aeration. First, proportion of rice bran and rice husk was determined. The maximum yield was obtained in the mixture of 400 ml rice bran mixed with 600 ml rice husk in plastic jar showing 83-fold increase in number after 56 days. In addition, the highest production was obtained when 76.9% RH was used by showing 60-fold increase in number after 35 days and when 25.0 ºC temperature was used by showing25-fold increase in number after 35 days. In conclusion T. putrescentiae can be mass reared in the mixture of 400 ml rice bran mixed with 600 ml rice husk in plastic jar at 25.0 ºC and 76.9% RH environment conditions.

Population genetic structure of the common bed bug in Europe and the USA

Authors: Sasínková Markéta[1], Balvín Ondřej[1], Martinů Jana[4], Nazarizadeh Masoud[4], Booth Warren[2], Vargo Edward L.[3] and Štefka Jan[5], [1]Czech University of Life Sciences Prague, Czech Republic, [2]Department of Biological Science, The University of Tulsa, OK, United States, [34]Department of Entomology, Texas A&M University, College Station, TX, United States, [4]Institute of Parasitology, Biology Centre CAS, České Budějovice, Czech Republic

Abstract: Bed bugs are obligate hematophagous ectoparasites, infesting shelters mainly of bats and birds. Two species are major human parasites: the common bed bug (Cimex lectularius L.) and the tropical bedbug (C. hemipterus F.). After being nearly eradicated after World War II, both are showing a comeback in the last few decades. The resurgence is attributed to various mechanisms of insecticide resistance and changes in human behavior such as an increase in international travel. Using ddRAD sequencing, we studied the population structure of C. lectularius across Europe and the USA. Our research disentangles the history and causes of the population expansion, assessing the relative importance of different dispersal routes, local demography, and rise and fixation of resistance-associated mutations. The population dynamics is also studied on a temporal scale, using extensive sampling started in 2009 and continuing to the present time. The preliminary results suggest a strikingly homogenous population across Europe, with a small proportion of outliers showing weak geographic patterns. The population also appears to be very stable on the scale of 10 years. In addition to that, our sampling effort revealed a presumably established population of C. hemipterus in central Europe, quite distant from its original range in tropical regions.

Pulsed stress hypothesis revisited – A case study of Metopolophium dirhodum and spring wheat

Authors: Saska Pavel[2], Kosová Klara[1], Platková Hana[2], Skuhrovec Jirí[2] and Vítámvás Pavel[3], [1]Crop Research Institute, [2]Functional Diversity group, Crop Research Institute, Praha, Czech Republic, [3]Plant Stress Biology and Biotechnology group, Crop Research Institute, Praha, Czech Republic

Abstract: The pulsed stress hypothesis predicts that fluid-feeding insects benefit from feeding on plants that are intermittently stressed by drought due to the increased nutrient availability and restored cell turgor, but support for this hypothesis is ambiguous. We test this hypothesis by using a system consisting of young spring wheat (Triticum aestivum L.) and the rose-grain aphid Metopolophium dirhodum (Walker) by following the age-stage, two-sex life table theory. We applied periods of drought stress (soil water capacity, SWC = 40) on four occasions relative to the population development of the aphid and compared those treatments with well-watered (SWC = 70) and continuous stress conditions (SWC = 40). The timing of the stresses appeared to be important in determining its effect on aphid performance. Even though we found some improvement in fecundity when the stress occurred before the aphids were placed on the plants, the overall effect of the early-timed pulsed stress treatments on the rate of increase was negative compared to the well-watered control, which was mainly due to prolonged nymph development. The drought pulse that was timed late, during the second week of aphid reproduction, did not show any effect relative to the well-watered control. This study, therefore, provides no clear support for the validity of the pulsed stress hypothesis. We further illustrate the risk of drawing false conclusions based on incomplete data or single parameters, such as fecundity or population size, after a limited period of time.

Reconstructing Evolutionary Dynamics of Phenomes: Integrating Phylogenetic Models and Ontologies

Authors: Sasso Porto Diego[1] and Tarasov Sergei[1], [1]Finnish Museum of Natural History - LUOMUS, Finland

Abstract: Inferring historical patterns and processes driving phenotypic trait changes across the Tree of life have been major goals of evolutionary biologists. In this regard, ancestral character state reconstruction is one of the most extensively used tools for gaining insights into the evolution of individual traits. However, organismal anatomy (=phenome) is not a random assembly of individual parts. It is a structured system of anatomical entities resulting from ontogeny and phylogeny, thus producing dependencies among traits. One approach to represent knowledge about trait dependencies is by using ontologies—structured controlled vocabularies formalizing relationships and concepts. Recent advances on phylogenetic methods allowed integrating knowledge from ontologies to perform ancestral state reconstructions for entire phenomes or particular body regions: Phylogenetic Ancestral Reconstruction of Anatomy by Mapping Ontologies (PARAMO). Here we describe three developments of PARAMO: new models for reconstructing evolutionary rate shifts of entire phenomes across lineages and time; tools for assessing evolutionary rates at different levels of the anatomical hierarchy; and reconstructing the dynamics of morphospace through time. We evaluated our new methods with a large dataset for the Hymenoptera. Our results support a complex evolutionary dynamic, with particularly high evolutionary rates inferred for traits along the branches leading to the Apocrita.

Amblydromalus limonicus (Acari: Phytoseiidae) for biological of Bemia tabaci (Hemiptera: Aleyrodidae) in gerbera field

Authors: Sato Mário[1], Baldo de Carvalho Aline[1] and de Souza Marques Sirlei[1], [1]Biological Institute, Laboratory of Acarology, Campinas, SP, Brazil

Abstract: The whitefly, Bemisia tabaci (Genn.) (Hemiptera: Aleyrodidae) is a cosmopolitan pest that attacks several crops, causing direct damage during feeding and indirect damage due to the transmission of viruses. The two-spotted spider mite, Tetranychus urticae Koch (Acari: Tetranychidae), is a key pest for gerbera and several other ornamental plants. Amblydromalus limonicus (Garman & McGregor) (Acari: Phytoseiidae) is an omnivorous predatory mite that feeds on several types of prey, including thrips, whiteflies, psyllids, and tetranychid mites. The purpose of this study was to evaluate the performance of A. limonicus for the control of B. tabaci in commercial gerbera fields, under greenhouse conditions. The effect of the release of A. limonicus in field was also evaluated for spider mite infestation. The experiment was carried out in Holambra County, State of São Paulo, Brazil. The experiment consisted of two treatments: 1) gerbera beds with release of A. limonicus; 2) gerbera beds without the release of predators (farmer standard). Each plot (gerbera bed) was of 4.4 m^2 (4m x 1.1m). Between the beds with release of A. limonicus and the beds without release of the predatory mite, there was a bed (without release of predators) separating the different treatments. The releases of A. limonicus were performed at a rate of 34 predatory mites per m^2. Releases were performed every two weeks. The experimental design was completely randomized with two treatments and six repetitions. Samples of 10 gerbera leaves were collected from each plot, every two weeks, during five months. To evaluate the population densities of the whitefly and spider mite, an area of 16 cm^2 was removed from the central region of each leaf and observed under stereomicroscope, under laboratory conditions. There was a downward trend in whitefly and spider mite population densities, with a significant reduction in the number of eggs of both species since the first evaluation after the start of A. limonicus releases. The maximum population reductions for B. tabaci and T. urticae were above 95%. The release of the predatory mite contributed for the reduction in the damages caused by B. tabaci and T. urticae to gerbera plants.

Prey-tracking behaviour and prey preferences in a tree-climbing firefly

Authors: Sato Nozomu, Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University, Japan

Abstract: Certain specialist predators utilise prey-tracking strategies to trace olfactory or visual signals left behind by their prey. For example, snail-eating predators search for prey using mucus trails of land snails and olfactory cues. Prey-tracking behaviour has been well studied in invertebrates and vertebrates, but less is known about predator preferences for specific prey traces. Here, we focused on the tree-climbing behaviour of Pyrocoelia atripennis, a snail-eating firefly endemic on the Yaeyama Islands in Japan, and hypothesised that tree-climbing behaviour is a predation strategy adapted to preferred prey preferences. Choice experiments showed that P. atripennis larvae prefer mucus trails of land snails over distilled water trails or no-trail, indicating that P. atripennis larvae have the mucus-tracking strategy. Prey preference tests showed that larvae preferred arboreal and semi-arboreal land snails over terrestrial snails. This preference is likely to relate to different defense traits among land snail species. For example, ground-dwelling species have a closed shell aperture and protective lid, which make them difficult prey items for firefly larvae. However, semi-arboreal and arboreal snails without shell lids are relatively easy prey items for firefly larvae. Thus, the tree-climbing behaviour of the firefly larvae is likely to be linked to a prey-foraging strategy. The mucus trails left by semi-arboreal land snails on plant stems may help larvae track their preferred prey on plants.

Okaramine B, a natural product lead for insect pest and vector control: studies using target-based and phenotypic screening

Authors: Sattelle David, University College London, United Kingdom

Abstract: Indole alkaloid okaramines are isolated from the fermentation products of Penicillium simplicissimum (strain AK40) grown on okara, an insoluble component of soybean that remains after pureed soybeans are filtered during the production of soy milk and tofu. Hayashi and colleagues showed that okaramines A and B were insecticidal, when assayed on larvae of a lepidopteran insect, the silkworm, Bombyx mori. Only much later was evidence obtained on okaramine mode of action. Okaramine actions on larvae were rapid and since many fast-acting insecticides target ion channels, studies were pursued on ion channels of silkworm larval neurons using patch-clamp electrophysiology. Okaramine B, the most active compound of the series, induced inward currents which reversed close to the chloride equilibrium potential and were blocked by fipronil. Thus it was tested on a silkworm RDL (resistant-to-dieldrin) ?-aminobutyric-acid-gated chloride channel (GABACl) and a silkworm L-glutamate-gated chloride channel (GluCl) expressed in Xenopus laevis oocytes. Okaramine B activated GluCl, but not RDL. GluCl activation by several closely related okaramines correlated with their insecticidal activity, suggesting that their actions on GluCls accounts for their insecticidal actions. A novel L-glutamate-gated anion channel (IscaGluCl1) has been cloned from the black-legged tick, Ixodes scapularis, which transmits multiple pathogens including the agents of Lyme disease and human granulocytic anaplasmosis. Functional expression in IscaGluCl1 in Xenopus laevis oocytes was demonstrated and okaramine B activated this tick GluCl. Using a high-throughput invertebrate automated phenotyping platform (INVAPP) and the algorithm Vectorgon, we have shown that larvae of the mosquito Aedes aegypti, an important vector of tropical diseases including yellow fever, dengue and zika, are immobilised by okaramine B. Unlike ivermectin, okaramine B was inactive at 10 µM on human a1ß2?2 GABACl and a1ß glycine-gated chloride channels and may provide a new lead compound for the development of novel, insect control chemicals.

