Abstract: Photopharmacological ligands provide a powerful way for optical control of the activity of a molecule, which will facilitate better understanding of toxicological mechanism. By blending of photoswitchable azobenzene or dithienylethene with nAChR agonists neonicotinoids, GABAR antagonist fipronil and RyR modulator diamides, we prepared series of photochromic ligands (PCLs) acting on insect nAChRs, GABARs or RyRs. Some PCLs showed different insecticidal activity before and after light irradiation. These PCLs were then used to optically control over the insect nAChRs (sodium channel), GABARs (chloride channel), RyRs (calcium channel), neurons and insect behavioral responses of mosquito larvae (Aedes albopictus) and cockroach (Periplaneta americana).

Using entomopathogenic nematode pheromones and group behavior to improve biocontrol

Authors: Shapiro-Ilan David[5], Oliveira-Hofman Camila[6], Lewis Ed[1], Kaplan Fatma[3], T. Alborn Hans[4] and Schliekelman Paul[2], [1]1Department of Entomology, Plant Pathology and Nematology, University of Idaho, Moscow, ID, United States, [2]Department of Statistics, University of Georgia, Athens, GA, United States, [3]Pheronym, Inc., Davis, CA, United States, [4]USDA-ARS CMAVE, Gainesville, FL, United States, [5]USDA-ARS, SEA SE Fruit and Tree Nut Research Unit Byron, GA, United States, [6]USDA-ARS, Southeastern Fruit and Tree Nut Research Lab, Byron, GA, United States

Abstract: Entomopathogenic nematodes are used to control a wide variety of economically important insect pests. However, field efficacy can be inconsistent. The ability of a nematode to find and infect (invade) a host insect is critical to successful pathogenesis. Thus, elucidating mechanisms that enhance nematode dispersal and infectivity will lead to improved efficacy. We discovered that entomopathogenic nematodes move in groups, like a pack of wolves seeking their prey. We also discovered that the nematodes produce ascaroside-based pheromones that induce dispersal and infectivity. In laboratory and greenhouse experiments, biocontrol efficacy against target pests was substantially increased when entomopathogenic nematodes were exposed to these pheromones. New research will expand upon these findings.

Mapping of inversion breakpoints on the X chromosome in the Maculipennis subgroup of malaria mosquitoes

Authors: Sharakhov Igor[2], Artemov Gleb[1] and Soboleva Evgenia[1], [1]Tomsk State University, Russia, [2]VirginiaTech, United States

Abstract: Closely related species of malaria mosquitoes often have fixed chromosomal inversions. Anopheles messeae Fall. belongs to the Palearctic Maculipennis subgroup with large areal and well-developed inversion polymorphism. An. messeae diverged from the An. maculipennis around 2 million years ago and has at least one fixed inversion in the 3R arm. However, the number and locations of fixed inversions on the X chromosome have not been determined. Here we developed 32 DNA-probes based of the An. atroparvus reference genome and hybridized them with polytene chromosomes of An. messeae. We mapped four breakpoint regions (BP) of the X chromosome inversions fixed between An. messeae and An. atroparvus/An. maculipennis, and which divided the X chromosome into five synteny blocks. LTR retrotransposons from Gypsy, BEL and Copia families were most abundant in BP. Polymorphic inversions X2 and X0 do not reuse the BP with exception of the proximal BP, which can be involved in X2. Reconstruction of the rearrangement events based on the synteny blocks order and direction using GRIMM-MGR, demonstrated that the X1 chromosome of An. messeae could have originated by two sequential inversions, one of which is nested into another one. The X1 arrangement is likely ancestral because it differs from An. maculipennis by only two inversions, which do not correspond to polymorphic inversions in An. messeae/An. daciae. Thus, studying chromosome evolution is a useful approach for understanding historic relationships among closely related species of malaria mosquitoes. The study was supported by the Russian Science Foundation grant № 21-14-00182 to I.V.S.