Reducing pesticides and increasing crop diversification conserve natural enemies and offer economic benefits for farmers – A case study in Cambodian rice fields

Authors: Sattler Cornelia[2], Asmara Ratna Hadi Buyung[5], Saban Choun[4], Settele Josef[2], Schrader Julian[2], Keo Makarakpakphea[1], Joy Flor Rica[5] and Chhun Sokunroth[3], [1]Department of Rice Crop, General Directorate of Agriculture, Cambodia, [2]Helmholtz Centre for Environmental Research – UFZ, Department of Community Ecology, Halle, Germany, [3]Provincial Development of Agriculture Forestry and Fisheries Battambang, Cambodia, [4]Provincial Development of Agriculture Forestry and Fisheries Prey Veng, Cambodia, [5]Sustainable Impact Platform, International Rice Research Institute, IRRI-Cambodia Office, Cambodia

Abstract: With the intensification of rice production, landscape heterogeneity decreased due to land transformation, leading to high external inputs of synthetic pesticides to reduce potential yield loss by insect pests. Although, it is well understood that outbreaks of insect pests can be induced by pesticides, farmers still use them abundantly. Ecological engineering is a landscape-based approach with the aim to reduce pesticide applications and to promote insect natural enemies with food resources. However, its ecological and socioeconomic benefits are still poorly understood.

Here, we implement ecological engineering in rice agroecosystems in Cambodia. We introduce bund plants, after surveying which plants are preferred given economic and nutritional benefits for farmers; and test whether ecological engineering promotes biological control by enhancing the abundance of beneficial arthropods. Over dry and wet rice cropping seasons, we identified and compared arthropod communities among ecologically engineered rice fields, fields farmed with conventional methods and control fields that had no bund plants present and were not treated with pesticides. We then compared the costs and benefits of each treatment for the farmers.

We found significantly higher numbers of beneficial arthropods in ecological engineered and control rice fields than in conventional ones, despite no differences in rice yield among fields. We found no significant differences in natural enemy abundance among ecologically engineered and control fields. Our results highlight that pesticide applications are the main drivers causing depauperated arthropod communities of natural enemies.

Bund plants surrounding the rice fields have manifold benefits including higher landscape heterogeneity and additional yields for farmers. Furthermore, our results revealed that withholding pesticides (implementing ecological engineering) did not negatively affect rice yield but led to lower overall costs for farmers.

Synthesis and applications. Our results highlight the negative impact of pesticides on arthropod communities in rice fields and points at the manifold possibilities provided by ecological engineering. The choice of bund plants should integrate information about farmers' choice to increase potential adoption by farmers. Proper implementation of ecological engineering in combination with farmers' choice of crops is a promising solution towards sustainable rice production.

Updates to EPA Registration and Efficacy Testing of Vector Control Products Under PRIA 4

Authors: Saunders Jennifer, Environmental Protection Agency, United States

Abstract: EPA-registered pesticide products are an important part of pest management programs to accomplish control of invertebrate pests. The Agency registers a wide range of vector control products, including wide-area mosquito adulticides and larvicides, skin-applied repellents, pesticide-impregnated clothing and nets, and modified mosquitoes. Product efficacy data for public health pests are required to be submitted to support a pesticide registration. The Agency has a number of guidelines intended to assist in the development of appropriate protocols to test product efficacy in support of pesticide registration. The Pesticide Registration Improvement Act (PRIA 4) mandated that EPA revise and implement four of its current efficacy guidelines by 2021, including EPA Product Performance Test Guideline 810.3500 Premises Treatments, originally published in March 1998. To increase clarity and consistency in efficacy testing and to include current scientific standards, in 2019 the Agency published a revised version of the guideline which now contains recommended test methodologies for a wide range of products intended to kill, control, flush, and/or knock down invertebrate premises pests, such as cockroaches, ticks, mosquitoes, flies, and wasps. The guideline also includes field testing methods for outdoor misting systems, flying-stinging Hymenoptera nest treatments, and outdoor residual foggers.

Strip cropping and natural enemies, a case study in cabbage – faba bean system

Authors: Saussure Stéphanie[1], Mäkinen Joonas[2], Nissinen Anne[2], Kaseva Janne[1], Blande James[2] and Himanen Sari[3], [1]Natural Resources Institute Finland, [2]University of Eastern Finland, [3]XAMK/Natural Resources Institute Finland

Abstract: Strip cropping is an agricultural practice aiming at regulating agroecosystem functions such as nutrient and water dynamics, while reducing pest damage and guaranteeing high yield. However, its influence on beneficial arthropods is mostly unknown. Over two years, we experimented on an organic cabbage (Brassica oleracea) – faba bean (Vicia faba) strip cropping system with three treatments: faba bean and cabbage monocrops, and alternating strips of the two. Three groups of generalist predators were sampled, namely carabid beetles (Coleoptera: Carabidae), staphylinids (Coleoptera: Staphylinidae), and spiders (Areneae) with pitfall traps for three one-week collection periods per year. Further, naturally occurring parasitoids targeting the diamond back moth were monitored by parasitism exposure experiment. We investigated strip cropping effect on the natural enemy abundances and the carabid beetle diversity. Our results showed that strip-cropping effect varies with year, sampling time and natural enemy group. Indeed, intercropping enhanced carabid activity-density and diversity and to some extent spider abundance, but reduced staphylinids abundance and parasitism rate of diamondback moth larva. Our results highlight that crop diversification through strip-cropping does not enhance abundance of all beneficial fauna in a homogenous manner and is not stable through time. Further studies are required to unravel the mechanisms at play.

Ozonolysis of Drosophila Cuticular Hydrocarbons

Authors: Savage Benjamin[1], Chung Henry[1], Grieshop Matthew[1] and Wang Zinan[1], [1]Michigan State University, United States

Abstract: Our research sought to characterize any sub-lethal effects that ozone might have on insects. We have currently found that D. suzukii exposure to high concentrations of ozone will result in ozonolysis of its cuticular hydrocarbons. The process of ozonolysis cleaves unsaturated alkenes, which are known to regulate mating behaviors in many drosophilan species. Data supports that mating behavior is significantly reduced after D. suzukii has undergone controlled ozone exposure. Current research seeks to understand these interactions further and develop methodology for determining drosophila speciation in terms of cuticular hydrocarbon chemical constituents.

Diet, life history traits and stress: Does the effect of dietary restriction on life history trade-offs depend on injury and infection?

Authors: Savola Eevi[1], Montgomery Clara[1], A. Walling Craig[1], Waldron Fergal[1], Monteith Katy[1] and Vale Pedro[1], [1]The University of Edinburgh, United Kingdom

Abstract: Dietary restriction (DR), limiting certain nutrients or the overall calorie content of food, extends lifespan in diverse taxa. This is thought to result from diet mediated changes in the resolution of the trade-off between lifespan and reproduction. Although the response to DR is considered to be evolutionarily conserved, some studies have suggested genetic and environmental variation in the response. In fact, a recent evolutionary theory suggests DR will not extend lifespan under more stressful conditions. By adding stressors, such as injury and infection, to the usual benign laboratory environments we test this prediction.

To test whether the DR response remains with injury and infection stress, we reared an outbred population of adult Drosophila melanogaster on 10 diets varying in protein content. We infected a subset of flies with a low dose of bacterial pathogen (Pseudomonas entomophila), injured a subset with a sterile pin prick and had a control subset. We monitored the flies for the key life history traits of lifespan and fecundity.

Next, to test how the host and pathogen responses varied on different diets, we repeated the injury and infection treatments on a low and intermediate protein diet and measured both bacterial growth and the relative expression of antimicrobial peptides (AMPs) genes at three time points post infection in the flies.

DR extended lifespan and reduced reproduction even when flies were challenged with injury and infection. However, when infected, flies on lower protein diets had particularly poor survival compared to the control or injury treatments. Across diets, bacterial growth did not differ in the flies, however some AMP gene expression levels differed at 24 hours post infection.

These results provide novel information on how infection stress together with dietary restriction affects variation in life history traits and the resolution of their trade-offs.

Halyomorpha halys egg parasitoids and early detection of Trissolcus mitsukurii in northern Italy

Authors: Scaccini Davide[1], Pozzebon Alberto[1], Duso Carlo[1], Scaccini Davide, Martinez-Sañudo Isabel[1] and Tirello Paola[1], [1]University of Padova DAFNAE - Department of Agronomy, Food, Natural Resources, Animals and Environment, Italy

Abstract: Brown marmorated stink bug, Halyomorpha halys (Stål) (Hemiptera: Pentatomidae) is an invasive pest species native to eastern Asia that is causing dramatic outbreaks in Veneto region (northern Italy). In a 3-year survey (2016 – 2018) carried out across different sites in this region, egg parasitoids of H. halys were studied by collecting naturally laid egg masses in orchards and vineyards. Emerged insects were identified morphologically, and barcoding with mitochondrial cytochrome c oxidase I (COI) was used to assess genetic relationships with other parasitoids populations. We recorded parasitoids/hyperparasitoids from three Hymenoptera families, i.e. Scelionidae (Trissolcus basalis (Wollaston), Trissolcus kozlovi Rjachovskij, and Trissolcus mitsukurii (Ashmead)), Eupelmidae (Anastatus bifasciatus (Geoffroy)), and Pteromalidae (the hyperparasitoid Acroclisoides sinicus (Huang & Liao)). Parasitoid presence varied between species, and the most common egg parasitoid was T. mitsukurii, which emerged from H. halys egg masses collected in all three years of the survey. The 'parasitoid impact' (i.e. number of parasitized eggs over the total number of field-collected eggs) was the highest for T. mitsukurii, followed by A. bifasciatus. Here we report the earliest known occurrence of T. mitsukurii in Europe, which emerged from H. halys egg masses two years earlier than previously published records. The phylogenetic tree for T. mitsukurii inferred from COI distinguished two clades, one covering samples from Italy, Japan and China, while the other from South Korea.

Seasonal population dynamics and damage potential of Halyomorpha halys on grapevine in Italy

Authors: Scaccini Davide, Pozzebon Alberto[1], Duso Carlo[1], Fornasiero Diego[2] and Tirello Paola[1], [1]University of Padova DAFNAE - Department of Agronomy, Food, Natural Resources, Animals and Environment, Italy

Abstract: The brown marmorated stink bug, Halyomorpha halys (Stål) (Hemiptera: Pentatomidae) is an invasive polyphagous pest native of Asia that is frequently observed in vineyards in Italy, and the impact of this pest on grapevine production is not fully understood. Field observations were performed to assess seasonal dynamics in population abundance in vineyards. In a cage experiment, we evaluated the damage on grape clusters induced by different infestation densities and considered different infestation period on different grapevine cultivars. In a field experiment, we studied the association between H. halys infestation and the occurrence of grey mold and sour rot by applying a factorial experiment with treatments defined by the combination of insecticide and fungicide applications. Field observation showed cultivar effect in seasonal dynamics of this pest. Halyomorpha halys infestations caused damage on berries, showing a higher susceptibility in red varieties, in particular, Cabernet Franc, and following 50% of grape cluster veraison. In the cage experiment, the infestation by Halyomorpha halys induced an increase in Botrytis cinerea incidence. In the field experiment, the proportion of cluster damaged by grey mould and sour rot were observed on treatments with higher Halyomorpha halys infestations density. The association between H. halys infestation and the incidence of grey mould and sour rot represent the main issue related to H. halys infestation in vineyards in Italy and this aspect should be carefully considered in the definition of IPM programs on grapevine.

Assessing the regulation of nitrogen homeostasis in Aedes aegypti females

Authors: Scaraffia Patricia[2], Isoe Jun[1], Petchampai Natthida[2] and Joseph Vena[2], [1]The University of Arizona, [2]Tulane University, United States

Abstract: Female mosquitoes cause almost five hundred thousand deaths worldwide each year because of their ability to transmit pathogens through blood-feeding. Ammonia, one of the metabolic by-products of blood meal digestion, cannot be stored inside cells, and therefore nitrogen balance must be regulated to prevent ammonia toxicity. Unlike mammals that can detoxify ammonia using the urea cycle, mosquitoes lack a urea cycle. They must either directly excrete ammonia or metabolize it efficiently through specific pathways that were not thought to be present in mosquitoes. To better understand how blood-fed Aedes aegypti females regulate nitrogen metabolism, we have analyzed the impact of silencing ornithine decarboxylase (ODC) by reverse genetics on sugar- and blood-fed Ae. aegypti females. Our data indicate that RNAi-mediated knockdown of ODC significantly decreases survival, delays serine protease expression, disrupts midgut proteolysis, alters uric acid and heme excretion, and impairs reproduction in females. Moreover, in tissues of sugar- and blood-fed dsRNA-injected Ae. females, we found that ODC deficiency induces a differential transcription of genes encoding proteins involved in multiple pathways, including arigininolysis, glucose and ammonia metabolism, ammonia transporters and oxidative stress response. Our findings provide evidence that ODC is essential to maintain nitrogen homeostasis in Ae. aegypti female mosquitoes.

Nutritional mutualism of Wolbachia with the common bed bug, Cimex lectularius

Authors: Schal Coby[1], Kakumanu Madhavi[1], Hickin Mauri[1] and Fisher Michael[1], [1]Department of Entomology and Plant Pathology North Carolina State University, United States

Abstract: The common bed bug, Cimex lectularius, harbors the endosymbiotic microorganism, Wolbachia, in a gonad-associated bacteriome. Wolbachia is an obligate nutritional mutualist. In exchange for protection, nutrients and vertical transmission, Wolbachia provides the bed bugs B-vitamins that are usually deficient in vertebrate blood. The obligatory nature of this association would suggest that all individuals in C. lectularius populations should be infected with Wolbachia. Yet, studies have reported variation in both infection frequency and relative abundance of Wolbachia in field-collected bed bugs. Quantification of Wolbachia over the life cycle of C. lectularius revealed highly dynamic changes in Wolbachia abundance during bed bug development, changing relative to life stage, intermolt stage, and blood-fed status. Findings suggest that disparities in Wolbachia infections may be due to low abundance during certain developmental stages of the bed bug.

Using a Wolbachia-free bed bug model, we address two questions in the Wolbachia-bed bug mutualism:

(1) Bed bugs, unlike other hemotaphagous arthropods, have not been linked to any human pathogen or disease. We investigated the effect of Wolbachia on virus replication of a model pathogen, feline calicivirus, in C. lectularius. There was no difference in virus titer between the Wolbachia-positive and Wolbachia-free groups, suggesting that Wolbachia is not involved in virus suppression within bed bugs.

(2) We investigated the contribution of Wolbachia to bed bug fitness by supplementing host blood with various vitamin mixes. Specific vitamins influenced bed bug development and fecundity.

The link between habitat preference and performance in pit-building predators

Authors: Scharf Inon, Tel Aviv University, Israel

Abstract: Pit-building insects are sit-and-wait predators that construct pit-traps in loose soil. Wormlion larvae are such predators, common in Mediterranean cities under man-made shelters. Together with pit-building antlions, they present a fine example of convergent evolution. The goal was to examine which habitats wormlions prefer and whether they perform better in their preferred habitats. I first demonstrated that wormlions prefer dry over wet sand, deep over shallow sand and fine over coarse sand. I then detected a match between habitat preference and performance: wormlions construct larger pits and hunt more successfully in the preferred habitats. My second goal was to examine what makes wormlions so successful in urban habitats and whether those from urban and more natural habitats differ in their behavior. Wormlions are probably so abundant in the city due to a more favorable arthropod composition in the city that provides plenty of suitable prey, compared to a less favorable arthropod composition in the countryside. Furthermore, urban wormlions construct larger pits, respond faster to prey and are choosier regarding their preferred microhabitat, suggesting that the city provides better opportunities for wormlions. Finally, I will discuss how disturbance affects pit relocation in wormlions and compare my findings to other trap-building predators (spiders and antlions).

Investigating a novel surface insecticide treatments for control of dermestids

Authors: Scheff Deanna[1] and Arthur Frank[1], [1]United States Department of Agriculture - Agricultural Research Service, United States

Abstract: Recently there has been and increasing interest and concern in the stored product industry regarding dermestid species in processed grain products, warehouses, and processing facilities. Trogoderma inclusum LeConte, larger cabinet beetle, and T. variabile Ballion, warehouse beetle, are two highly destructive dermestids that infest a variety of food products and are often captured in insect traps. T. variabile is capable of moving across multiple floors of a facility. Recent advances on surface treatment applications have been reported for other species of stored product insects, but there is no data regarding efficacy against Trogoderma spp. Therefore, we investigated efficacy of two formulations of insecticide (methoprene + deltamethrin and methoprene + deltamethrin + piperonyl butoxide synergist, PBO), applied to concrete or metal surfaces, on adult and larvae of T. variabile and T. inclusum. Results for both species, regardless of life stage, show minimal positive effect of the PBO when added to the standard methoprene + deltamethrin formulation. The application of both insecticides was more effective on the metal surface compared to the concrete surface. Though adult mortality was <100% on both treated surfaces, the methoprene portion of the insecticide was highly effective and prevented exposed larvae from developing to the adult stage. These insecticides can be highly effective on population control of Trogoderma spp. in warehouses, storage facilities, or grain bins which all have different substrates. By controlling populations of stored product insects, it will in turn provide extended production of stored grain products.

Halloween genes spook, shadow and shade determine oocyte length in the desert locust, Schistocerca gregaria

Authors: Schellens Sam[2], Lenaerts Cynthia[1], Pérez Baca María del Rocío[4], Cools Dorien[2], Peeters Paulien[2], Marchal Elisabeth[3] and Vanden Broeck Jozef[1], [1]Catholic University of Leuven, Belgium, [2]KU Leuven, Belgium, [3]KU Leuven / Imec, [4]KU Leuven / UGent

Abstract: Ecdysteroids are widely investigated for their role during the molting cascade in insects. However, they are also involved in the development of the female reproductive system. Ecdysteroids are synthesized from cholesterol, which is further converted into the main molting hormone, 20-hydoxyecdysone. This biosynthetic conversion process heavily relies on the activity of cytochrome P450 hydroxylases, which are encoded by the Halloween genes. Five Halloween genes, spook (spo), phantom (phm), disembodied (dib), shadow (sad) and shade (shd) were identified and their spatiotemporal expression profiles were characterized in the desert locust, Schistocerca gregaria. Here, we investigated the possible role(s) of these genes during oocyte maturation using RNA-interference mediated knockdown experiments. Our results showed that depleting the expression of SchgrSpo, SchgrSad and SchgrShd had a significant impact on oocyte development, oviposition and hatching of the eggs. Moreover, the shape of the growing oocytes, as well as the deposited eggs, was very drastically altered by the experimental treatments. Consequently, it can be proposed that these three enzymes play an important role during oocyte maturation.

We are very grateful to the Special Research Fund of KU Leuven, the European Union's Horizon 2020 Research and Innovation program, and the Research Foundation of Flanders for their financial support.

Engineering the white pupae phenotype for sustainable pest control

Authors: Schetelig Marc[1], Aumann Roswitha[1] and Häcker Irina[1], [1]Justus-Liebig University Giessen, Germany

Abstract: Mass releases of sterilized male insects, in the frame of sterile insect technique (SIT) programs, have helped suppress insect pest populations since the 1950s in a sustainable and species-specific way, which additionally is immune to resistance development. In several major horticultural pests a key phenotype, white pupae (wp), has been used for decades to selectively remove females before sterile male releases, yet the gene responsible remained unknown. We used classical and modern genetic approaches to identify and functionally characterize causal wp– mutations in these fruit fly species. We found that the wp phenotype is produced by parallel mutations in a single, conserved gene. CRISPR/Cas9-mediated knockout of the wp gene leads to the rapid generation of white pupae strains in C. capitata and B. tryoni. The conserved phenotype and independent nature of wp– mutations suggest this technique can provide a generic approach to produce sexing strains in other major medical and agricultural insect pests, allowing the application of the environmentally friendly SIT method to novel pest species.

Global data access, data visbility, and data citation in entomology

Authors: Schigel Dmitry, Global Biodiversity Information Facility (GBIF), Secretariat, Denmark

Abstract: GBIF—the Global Biodiversity Information Facility—is an international network and research infrastructure funded by the governments and providing anyone, anywhere, free and open access to data about all types of life on Earth, including data on insects. Coordinated through its Secretariat in Copenhagen, the GBIF network of countries and organizations, working through participant nodes, provides organizations around the world with data standards and tools to enable sharing primary data on the species occurrences in space and time. The GBIF network links together data from diverse sources such as museum collections, field surveys and citizen scientists' observations—more than 2.1 billion species occurrence records in total in April 2022. More than 1,800 institutions around the worldwide publish datasets under the machine-readable Creative Commons licenses. Data openness, together with DOI-based credit and provenance mechanisms, support the use and applications by researchers, scientists and others users in peer-reviewed publications as well as assessment and policy papers. These studies only take place at such scale and taxonomic coverage because of the integrated, freely and quickly accessible integrated biodiversity data.

GBIF.org is a central access and discovery point for biodiversity data worldwide, and is the largest collection of spatiotemporal biodiversity evidence in the world. Heterogeneity, complexity and diversity of the data publishers and data sources leads to the biases in taxonomic, spatial and temporal coverage. Open biodiversity data require educated data use and management, dealing with the outliers and uncertainties, and taking other steps to optimize data fitness for use in research and practice. Adequate data use is, of course, only possible if data content is centrally and digitally available and data indexing enables filtering and search. Commonly, users access data by searching by taxon name, locality, date and a few others parameters. Data from resources shared through GBIF.org can be downloaded or accessed through GBIF API, and every data download is issued with a unique DOI that provides a registry of the data sources that contributed to the download, as well as a mechanism that enables both machine- and human-readable data citations.

By April 2022, insect data in GBIF are represented by 154.5 million occurrence records and over 1.1 million names (Fig.1), dominated by human observations and preserved specimens. The number of records by higher taxa is largely controlled by the observation and sampling effort, and the popularity of the taxa among non-professional, but not the species numbers, functional importance or other biodiversity drivers. The presentation will cover the status and future plans of this work and highlight individual, organisational and national benefits of integrated data approach in entomology. Fig. 1. Taxonomic distribution of insect occurrences in GBIF https://www.gbif.org/species/216 by 19 April 2022.