Unraveling the 3D genome of human malaria vectors

Authors: Sharakhov Igor[3], Tyapkin Alexander[1], Nuriddinov Miroslav[1], Battulin Nariman[1], Belokopytova Polina[1], Lukyanchikova Varvara[2] and Fishman Veniamin[1], [1]Institute of Cytology and Genetics, Novosibirsk State University, Russia, [2]Novosibirsk State University, Novosibirsk, Russia, [3]VirginiaTech, United States

Abstract: Chromosomes are hierarchically folded within cell nuclei into territories, domains and subdomains, but the functional importance and evolutionary dynamics of these hierarchies are poorly defined. Here, we comprehensively profile genome organizations of five Anopheles mosquito species and show how different levels of chromatin architecture influence each other. Patterns observed on Hi-C maps are associated with known cytological structures, epigenetic profiles, and gene expression levels. Evolutionary analysis reveals conservation of chromatin architecture within synteny blocks for tens of millions of years and enrichment of synteny breakpoints in regions with increased genomic insulation. However, in-depth analysis shows a confounding effect of gene density on both insulation and distribution of synteny breakpoints, suggesting limited causal relationship between breakpoints and regions with increased genomic insulation. At the level of individual loci, we identify specific, extremely long-ranged looping interactions, conserved for ~100 million years. We demonstrate that the mechanisms underlying these looping contacts differ from previously described Polycombdependent interactions and clustering of active chromatin.

A chromosome map of Anopheles messeae: application for physical genome mapping and population genetics

Authors: Sharakhova Maria[1], Sharakhov Igor[7], Artemov Gleb[6], Gordeev Mikhail[5], Moskaev Anton[4], Fedorova Valentina[3] and Stegniy Vladimir[2], [1]Department of Entomology, Virginia Polytechnic and State University, Blacksburg, United States, [2]Laboratory of Ecology, Genetics and Environment Protection, Tomsk State University, Tomsk, Russia, [3]Laboratory of Ecology, Genetics, and Environment Protection, Tomsk State University, Tomsk, Russia, [4]Moscow Region State University, Russia, [5]Moscow Region State University, Russia, [6]Tomsk State University, Russia, [7]VirginiaTech, United States

Abstract: The development of high-quality genome assemblies requires anchoring genomic supercontigs to the precise chromosome locations. Recent studies developed chromosome maps for several malaria vectors from the Maculipennis group – Anopheles atroparvus, An. sacharovi and An. beklemishevi. The cytogenetic map for An. atroparvus helped to improve the quality of the genome assembly for this species. However, a chromosome map for An. messeae, the species with the widest distribution in Eurasia, is still missing. In this study, we developed a standard map for the chromosomes from salivary glands of An. messeae. High-quality images of orcein-stained squashed chromosomes were processed to obtain straight chromosome arms. Five DNA probes were mapped to the different chromosome arms using fluorescence in situ hybridization (FISH) to prove the robustness of the map for physical mapping. In addition, we describe chromosomal location of five polymorphic inversions. Using microdissection of polytene chromosome we developed DNA probes, overlapped the breakpoints of polymorphic inversions. These probes were applied for precise chromosome mapping of polymorphic inversion borders. Cytogenetic analysis is a robust technique for identification of chromosomal inversions in natural populations. The standard map includes the standard inversion arrangements XL1, 2R0, 3R0 and 3L0 and the standard 2L arm, which lacks the inversions. To simplify inversion identification, we also developed maps for two inversion variants of the X chromosome (XL0 and XL2) as well as 2R1, 3R1, and 3L1. Moreover, we presented images of heterozygous inversion variants for each chromosome arm. The utility of the chromosome maps was demonstrated in our analysis of inversion polymorphism in several natural populations of An. messeae.

Acknowledgments: The image processing and fluorescent in situ hybridization were supported by the Russian Science Foundation grant No. 19-14-00130 to MVS. The development of the DNA-probes for polymorphic inversions mapping was funded by Russian Foundation for Basic Research according to the research project 18-34-20106 to GNA. Mosquito collections and chromosome preparations were supported by the Russian Foundation for Basic Research 18-04-01117 to MIG.

A chromosome-based tool for identification of mosquito species Aedes behningi, Ae. excrucians, Ae. euedes and Ae. communis (Diptera: Culicidae) in Russia.

Authors: Sharakhova Maria[1], Svetlana Alekseeva[4], Sibataev Anuarbek[3], Wasserlauf Irina[3], Stegniy Vladimir[2] and Andreeva Yulia[3], [1]Department of Entomology, Virginia Polytechnic and State University, Blacksburg, United States, [2]Laboratory of Ecology, Genetics and Environment Protection, Tomsk State University, Tomsk, Russia, [3]Tomsk State University (TSU), Russia, [4]Tomsk State University (TSU), Russia