A regulatory mechanism for thermotolerance in kissing bugs, and its consequences for geographical distribution

Authors: Schilman Pablo[2] and Alvarez Costa Agustin[1], [1]DBBE, School of Sciences, University of Buenos Aires & IBBEA (CONICET-UBA), Argentina, [2]IBBEA (CONICET-UBA). DBBE, FCEyN - Universidad de Buenos Aires. ARGENTINA, Argentina

Abstract: Temperature affects practically all the physiological processes of organisms, and is the most important abiotic factor in the geographic distribution of insects. The thermal tolerance range is given by the minimum critical temperature (CTmin) and the maximum critical temperature (CTmax). I will present results showing how the geographical distribution of seven species of triatomines, vectors of Chagas disease, can be explained, in part, by their thermo-tolerance range. Briefly, we analyzed the relationship between the ecological niche and the limits of the physiological thermal niche in seven species of triatomines. For this, we combined two methodological approaches: species distribution models, and physiological tolerances. In triatomines, thermo-tolerance range increases with increasing latitude mainly due to better cold tolerances, and we also found positive effects of acclimation on thermotolerance, especially on the CTmin. For one of the seven species studied, i.e., Rhodnius prolixus, a model organism in insect physiology, and an important vector of Chagas disease, we demonstrated, by thermolimit respirometry and video thermo-imaging, a significant decrease of body-temperature and extension of its upper limits of temperature tolerance (CTmax) by evaporative cooling. Studying the relationship between the physiological mechanisms that allow modulating the effects of high temperatures and geographical distribution is of great importance especially when analyzing invasive insects, pests or vectors of diseases such as triatomines.

Modulation of thermal tolerance by heat or cold hardening in the hematophagous insect Rhodnius prolixus: the role of heat shock proteins

Authors: Schilman Pablo[2], Colecchia-Corso Maria Luisa[1], Pontes Gina[1], Latorre-Estivalis Jose M.[3] and Pereira Marcos H.[4], [1]IBBEA (CONICET-UBA). DBBE, FCEyN - Universidad de Buenos Aires. ARGENTINA, [2]IBBEA (CONICET-UBA). DBBE, FCEyN - Universidad de Buenos Aires. ARGENTINA, Argentina, [3]IFIByNE (CONICET-UBA). ARGENTINA, [4]Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Abstract: Temperature is an important abiotic factor affecting many physiological processes in ectotherms, including insects. The thermal stress produced by extreme temperatures can have deleterious effects on insects. So, there are many mechanisms to withstand it including the production of heat shock proteins (HSPs). We investigated the effect of a moderate heat or cold shock on thermotolerance of the hematophagous insect Rhodnius prolixus, as well as the role of HSPs. For that, groups of insects were exposed 1 h to two hardening temperatures (10 or 37°C) or keep at 25°C (control group), and thereafter standard thermotolerance tests, such as, critical thermal maxima (CTmax) and critical thermal minimum (CTmin) were performed. Results showed that heat hardening (37°C) increase thermotolerance by affecting both, CTmax and CTmin. In the same way, cold hardening (10°C) increased tolerance to high and low temperatures, which strongly suggest that both, heat and cold hardening could induce a thermotolerance improvement. In addition, HSP70/HSP90 RNAi knockdown insects showed lower resistance to low and high temperatures compared with their controls. These results provide further insight into the physiological adaptations of hematophagous insects to harsh environmental conditions.

A high-quality genome of bark beetle Ips typographus by PacBio sequencing: major milestones completed and first comparison to other Coleopteran herbivores

Authors: Schlyter Fredrik[1], Vogel Heiko[2], Löfstedt Christer[7], Große-Wilde Ewald[4], Roy Amit[5], Powell Daniel[6], N Andersson Martin[3] and Krokene Paal[8], [1]Czech University of Life Sciences Prague and Lund University, Sweden, Czech Republic, [2]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [3]Dept Biology, Functional Zool. Unit, Lund University, Sweden, [4]Dept Evol. Neuroethol., Max Planck Inst. Chem. Ecol., Jena, Germany, and EXTEMIT-K, ETM, FFWS, CULS, Prague, Czech Republic., Czech Republic, [5]EXTEMIT-K, ETM, FFWS, CULS, Prague, Czech Republic, [6]EXTEMIT-K, ETM, FFWS, CULS, Prague, Czech Republic and Dept Biology, Functional Zool. Unit, Lund University, Sweden, [7]Lund University, Sweden, [8]Mol. Plant Biol., Div. Biotech. & Plant Health, NIBIO, Ås, Norway

Abstract: For Ips typographus, a major pest of Picea spp in the Palearctic, we have generated a high-quality genome sequencing database as the best possible foundation for analysis of specific genes in our own research (chemosensation, detoxification, immune response), and other current European research, as well as the bark beetle scientific community in general.

Workflow: We have created a highly inbred line (sibling-mating single beetle pairs for 10 generations) to allow sequencing with Pacific Biosystems technology. The inbreeding reduced heterozygosity, i.e. reduce the amount of natural sequence variation due to allelic variation, which is very detrimental when working with PB. The resultant assembly is of extraordinary quality, with a total size of ~239 MB present in 279 contigs. From the assembly the longest contig was 16 million bp, while the mtDNA exists as a single 28 kbp contig.

Stranded RNA-Seq data from multiple life stages and tissues previously generated by the CULS group was aligned to the genome assembly. State-of-the art software and workflow (RepeatModeler, Repbase, RepeatMasker MAKER3, HiSat12 etc) analysis of genome and transcriptome sequences supporting gave “automated” gene model predictions, allowing inter alia an comparison to other high-quality beetle genomes.

There are a total of 23,937 genes predicted with at least some form of supporting evidence and missing only 38 (2.3%) of the BOSCO insect orthologs. This is comparable with the Asian longhorn beetle (22,035 genes). Genes number for chemosensation, detoxification, and pesticide resistance was similar or higher compared to 11 Coleoptera genomes.

Outlook: The sequence data and first analysis is prepared for submission. Direct use of data will follow during 2020 and onwards, including manual annotation for chemosensation and detoxification genes, for the downstream de-orphanisation of olfactory receptors, insect-tree RNA-Seq transcriptomics, and for gene knockout and -knockdown experiments. In the longer term, the result will be an annotated, very high-quality genome, that we hope will be useful not only for study of evolution, ecology, and, management in Ips spp, but also for other Ipini and Scolytinae.

Moving from univariate biodiversity to community responses to agricultural environments

Authors: Schmidt Jason, University of Georgia, United States

Abstract: Here using a data from a variety of agricultural systems collected over the past five years, we explore challenges, similarities and differences in understanding the structure of communities and associated trophic interactions determined through molecular gut content analysis.

Anatomy of male and female genitalia of Acanthoscelides obtectus (Chrysomelidae: Bruchinae) in interaction

Authors: Schmitt Michael[1] and Aileen Neumann[2], [2]University of Greifswald, General & Systematic Zoology, Germany, [1]Universitaet Greifswald Allgemeine & Systematische Zoologie, Greifswald, Germany

Abstract: The membraneous endophallus of male A.obtectus is armed with spicules. We checked if these spicules penetrate the wall of the female bursa copulatrix during copulation. Other than in Callosobruchus maculatus, these spicules leave no traces of penetration, as revealed by microscopical investigations. Identification of the exact relative position of male and female copulatory organs while mated by means of MicroCT confirmed that the spicules do not cause wounds in the bursa wall. During copulation, only the tip of the median lobe of the aedeagus is inserted into the female genital opening. The everted endophallus extends over the full length of the ovipositor, and the spermatophore is placed in the bursa. Females hinder mounting of the males by kicking them off by vehement movements of their hind legs. Copulation is generally terminated by the females who push off the males with their hind legs.

Diverse or simple: (non-)volatile chemical cues that predict bee foraging choices.

Authors: Schmitt Thomas[3], Leonhardt Sara[2], Ruedenauer Fabian[2] and Spaethe Johannes[1], [1]Department of Behavioural Physiology and Sociobiology (Zoology II), Biozentrum, University of Wuerzburg, Germany, [2]Technical University of Munich, Germany, [3]University of Würzburg, Germany

Abstract: Bees, like most herbivores, often face a considerable diversity of chemical cues and thus complex information pattern when foraging, but have to make quick decisions on whether or not a resource is appropriate.
We wanted to better understand how social bees master this challenge, whether e.g. they select and focus on meaningful cues, rely on colony feedback or learn entire chemical profiles of preferred resources. We therefore studied the role of chemical information for pollen collection in bumblebees (Apidae: Bombus terrestris) and resin collection in stingless bees (Apidae: Tetragonula carbonaria), combining different behavioral assays and chemical analyses of resources.
We found that cue perception differs with the type of resource collected. For instance, stingless bees learn the entire complex volatile profiles of preferred resin sources and specifically target these resins, while bumblebees appear to prioritize lipid perception when assessing pollen appropriateness and generally select pollen of comparatively lower fat content. In both cases, decisions appear to ultimately affect colony fitness. Resins specifically targeted by stingless bees show comparatively high bioactivity (e.g. antimicrobial, predator repellent); and fatty pollen severely decreases survival of bumblebees.

Evidence for a chemical arms race: Lections from the chemical mimicry system of a cuckoo wasp

Authors: Schmitt Thomas[4], Polidori Carlo[3], Wurdack Mareike[1], Niehuis Oliver[2] and Castillo Ruth[1], [1]Department of Animal Ecology and Tropical Biology, University of Würzburg, Germany, [2]Department of Evolutionary Biology and Ecology, University of Freiburg, Germany, [3]Instituto de Ciencias Ambientales (ICAM), Universidad de Castilla la Mancha, Spain, [4]University of Würzburg, Germany

Abstract: Brood parasites can exert strong selection on their hosts by exploiting their hosts' parental care. This can lead to coevolutionary processes in which adaptations by the parasites face counter-adaptations by the hosts. We studied interactions between 1) digger wasps, 2) the digger wasps' prey and 3) the digger wasps' brood parasites. We found evidence for a coevolutionary arms race between hosts and their brood parasites, which mimic the cuticular hydrocarbon (CHC) profiles of their hosts. Digger wasps of the genera Cerceris and Philanthus hunt either Coleoptera or Hymenoptera. It was previously shown that these wasps preserve only Hymenoptera prey against fungal infestation by applying a specific hydrocarbon mixture identical to their own (i.e., the predator's) body surface CHC profile. The hydrocarbon profile of Hymenoptera-hunting, but notably not of Coleoptera-hunting species, thus needs to retain its anti-fungal properties which limits the CHC profile diversification. We hypothesized that Coleoptera-hunting digger wasps benefit from relaxed selection on their CHC profile in order to escape from chemical mimicry by their parasites. We found: 1) less overlap in the CHC profiles of Coleoptera-hunters and their parasites, compared to that of Hymenoptera-hunters and their brood parasites: 2) that CHC profiles of Coleoptera-hunters are more diversified in females than in males; and 3) that female cuckoo wasps of Coleoptera-hunters "follow" the chemical space of their female hosts. We conclude that species preying on Coleoptera have diversified their CHC profile as an adaptation to escape chemical mimicry from their brood parasites. This strategy cannot be adopted by Hymenoptera-hunters, which must maintain a specific CHC profile for prey preservation.

Spatiotemporal genomic analyses and insights into pest evolution

Authors: Schoville Sean, Dept. of Entomology University of Wisconsin, United States

Abstract: Agricultural pests are extraordinarily successful in responding to environmental and human-imposed selection pressures. The ability of agricultural pests to overcome these challenges threatens food security and the development of sustainable agricultural practices. A growing body of research demonstrates that rapid phenotypic evolution is prevalent in agricultural pests, but questions remain about the molecular mechanisms that underlie rapid evolutionary change. I discuss the strengths of population genomic studies that stratify population samples both in space and in time, leveraging a hypothesis-testing framework in order to investigate how pests evolve. These genome-scale data provide a broad framework to investigate evolutionary mechanisms, understand the genetic basis of pest phenotypes, and to improve management outcomes in agroecosystems. Focusing on my own study system, the Colorado potato beetle, Leptinotarsa decemlineata, I demonstrate how underlying standing genetic variation and polygenic trait architecture contributes to the beetle's ability to rapidly evolve to insecticide resistance. Comparative genomic data of related species further support the role of high standing variation and elevated rates of positive selection in driving rapid evolution in this pest lineage. Comparing these results to other recent studies suggests that certain species-specific traits may contribute to rapid evolution, though there remain a number of challenges to interpreting spatiotemporal genomic data.

The genetic basis of color variation in Nebria ingens complex in alpine habitats of the Sierra Nevada

Authors: Schoville Sean[2], Weng Yi-Ming[3] and Kavanaugh Dave[1], [1]California Academy of Sciences, United States, [2]Dept. of Entomology University of Wisconsin, United States, [3]University of Wisconsin-Madison, United States

Abstract: Understanding how microevolution results in species' diversity and natural selection is one of the primary goals of evolutionary biology. Knowledge of the genetic basis of morphological and physiological traits is increasingly important in documenting evidence of organismal adaptation to the environment. To detect the genes that underlie complex phenotypic traits, one can employ association mapping approaches to identify the genetic markers that have conspicuously high statistical association with the focal phenotype. These approaches are rarely applied in non-model organisms due to cost and demanding experimental designs, however natural hybrid zones offer a powerful context to effectively apply these methods. In this study, we focus on several morphological traits including metallic color of carabid beetles, by applying association mapping to the Nebria ingens complex in the Sierra Nevada Mountains of California. Two subspecies, N. i. ingens and N. i. riversi, as well as many hybrid populations were sampled for phenotypic variation and genotyped using low-coverage whole genome sequencing. Reads were mapped to a reference genome assembled from long read PacBio sequencing. Our preliminary results provide the first identification of metallic color pattern genes in beetles.

Population genetic structure supports local persistence in multiple glacial refugia in the montane net-winged midge Liponeura cinerascens cinerascens LOEW 1844 (Diptera: Blephariceridae)

Authors: Schröder Oskar[2], Cavanaugh Kirstin[2], Seifert Linda[1], Bonada Núria[3] and Schell Tilman[2], [1]Bavarian Forest National Park, Germany, [2]Senckenberg Research Insititute and Natural History Museum, Germany, [3]University of Barcelona, Spain

Abstract: Populations of stream organisms exhibit varying levels of isolation, depending on where they have their preferred habitat within the dendritic network and how well they can – and actually do – disperse in aquatic or terrestrial life stages. Net-winged midges generally prefer microhabitats with boulders and strong current that naturally occur in isolated stream sections, often across distinct mountain ranges. Here we study the population genetic structure of the net-winged midge L. c. cinerascens based on range-wide microsatellite genotyping and COI sequencing of individuals from the Pyrenees, Jura Mountains, Bavarian Forest and Carpathians. Our results indicate distinct genetic differentiation between mountain ranges, coupled with near panmictic gene flow across distances exceeding 100km within each studied mountain range. These results suggest that adult and larval mobility allow L. c. cinerascens to disperse between watercourses in highly structured mountain ranges. Lowland regions, however, pose a significant dispersal barrier, possibly because high gradient stretches with boulders are rare in such landscapes. Distinct COI lineages, microsatellite population genetic structure and high levels of regionally private alleles provide evidence that mountain range populations have been evolving independently from each other for several million years. We posit 1) that each of the studied mountain regions represents an independent Pleistocene glacial refuge, and 2) that L. c. cinerascens was able to persist glacial cycles in extra-Mediterranean periglacial refugia in the Jura Mountains, Bavarian Forest and Carpathians.

Investigating grain aphid insecticide resistance and BYDV transmission in post-Neonicotinoid Ireland

Authors: Schughart Maximilian, Teagasc, Ireland

Abstract: The grain aphid Sitobion avenae is a major agricultural pest in Europe. It damages crops by feeding on the grain and transmitting barley yellow dwarf viruses (BYDV), which can result in high yield losses. In recent years, aphid control for farmers has become more challenging due to the EU-ban on Neonicotinoids, as well as the emergence of resistance to Pyrethroids in a clonal lineage of S. avenae, caused by a mutation (knock-down resistance; kdr) in the insecticide target membrane molecule. Therefore, with the loss of Neonicotinoids and Pyrethroids remaining the primary control option, it has been hypothesized that the incidence of Pyrethroid resistant grain aphids will rise, due to the favourable selection after spray application. In order to investigate the incidence of kdr- and BYDV- carrying grain aphids in post-Neonicotinoid Ireland, a two year field survey has been carried out in 50 fields in crop growing regions across the country. Our results indicate that both kdr and BYDV are widely present in Irish grain aphid populations, underlining potential future difficulties in controlling S. avenae, and subsequently BYDV, in years where weather conditions are favourable for aphid flight and where chemical control options are limited.

Alien vs. Herbivore: Ant-mediated plant defense as an option for biological control of leafcutter ants

Authors: Schulze-Sylvester Maria[1], Sylvester Francisco, Torres Víctor Manuel and Corronca José Antonio, [1]Geisenheim University, Germany

Abstract: Leafcutter ants are a major pest in vineyards in Argentina, but biological control methods have not been successful so far. The Argentine ant Linepithema humile (Mayr) is a common invader of vineyards worldwide and has a strong preference for carbohydrates. Sugary rewards can trigger ants to act as plant bodyguards against a wide range of herbivores. In a first 10-week field experiment, we attracted L. humile ants to a group of vines using sugar feeders, while empty feeders were used for a second group. Ant-excluded control plants were also deployed. We found that the leafcutter ant Amoimyrmex bruchi caused >90% leaf area reductions in vines without L. humile, while plants with L. humile were rarely attacked. In a second short field experiment, we evaluated the impact of L. humile on A. bruchi foraging behaviour. The presence of L. humile decreased A. bruchi's foraging activity and the amount of material transported by it. The development of biological control strategies that include the ecological services of ants as natural enemies of herbivorous pests could become a useful tool in sustainable viticulture and horticulture.

The insect Hermetia illucens: a sustainable source of molecules of high biological and economic value

Authors: Scieuzo Carmen[2], Falabella Patrizia[2], Franco Antonio[2], Triunfo Micaela[2], Schmitt Eric[1] and Salvia Rosanna[2], [1]Protix, [2]University of Basilicata

Abstract: The worldwide growing protein demand for farm animals breeding can no longer be satisfied by the intensive farms and the intensive use of agricultural land. Insect proteins can play an important role in the progressive substitution of proteins commonly used to feed animals, and prospectively in the progressive integration as novel food. Some insect species, such as the Diptera Hermetia illucens (BSF), can be reared on different types of organic waste, obtaining valuable secondary products: larvae/meal rich in protein and lipid, for aquaculture, poultry and pigs; chitin, exploitable in biomedical, pharmaceutical and agri-food fields; larval frass usable for crop fertilization. To study the effect of different substrates on insect growth, larval component and substrate reduction, 10000 larvae were reared on three byproducts from the agri-food chain (strawberry, tangerine, orange) and on a standard diet. The results highlight that BSF can successfully feed on all the tested substrates, although development time, growth rate, final larval biomass and larval components are affected by different substrates. The bioconversion process of agrifood by-products by BSF is a valid means for their valorization and for the sustainable production of alternative animal proteins and molecules of high biological and economic value, with a circular economy view.

Olfactory perception of Hermetia illucens: a source of inspiration for the development of new biosensors for the monitoring of agrifood products shelf life

Authors: Scieuzo Carmen[2], Falabella Patrizia[2], Salvia Rosanna[2], Vogel Heiko[1] and Persaud Krishna[3], [1]Max Planck Institute for Chemical Ecology, [2]University of Basilicata, [3]University of Manchester

Abstract: Insect physiology study at the molecular level and innovative technology implementation allows the development of applications useful to human. An example is the olfactory perception of Hermetia illucens, a saprophagous Diptera that has aroused interest for organic waste bioconversion. Females oviposit on decaying organic matter and larvae feed on it. Through RNAseq, de novo assembly and annotation of larval, male/female adult transcriptomes, we identified H. illucens Odorant Binding Proteins (OBPs) that mediate chemoreception of volatile organic compounds (VOCs) found in decaying substrates. We detected 15 HillOBPs expressed both in larvae and adults. The use of OBPs specific for organic decomposition VOCs are proposed as sensing layers of innovative Quartz-Crystal- Microbalances (QCMs) sensors, for monitoring food product preservation and shelf-life, in a new approach to food logistics. Affinities with 57 identified VOCs, emitted by different decomposing substrates colonized by H.illucens larvae, were calculated by molecular docking technique and were confirmed for 4 cloned, expressed and purified HillOBPs immobilized on a gold-layer of QCMs. These experiments provided useful information about biosensor selectivity, as the ability to discriminate ligands of different nature. Four compounds indicative of lipidic decomposition were detected with high affinity in a pool of VOCs, known to be spoilage markers.

Conditional female transformation for enhanced genetic control of New World screwworm and Australian sheep blowfly

Authors: Scott Maxwell[1], Arp Alex[2], Williamson Megan[1] and Yan Ying[1], [1]North Carolina State University, United States, [2]USDA-ARS, United States

Abstract: The New World screwworm and the Australian sheep blowfly are major pests of livestock. Screwworm and blowfly females lay their eggs in an open wound and the hatched larvae eat the animal alive. In addition to being a major animal welfare issue, economic losses from screwworm in South America were estimated in 2005 to be almost $4 billion annually. The goal of this project is to develop screwworm and blowfly strains for efficient suppression of screwworm populations in Uruguay through downregulation of the transformer (tra) gene. tra is essential for female development in screwworm and blowfly. An unidentified Y-linked male-determining gene (M) switches off tra in males. In females, tra switches the doublesex and fruitless genes into their “female-mode”, which leads to female development and behavior. Injection of double-stranded RNA into pre-blastoderm embryos led to females developing male characteristics. The conditional transformation strains carry two gene constructs. A driver expresses the tTA transcription factor. The effector is “tetO-traIR”, carries two copies of approx. 500-700bp region of the tra genes in inverted orientation. The transcribed RNA is self-complementary and forms a 500-700bp dsRNA. In the absence of tetracycline, tTA activates expression traIR, producing dsRNA that leads to degradation of tra mRNA and consequently females develop as males. An advantage of this approach compared to female-killing strategies, is that all eggs produced in a mass rearing facility develop as males.

Development and evaluation of modified strains of Drosophila suzukii for genetic suppression

Authors: Scott Maxwell[1], Yadav Amarish[1], Yamamoto Akihiko[2], Belikoff Esther[1], Li Fang[1], Bolz Kara[1] and Reid William[1], [1]North Carolina State University, United States

Abstract: Drosophila suzukii larvae are capable of infesting a wide range of host fruit but appear to be most significant pests in stone fruits (peach, cherry, and plum) and berries (caneberries, blueberries, and strawberries). As a compliment to existing approaches, we have been developing genetically modified strains of D. suzukii for population suppression. Several fs-RIDL strains have been made and evaluated. The strains are all based on the tetracycline transactivator (tTA), which binds very specifically to the tet operator sequence from bacteria. Binding is disrupted by the addition of tetracycline to the diet. The fs-RIDL strains produce only males on standard diet but females are fully viable and fertile on diet supplemented with tetracycline. We are currently evaluating the potential of the strains for population suppression in small cage experiments in containment.

Several Cas9-based genetic strategies have recently been proposed that could be more efficient, and thus less costly, than fs-RIDL. As a first step towards development of Cas9-based strains for population suppression, we have made transgenic strains that express Cas9 in the male and female germlines. The strains were evaluated by crossing to transgenic strains that express gRNAs that target the white and Sex lethal (Sxl) genes. The most active Cas9 lines produced a high proportion of white-eyed offspring after crossing with a white gRNA line. Crosses with Sxl gRNA lines produced female offspring that were sterile. This suggested a conserved role for Sxl in the female germline. The Cas9 strains could be used to evaluate homing gene drive constructs that target genes required for female development or fertility.

Opportunities and challenges for innovation in Aedes surveillance, control and disease prevention in a globally changing climate

Authors: Scott Thomas, University of California, Davis, CA, United States

Abstract: Although vector control is well documented as an effective strategy for prevention of mosquito-borne disease, the burden of several Aedes-transmitted diseases is increasing. It is reasonable to ask why vector control for those viral infections not been effective more often? Unsuccessful programs are often attributed to a lack of resources, lack of political will or ineffective implementation. Also responsible, however, are deficiencies in understanding vector ecology and pathogen transmission, methods for assessing and responding to risk, failure to use existing knowledge and surveillance for control decisions, and a changing global climate. In brief, concepts in disease prevention remain incompletely defined and underutilized. Current dengue prevention emphasizes universal surveillance and control, which has stifled development of a conceptual and factual foundation for adaptive disease management. There is an urgent need for a new framework for surveillance and intervention that (1) better defines relationships between measures of risk and human infection and (2) uses that information to direct public health measures that prevent disease. In this talk I will explore enhancing Aedes-transmitted disease prevention with locally adaptable tools and strategies that account for heterogeneities in transmission.

High Quality Genomic Resources for Stored Product Insects to Improve Integrated Pest Management Tactics

Authors: Scully Erin[1], Sim Sheina[4], Geib Scott[3] and Childers Anna[2], [1]USDA Agricultural Research Service, United States, [2]USDA-ARS Beltsville Agricultural Research Center, United States, [3]USDA-ARS Daniel K. Inouye U.S. Pacific Basin Agricultural Research Center, United States, [4]USDA-ARS Daniel K. Inouye US Pacific Basin Agricultural Research Center, Tropical Crop and Commodity Protection Research Unit, Hilo, Hawaii, United States

Abstract: Stored product insects threaten global food security by causing millions of dollars of losses post-harvest around the globe. Although tactics, such as mating disruption, fumigation, and sanitation provide successful control of these insects in many environments, resistance to insecticides and fumigants and tolerance to cold to mating disruption have been observed in field populations, necessitating the development and diversification of integrated pest management tactics in this system. Until recently, the only genome assembly available for this diverse group of insects was Tribolium castaneum (red flour beetle) and challenges including cost, heterozygosity, and DNA input impeded the advancement of these resources for species. However, long-read assemblies generated from low DNA input on the PacBio instrument for six different families of stored product insects through USDA's AgPest100 initiative are allowing us to release resources for this important group of insects at an unprecedented scale and obtain a glimpse into the genetic factors that enable these pests to adapt to management tactics and survive inhospitable conditions, including cold temperatures and lack of food resources. Overall, these resources will allow us to look for common resistance tactics among this diverse group of insects and also common genetic features that could be used to manage many species of stored product insects simultaneously.

Generation of genomics resources for the meadow spittlebug Philaenus spumarius

Authors: Seabra Sofia[1], Mathers Thomas[4], Biello Roberto[3], Carina Neto Ana[2], Sofia Rodrigues Ana[1], Teresa Rebelo Maria[2], Paulo Octavio[1], Liu Qun[3], Mugford Sam[3] and Hogenhout Saskia[4], [1]Centre for Ecology, Evolution and Environmental Changes (cE3c), Departamento de Biologia Animal, Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal, [2]Centre for Environmental and Marine Studies (CESAM), Departamento de Biologia Animal, Faculdade de Ciências, Universidade de Lisboa, Lisbon, Portugal, [3]Department of Crop Genetics, John Innes Centre, Norwich Research Park, Norwich, United Kingdom, [4]John Innes Centre, United Kingdom

Abstract: Philaenus spumarius (Linnaeus, 1758) and other spittlebug species (order Hemiptera) are xylem-feeding insects that vector the bacterial pathogen Xylella fastidiosa, which has caused dramatic declines of a wide variety of plant species and most recently destroyed the olive production industry in southern Italy. Spittlebugs were not considered major threats to agriculture in Europe before the discovery that they are able to transmit X. fastidiosa. P. spumarius is native to the Palearctic regions, and was unintentionally introduced in other regions, e.g. USA and New Zealand. The insect quickly adapts to new environments, and may be considered invasive. As a first step to improve our knowledge of the evolution and genomics of this species, we generated a draft assembly of the 2.7 Gb genome of P. spumarius. The assembly has a scaffold N50 length of 120Kb with the longest scaffold of ~4 Mb and a high (2.3%) heterozygosity level. Annotation of the genome revealed a highly repetitive genome and presence of 97% of conserved genes among arthropods suggesting a complete genome assembly. The assembly of the genome of a second froghopper species, Aphrophora salicina, revealed a genome size of 2.3 Gb. This assembly had a scaffold N50 length of 625Kb with the longest scaffold of ~5 Mb and a lower (0.7%) heterozygosity level.

We started to generate genome assemblies of other 16 potential vector of X. fastidiosa as well. In the future these will form the basis of comparative genome analyses to assess differences between phloem and xylem feedings insects within Hemiptera. They will also allow assessing the population structure and putative dispersal of these species between host plants. This research is part of a larger UK-government funded collaborative project (named BRIGIT; https://www.jic.ac.uk/brigit) and all genome sequence data and annotations generated in this project will be made freely available via http://sapfeederhub.jic.ac.uk/.

Male-biased sex-ratio of the meadow spittlebug, Philaenus spumarius (Hemiptera: Aphrophoridae) detected in forest populations of Turkey.

Authors: Seabra Sofia[2], Yurtsever Selcuk[1], [1]Biology Department, Science Faculty, Trakya University, Turkey, [2]Centre for Ecology, Evolution and Environmental Changes) Faculdade de Ciências, Universidade de Lisboa, Portugal

Abstract: Recent data obtained from some natural populations of Turkey for Philaenus spumarius are presented here. Preliminary results showed that the adult proportions of males were extremely high, compared to females particularly in autumn samples. The percentage of males in some samples increased up to 90%, and has usually been around 80%. This is a quite the reverse situation to many European and North American populations where the frequency of males are in highest early in the season due to slightly earlier average emergence in adult form and that they slowly decline as a proportion of populations toward and into fall. Mechanisms playing role on this male-biased sex-ratio need to be investigated in future studies, namely the effects of temperature on differential hatching and development between male and females; or the presence of endoparasites or endosymbionts, which are known to affect population sex ratio, although most usually they cause a female-biased ratio. Also, the impact of this sex-ratio distortion on the population dynamics should be addressed. Understanding this system may provide important data to incorporate in risk assessment models for the transmission of the plant pathogen Xylella fastidiosa by this known insect vector in Europe.

Identification of novel RNAi targets to control brown marmorated stink bugs (Halyomorpha halys) using proteomics

Authors: Sébastien Alexandra[2], Scott-Dupree Cynthia[2], J. Foster Leonard[1] and Stoynov Nikolay[1], [1]University of British Columbia, Canada, [2]University of Guelph, Canada

Abstract: Originally from East Asia, and now established in Europe and North America, brown marmorated stink bugs (Halyomorpha halys; BMSB) are an invasive pest that causes severe damage to an extensive number of crops. While generalist chemical controls are failing to meet growers' needs, RNA interference (RNAi) has shown remarkable potential in killing most of the treated individuals by disrupting the expression of specific target genes. Further development of dsRNA to target multiple genes can allow the rotation of treatments in the field, and avoid building resistance in the BMSB populations, thus insuring a potential long-term usage of RNAi to control BMSB. To do so, we have analysed the proteins present in all the different BMSB life stages (from eggs to adult, both males and females) using a Tims TOFF mass spectrometer and the MaxQuant program. We present here the results of our data analysis on the differences in protein profiles between stages, and highlight which pathways are especially enriched. Furthermore, we discuss novel potential targets for RNAi, which could affect most stages, and that we are planning to validated in vivo. This research is the first step to support the development of an efficient, multi-target RNAi control for BMSB.

Species-selective agonists of juvenile hormone receptor signaling

Authors: Sedlak David[5], Jindra Marek[2], Kolla Jayprakash[3], Tumova Sarka[1], Milacek Matej[4], Bittova Lenka[1], Muthu Magesh[3], Lisova Michaela[3] and Martinkova Olga[3], [1]Biology Center, CAS, [2]Biology Centre CAS, Czech Republic, [3]CZ-OPENSCREEN, Institute of Molecular Genetics, Czech Academy of Sciences, [4]Faculty of Science, University of South Bohemia, [5]Institute of molecular genetics AS CR, Czech Republic

Abstract: Diverse synthetic compounds mimic juvenile hormone (JH) effects and are used to disrupt insect development as pesticides of the insect growth regulator (IGR) class. Juvenoid IGRs are agonists of the JH receptor (JHR). However, current IGRs have poor selectivity towards target pest species. To discover selective JHR agonists, we performed automated, high-throughput chemical screening, initially in a Drosophila cell line carrying a JHR-dependent transcriptional reporter. Primary hits were validated through follow-up assays including ligand-receptor binding, dimerization of the JHR subunits, and effects on developing insects. This campaign uncovered novel compounds with JHR agonist activities exceeding those of a reference juvenoid methoprene. To identify species-selective juvenoids, we devised cell-based reporter systems utilizing JHR proteins from several target insects. Hits from high-throughput chemical screens were further diversified, yielding potent agonists, some of which preferentially activated JHRs of particular insects. When tested in vivo, the discovered compounds blocked metamorphosis of target species. These results demonstrate feasibility of our approach toward discovery of novel and selective JHR agonists for potential use as research tools and eco-friendly means of pest control.

Supported by grant 20-05151X (Czech Science Foundation) and project LM2018130 (MEYS) to the National Infrastructure for Chemical Biology CZ-OPENSCREEN.

Lessons learned: Biological control of eastern spruce budworm in Canada

Authors: Seehausen Lukas[1], Régnière Jacques[2] and M. Smith Sandy[3], [1]CABI, Switzerland, [2]Canadian Forest Service, Canada, [3]University of Toronto, Canada

Abstract: The eastern spruce budworm (SBW) Choristoneura fumiferana (Lepidoptera: Tortricidae) is the most important forest defoliator in eastern North America. Because of the important economic losses to the forest industry, many attempts to decrease SBW population levels or to protect trees from defoliation during outbreaks have been undertaken, using various methods such as chemical and biological insecticides, mating disruption or biological control.

Most of the attempts of biological control were intentional introductions of natural enemies, also called classical biological control (CBC), using mainly species from Europe but also parasitoids from C. occidentalis from western Canada (relocations). However, none of the CBC attempts against SBW are regarded as successful. Augmentation of native species as biological control agents has been attempted with a few natural enemies such as the egg parasitoid Trichogramma minutum (Hymenoptera: Trichogrammatidae) being by far the most prominent and successful example. Several other augmentative programs have been attempted although they remain hidden in the gray literature. As with many pests, conservation biological control is often mentioned by authors but has received very little attention in practice, and the same is true for integrative pest management (IPM) approaches.

The review of biological control attempts against SBW in Canada has many valuable lessons to teach us about the applicability of this pest management approach against outbreaking defoliators. For example, it highlights the relative lack of success that CBC has had against indigenous pests, in contrast to the augmentation of native natural enemies where there has been some measure of effective control. Opportunities for the future of SBW management can also be identified in review. With new ecological insights (e.g. density-dependence of parasitism of T. minutum) and new techniques (e.g. UAVs and rearing techniques), the efficacy of biological control could be increased and overall costs decreased. Given the recent focus on early intervention strategies, IPM approaches that include biological control as a management option should be considered.

Potential impact of climate change on an important parasitoid of a North American outbreaking forest defoliator

Authors: Seehausen Lukas[1], Cusson Michel[3], Martel Veronique[4] and Régnière Jacques[2], [1]CABI, Switzerland, [2]Canadian Forest Service, Canada, [3]Laurentian Forestry Centre, Natural Resources Canada, Quebec City, QC, Canada, [4]Natural Resources Canada, Canada

Abstract: Choristoneura fumiferana (Lepidoptera: Tortricidea), the spruce budworm (SBW), is the most important outbreaking defoliator in conifer forests of northeastern North America. The SBW food-web has five trophic levels including almost 100 species of parasitoids. Different species of natural enemies have different abundances and impacts depending on the outbreak phase. For example, the multivoltine Tranosema rostrale (Hymenoptera: Ichneumonidae) is the most important species during the extended period between outbreaks while other univoltine species such as Glypta fumiferanae (Hymenoptera: Ichneumonidae) and Apanteles fumiferanae (Hymenoptera: Braconidae) are more important during the rise in population density.

Models predict that climate change will impact the distribution and severity of SBW outbreaks. However, its impact on the interaction between the budworm and its natural enemies is not clear. A research project on T. rostrale showed that its overall performance was greatly reduced at high temperatures. Further experiments have shown that the underlying mechanisms involve both a downregulation of the parasitoid's polydnavirus gene transcription and an enhancement of host immunity gene transcription. Physiological experiments confirmed an increased encapsulation activity in SBW larvae at high temperature. In accordance with these results, a temperature-dependent individual-based model predicts that regions of higher T. rostrale performance shift northwards under a climate warming scenario.

What makes a good natural enemy for classical biological control of arthropods?

Authors: Seehausen Lukas

Abstract: Criteria that are used to select parasitoids and predators for classical biological control are mainly based on two characteristics: their ability to control the pest in the area of origin or in other areas of introduction and their host or prey specificity to prevent non-target effects. Beyond this, selection criteria are traditionally focused on particular biological traits of natural enemies that are thought to favour establishment of the agent and target control. But statistical analyses show that few of these traits actually influence the outcome of classical biological control. Therefore, the criteria should also focus on target traits and more consideration is needed for issues such as climate suitability, the composition of the natural enemy complex in the region of introduction, and the occurrence of sibling species or biotypes with specific attributes. The increasing use of integrative characterization of insects, i.e. the combination of morphological and genetic taxonomic tools with biological and ecological studies to investigate inter- and intra-specific differences of insects, has become an important tool to select better biological control agents. However, to validate these criteria and improve risk assessments, it is paramount to conduct post-release studies, which are unfortunately still rather uncommon in insect biological control.

Arthropod decline in grasslands and forests is associated with landscape-level drivers

Authors: Seibold Sebastian[2], Gossner Martin. M.[11], Penone Caterina[5], Ammer Christian[7], Prati Daniel[5], Ambarli Didem[4], Schulze Ernst-Detlef[1], Habel Jan-Christian[9], Vogt Juliane[4], Bauhus Jürgen[6], Müller Jörg[10], E. Linsenmair Karl[10], Fischer Markus[5], Simons Nadja[3], Bluethgen Nico[3], Schall Peter[7], Wöllauer Stephan[8], Nauss Thomass[8] and W. Weisser Wolfgang[4], [1]Max-Planck Institue Jena, Germany, [2]Technical University of Munich, Germany, [3]TU Darmstadt, Germany, [4]TU Munich, Germany, [5]University of Bern, Switzerland, [6]University of Freiburg, Germany, [7]University of Göttingen, Germany, [8]University of Marburg, Germany, [9]University of Salzburg, Austria, [10]University of Würzburg, Germany, [11]WSL, Switzerland

Abstract: Recent reports of local extinctions of arthropod species1, and of massive declines in arthropod biomass, point to land-use intensification as a major driver of decreasing biodiversity. However, to our knowledge, there are no multisite time series of arthropod occurrences across gradients of land-use intensity with which to confirm causal relationships. Moreover, it remains unclear which land-use types and arthropod groups are affected, and whether the observed declines in biomass and diversity are linked to one another. Here we analyse data from more than 1 million individual

arthropods (about 2,700 species), from standardized inventories taken between 2008 and 2017 at 150 grassland and 140 forest sites in 3 regions of Germany. Overall gamma diversity in grasslands and forests decreased over time, indicating loss of species across sites and regions. In annually sampled grasslands, biomass, abundance and number of species declined by 67%, 78% and 34%, respectively. The decline was consistent across trophic levels and mainly affected rare species; its magnitude was

independent of local land-use intensity. However, sites embedded in landscapes with a higher cover of agricultural land showed a stronger temporal decline. In 30 forest sites with annual inventories, biomass and species number—but not abundance—decreased by 41% and 36%, respectively. This was supported by analyses of all forest sites sampled in three-year intervals. The decline affected rare and abundant species, and trends differed across trophic levels. Our results show that there are widespread declines in arthropod biomass, abundance and the number of species across trophic levels. Arthropod declines in forests demonstrate that loss is not restricted to open habitats. Our results suggest that major drivers of arthropod decline act at larger spatial scales, and are (at least for grasslands) associated with agriculture at the landscape level. This

implies that policies need to address the landscape scale to mitigate the negative effects of land-use practices.

Diplurans, the forgotten soil-cave-organisms

Authors: Sendra Alberto, Research Team on Soil Biology and Subterranean Ecosystems. Department of Life Sciences. Faculty of Science. University of Alcalá (UAH).Spain

Abstract: Diplurans are basal terrestrial hexapods equipped with tracheal system, devices for indirect transfer of spermatophores, and remnants of Malpighian tubules. They can be considered as one of the first land colonizers most likely in the Early Ordovician. Their morphology and behaviour reveal a primitive life link to cryptic subsurface habitats in soil and cave ecosystems at up to one thousand meters depth, not far from the limit of terrestrial fauna. In spite of their phylogenetic interest and importance as part of the soil and also cave community, diplurans receive little attention in research and they have been almost forgotten about in scientific literature. However, diplurans play a part in their own neglect, especially with regard to their important role in the trophic chains. Ecological studies in soil and cave environments largely ignore diplurans mainly because of taxonomic difficulties, such as the distinction of genera and species by few sophisticated characters. Fortunately, these tiny differences were masterly managed thanks to a handful of forward-thinking taxonomists (Filippo Silvestri, Bruno Condé, Jean Pagés, among others) who advanced the description of globally about 1000 species to date. Nowadays, scanning electron microscopic studies of cuticle surface or sensilla join with advances in molecular analysis help us to build a more natural phylogeny in diplurans, a necessary tool to understand the dipluran distribution areas and resolve biogeographical and paleobiogeographical questions. Diplurans display many more trophic levels than other groups of soil arthropods and include herbivores (Parajapygidae, Octostigmatidae), zoophages (Projapygidae, Campodeidae), detritivores (Campodeidae) and also top carnivores (Japygidae, Heterojapygidae). Six of seven dipluran species live in unconsolidated materials in soils from O to C horizons. Although having little capacity to excavate, diplurans are able to move through small spaces left behind by roots or holes made by other soil animals. But diplurans, mainly Campodeids flourish in cave ecosystems, in all kind of caves in limestone to volcanic rocks. Turning to the fields of anatomy and biological studies, great advances have been made in aspects such as internal and external morphology including sensorial equipment and glands involved in the moulting process, growth and reproduction cycles (Camille Bareth among others). The prospects for future research in all fields are exciting, potentially including genetics for phylogenetic studies to better understand the amazing tiny anatomical structures involved in the survival of these primitive terrestrial animals in the subsurface of the Earth.

DNA metabarcoding revealed expected but also some exceptional prey species in the diet of carabid beetles in Mediterranean agriculture

Authors: Šerić Jelaska Lucija, University of Zagreb, Faculty of Science, Croatia

Abstract: Carabids are mainly predatory beetles but still certain proportion of them are omnivores and herbivores. Since they feed on pest insects and weeds and being abundant among the soil-active arthropods capable of consuming close to their body mass of food daily, carabids are considered important within the agroecosystem food webs. The DNA metabarcoding as one of the state-of-the-art methods for depicting trophic interactions were used to evaluate the ecosystem services of carabids within Mediterranean vineyards and olive orchards in Croatia, under Integrated Pest Management (IPM) and Ecological Pest Management (EPM). Carabids were collected at five sites including unmanaged site, and subdued to the molecular gut content analyses using NGS. After dissection, DNA from the gut content was extracted and amplified using general and newly designed carbide-exclusion primers within COI gene, and successfully sequenced. Here we present the results of trophic interactions in respect of carabids potential to feed on agricultural pests but also on overall diversity that was discovered by eDNA. High diversity of invertebrates within their gut content, intraguild predation and plant DNA were revealed. The results support the use of agricultural measures to promote higher biodiversity in the Mediterranean, and to sustain natural enemies of crop pests.

From bee hives to farm lands: promoting pollinator health and sustainability

Authors: Seshadri Arathi, USDA ARS/WRRC Invasive Species and Pollinator Health Unit Davis CA, United States

Abstract: Pollinator populations have been facing several debilitating challenges for several decades now. These challenges include intensification of agricultural practices, habitat degradation, increased need for migratory honey bee colonies, indiscriminate use of agrochemicals, and pests and diseases. Simple but effective management practices including reinstating habitat diversity around farmlands, integrated hive management, minimizing and using agrochemicals appropriately while increasing nutritional diversity for pollinators have played a significant role in improving pollinator health and sustainability. Farm management practices promoting pollinator diversity and abundance include planting pollinator habitats along margins of fields growing herbicide tolerant crops, incorporating pollinator-friendly forbs into cover crop mixes and retiring sensitive farmland from agricultural practices and restoring them into natural habitats. Urban areas considered as bee diversity hotspots can foster native pollinator populations through the actions of interested citizens enthusiastic to promote and protect bee-friendly habitats. Lastly, improving the health of honey bees, the most efficient of pollinators, happens by improving the overall nutritional status, which is a product of the availability of important dietary resources in the environment and the physiological capacity of bees to harvest these resources. Migratory beekeeping, where honey bee colonies are placed in fields needing pollination for successful fruit production has placed a lot of strain on honey bees as they are exposed to pollen and nectar from a single crop for a brief period before moving onto a different crop field. Hives are likely to experience shortages of certain nutrients or exposure to certain potentially toxic phytochemicals, depending on the crop they are pollinating. Developing targeted solutions towards the betterment of colony nutrition even as hives are pollinating crops ensures healthy colonies for continued pollination services to the farming community. This is also important for other commercial pollinators including bumblebees and leaf-cutter bees. Results from our ongoing research on these topics will be presented and the implications of our findings on pollinator health and sustainability will be discussed.

Potential role of radiation hormesis in augmenting biorational pest suppression approaches against a serious polyphagous pest, Spodoptera litura (Fabr.) [Lepidoptera: Noctuidae]

Authors: Seth Rakesh Kumar[2], Sengupta Madhumita[1], Vimal Neha[1], Angmo Nilza[1] and Seth Ranjana[1], [1]Applied Entomology and Radiation Biology Unit, Department of Zoology, University of Delhi, India, [2]Department of Zoology, University of Delhi, India

Abstract: Radiation hormesis is a phenomenon using very low level of ionizing radiation for stimulating the various behavioural and physiological activities of organisms. This property of radiation hormesis can be exploited in various biorational approaches of insect pest control. Biological responses to ionizing radiation often conform to a 'linear-no-threshold' (LNT) model, which predicts that the degree of damage scales linearly with the irradiation dose. Generally, the radiation exposure is well documented to have a range of negative effects on cellular, developmental and behavioral traits. However, a considerable evidence supports an alternative model known as hormesis, in which low-level stress (radiation) exposures can have beneficial or stimulatory effects on biological performance even though the higher levels are inhibitory. Although the hormetic dose–response relationships have been documented across broad phylogenies (bacteria to mammals), radiation hormesis has rarely been studied in a life history framework of insects. Understanding the fitness-related influence of radiation may be important in augmenting certain biological based insect control tactics. Radiation hormesis using gamma radiation from Co-60 Teletherapy unit was studied in various pre-imaginal stages of a tropical pest, Spodoptera litura (Fabr.) in order to stimulate the insect's physiological system. In the initial phase, low doses, 0.25-1.25Gy, were evaluated on 0-1 day old eggs, third instar larval stage (L3) and 2-3 day old pupa in terms of growth index and adult behaviour (survival and mating success), with an aim to rearing the quality moths. The results indicated the potential hormetic gamma doses as 0.75 Gy and 1.0 Gy for egg, 1.0 Gy for L3 and 1.0 Gy for pupa. These hormetic doses enhanced the longevity of moths and increased their mating success. In the next phase, the irradiated adults derived from preimaginal ontogenic stages, having absorbed hormetic radiation, were examined to show better survival and more insemination rate at the sub-sterilizing dose (130 Gy) proposed for the F1 sterility technique. Further, the study on influence of the hormetic radiation (given in juvenile development) on the reproductive fitness and the expression of certain physiologically vital genes (associated with survival, antioxidant defense and reproduction) related to substerile male parents and their F1 progeny is in progress.

Also, the low gamma dose range of 1.25 -1.5 Gy administered to the dauers of entomopathogenic nematodes (EPNs), Steinernema glaseri and S. thermophilum against host larvae of S.litura induced faster host mortality and enhanced parasitoid proliferation.

The radiation hormesis may play a positive role in augmenting radiation mediated F1 sterility technique (parabiological tactic) and classical biological control methods. Further, the multifaceted role of radiation hormesis is discussed in augmenting various biorational pest suppression approaches and improving the quality of useful insects.

Creation of new industrial sericulture using genetically modified silkworms

Authors: Sezutsu Hideki, 1) Transgenic Silkworm Research Unit, Institute of Agrobiological Sciences, National Agriculture and Food Research Organization (NARO) 2) Department of Integrat

Abstract: Recently, a new industrial sericulture has been developing using genetically modified silkworms (transgenic silkworms). An innovative method for generating transgenic silkworms was established in 2000, and since the epoch-making technological development, long-standing efforts have succeeded in developing novel silks that enable the manufacture of new textile materials or regenerative medical uses. Furthermore, a new system of recombinant protein production has been developed successfully. As a novel silk, the fluorescent silk has been developed by fusing the fibroin with the fluorescent protein. Using the fluorescent silk, some trial products, such as a silk dress, have been made. Another modified silk, spider silk, has been developed incorporating a gene from a spider species encoding a dragline protein. A silk for improving the adhesive abilities or the growth of cells was also constructed. Using the silks, an artificial blood vessel and the sponge sheet has been made. In a system for producing recombinant proteins in the sericin layer of the silk, transgenic silkworms have been shown to produce a wide variety of biologically active proteins, including antibodies, enzymes and so on for cosmetic, pharmaceutical and medical applications. Some of these recombinant proteins for cosmetic products and diagnostic pharmaceuticals have been in commercial use since 2011. Moreover, a clinical trial of antibody drug will be performed in the next few years. For the mass production of new the new silks or recombinant proteins using transgenic silkworms, the regulations for the handling of genetically modified organisms should be followed. In Japan, rearing with prevention of the dispersal of transgenic silkworms (type 2 use) and rearing without preventing their dispersal (type 1 use) are both in use. Rearing by the measure of type 2 use is already established for the practical production of recombinant proteins by several companies. For the establishment of the protocol of type 1 use, several transgenic silkworm strains producing recombinant silk has been reared in a limited area to assess its impact on the biodiversity. In 2017, a silk-raising farmer Japan began rearing transgenic silkworms that produce green fluorescent silks, according to the protocol of type 1 use. In addition, a company developed a new mass rearing apparatus for transgenic silkworms. Another company completed a large-scale year-round aseptic sericulture plant. Thus, a new industrial sericulture using transgenic silkworms has already begun.

Thermal tolerance mediates predator-prey interactions to determine elevation distributions of mayflies

Authors: Shah Alisha A.[2] and K. Ghalambor Cameron[1], [1]Colorado State University, United States, [2]University of Montana, United States

Abstract: Temperature is often implicated as a primary mechanism driving species turnover across elevation gradients. The modified climate variability hypothesis proposed by Janzen (1967), posits that the seasonal temperature variation experienced across temperate mountains should favor the evolution of species with broad thermal tolerances, greater dispersal ability, and wider elevation range sizes. On the other hand, tropical mountain species should evolve narrower thermal tolerances in response to stable temperatures, restricted dispersal across elevation, and narrower range limits. Previously, we demonstrated that tropical aquatic insects from the Ecuadorian Andes have narrower thermal breadths (CTmax – CTmin) and lowered acclimation ability compared to their temperate relatives from the Colorado Rocky Mountains. However, thermal breadth alone does not adequately explain the abrupt cessation of one species' occurrence and the beginning of another's in certain streams sites. We therefore propose that important biotic interactions, such as predation, mediated by temperature, may play a role in determining mayfly elevation range limits, and explain the observed pattern of species turnover. We tested this hypothesis in the temperate and tropical systems by artificially simulating range expansions of low elevation mayflies to high elevation streams and high elevation mayflies to low elevation streams, in a lab setting. "Transplanted" mayflies were exposed to suboptimal temperatures in the presence of native stonefly predators. Survival of transplanted mayflies was measured after 24h and compared to that of native mayflies in the same testing arena. We predicted that transplanted mayflies would be preyed upon more heavily than native mayflies because lowered performance in response to suboptimal temperatures would exacerbate their susceptibility to the predators. We also predicted that this effect would be stronger in the tropical Andean species where thermal breadths are even narrower. Temperatures are rising at an unprecedented rate in mountain streams, which are some of the most biodiverse ecosystems in the world. The effects of warming may be especially bad in tropical mountain systems where species are more thermally sensitive. To better predict how aquatic species will respond to changing temperature, it is imperative for us to gain a mechanistic understanding of how temperature affects distributions of resident taxa, and how tolerance to temperature shapes the outcome of interactions among species in freshwater communities.

Use of DNA Barcodes to identify invasive Spodoptera frugiperda (Noctuidae: Lepidoptera) species in Pakistan

Authors: Shahbaz Ahmad, Department of Entomology

Abstract: Spodoptera frugiperda (Noctuidae: Lepidoptera) is the most damaging agricultural pest which has invaded Asian countries in recent years. The current investigation confirms the occurrence of fall armyworm in Pakistan and discusses its phylogenetic relationship with S. litura and S. exigua. The cytochrome c oxidase subunit I (COI) gene, ‘‘a universal barcoding region’’ of FAW having 650 bp, was isolated using specific primers. Maximum likelihood phylogenetic analysis of S. frugiperda, S. exigua, S. litura, and many others revealed significant variations among the sequences. S. frugiperda showed intraspecific disparities with reference to different geographical locations. Multiple sequence alignment presented similarities and differences found between the barcodes of the three pest species. The study proves the utility of the COI barcoding region for the identification and discusses phylogenetic interrelations existing between the pest species.

Characterization of CYP18A1 a key steroid hormone inactivation, is essential for metamorphosis in Chilo suppressalis.

Authors: Shahzad Muhammad Faisal, Gomal University

Abstract: Juvenile and ecdysteroids hormones are key regulators in insects development and metamorphosis. Regulatory processes must be precisly timed in insects development to ensure appropriate cell growth and differentiation at each defined life-stage. Major developmental transition are triggered by steroid hormones for coordination molting and metamorphosis. In contrast, less is known in ecdysteroids inactivation in in the lepidopteran species. Here we reported the ecdysteroid agonist-responsive cytochrome P450, CYP18A1 in rice striped stem borer, Chilo suppressalis. Prompting our hypothesis it exerts ecdysteroids inactivation action those reported in other insect species. We amplified full length of Chilo suppressalis CYP18A1by rapid amplification of cDNA ends. Temporal and spatial expression pattern of CYP18A1 showed that it was predominantly expressed in the midgut during wandering and early pupal stage like other lepidopteran model insects. RNAi knockdown of CYP18A1 resulted in pupal lethality, suggesting essential role of ecdysteroid inactivation for proper pupal development. Thus our results strongly suggest that CYP18A1 is involved in steroid hormones inactivation in rice striped stem borer, Chilo suppressalis, as seen in other species.

The black soldier fly (Diptera: Stratiomyidae: Hermetia illucens) as a natural enemy reducing pest populations from agricultural wastes

Authors: Shaltiel-Harpaz Liora, MIGAL- Galilee Research Centre, Israel, and Dept of Environmental Sciences, Tel Aviv University, Israel

Abstract: In Israel, tons of agricultural plant wastes are produced annually, mostly handled in an environmentally inconsiderate way, becoming a source of area-wide reinfestation of pests. In this study, we investigated the ability of the BSF larvae to treat three types of agricultural wastes, and to reduce their pest populations: apples, tomatoes and mushrooms. Apples left in the orchards after picking are a source of the Mediterranean fruit fly Ceratitis capitata. Tomato plants are the provenance of Tuta absoluta infestations. Mushroom-growing wastes are the origin of the phorid fly Megaselia haltera spreading. In laboratory experiments, we compared the pest populations that emerged from wastes treated and untreated by BSF, with and without pretreatments. The results indicate that BSF larvae significantly reduced C.capitata adults' emergence from apples, as long as the fruits were cut. BSF also significantly diminished T.absoluta emergence from tomato leafs. Forid fly population on the other hand was not significantly different than control treatment. Using Drosophila fly as a model we have found that BSF larvae can reduce Drosophila population by entomophagy of eggs and larvae but not pupae. We conclude BSF, can be successful as a part of Integrated Crop Management reducing both waste biomass and pest populations.

Photochromic insecticides for spatiotemporal modulation of ion channels