Abstract: Mosquitos from genus Aedes represent carriers of human diseases. About 30 species from this genus were found in Tomsk region in Russia. Thus, precise identification of Aedes species is of medical importance. However, because of the absence of clear morphological differnces or molecular markers, the tools for precise species identification are still missing. In this study, the karyotypes were analyzed in 4 species from the genus Aedes: Ae. behningi, Ae. excrucians, Ae. euedes and Ae. communis. Mosquitoes were collected in Tomsk region, Russia at larval stage. 4-instar mosquito's larvae were used for the cytogenetic analysis. The mosquitos from genus Aedes have three pairs of chromosomes. In this study, chromosome lengths were measured using ImageJ program. For the analysis of the chromosome banding patterns, staining with lacto-aceto-orcein and DAPI were performed. In addition, the locations of ribosomal genes (rDNA) were identified by fluorescence in situ hybridization (FISH). The results were analyzed using light and fluorescence microscopies. Chromosomes were numbered according to the standard classification of the Aedes chromosomes, as the smallest chromosome 1, the longest chromosome 2, and the intermediate chromosome 3. The centromeric index was calculated as $Jc = p/(? + q)$, where p is the short chromosome arm and q is the long arm. The study identified that all three chromosomes in studied species are metacentric but the chromosome lengths varied between the species. Ae. excrucians has longest chromosomes, Ae. behningi has shortest chromosomes, Ae. euedes and Ae. communis have intermediate chromosome lengths. According to the analysis of the chromosome patterns we developed chromosome idiograms that reflect interspecies differences among the species Ae. behningi, Ae. excrucians, Ae. euedes and Ae. communis. Lacto-aceto-orsein staining revealed a significant difference in the position of bands in chromosome 1, DAPI bands indicate a distinction across all three pairs of chromosomes. It is known that DAPI staining detects DNA enriched with AT repeats. FISH revealed the location of rDNA loci in the chromosomes. Ae. behningi, Ae. excrucians, Ae. euedes have one rDNA locus in chromosome 1 but in Ae. communis chromosomes the rDNA locus was found in chromosome 2 suggesting that a translocation between these probably occurred in evolution of these species. Thus, this study developed a chromosome-based tools for the species identification. The chromosome length, chromosome banding pattern and location of rDNA allows to clearly distinguish 4 aedini from the genus Aedes.

A physical map of the Aedes albopictus genome

Authors: Sharakhova Maria[4], Masri Reem[2], Sharma Atashi[1], Karagodin Dimitriy[5] and Jenrette Jeremy[3], [1]Department of Entomology and Fralin Life Science Institute, Virginia Polytechnic and State University, Blacksburg VA, United States, [2]Department of Entomology and Fralin Life Science Institute, Virginia Polytechnic and State University, Blacksburg VA, United States, [3]Department of Entomology and the Fralin Life Science Institute, Virginia Polytechnic and State University, Blacksburg, United States, [4]Department of Entomology, Virginia Polytechnic and State University, Blacksburg, United States, [5]Laboratory of Evolutionary Genomics of Insects, the Federal Research Center Institute of Cytology and Genetics, Siberian Branch of the Russian Academy of Scienc

Abstract: The Asian tiger mosquito, Aedes albopictus is an aggressive, day-time biting insect that is emerging throughout the world as a public health threat following its primary role in recent dengue (DENV) and Chikungunya (CHIKV) outbreaks. Part of its impact on human health is due to its ability to adapt to suburban and urban environments, develop egg diapause when exposed to short day length, and its opportunistic blood choice (preferring to bite humans if available). Progress in understanding the science of mosquitoes and building up the instruments to battle them has been eased back by the absence of a great genome assembly. In this study we developed a new approach using fluorescence in situ hybridization to validate and orient fifty transcripts or gene exons from twenty largest genomic supercontigs to the mitotic chromosomes of Ae. albopictus. Physical mapping allows to check for the quality of the assembled genome by confirming or dismissing assembly predictions. Our approach was based on amplification of DNA probes using cDNA instead of Bacterial Artificial Chromosome (BAC) clones because utilizing BAC clones for highly repetitive genomes such as Ae. albopictus becomes extremely challenging. In addition, we mapped 18S rDNA in the region of the secondary constriction in region 1q22. The intensity of the signal significantly varied among chromosomes suggesting variations in number of ribosomal genes. We also mapped the largest bioinformatically-identified viral integration in the assembly confirming that this viral DNA is integrated to the chromosome 2q close to the telomere end. Physical mapping of PPO genes supported the genomic data of the presence of three clusters of these genes in chromosome 2.

Advances in physical mapping of malaria mosquito genomes

Authors: Sharakhova Maria[1], Sharakhov Igor[7], Artemov Gleb[6], Gordeev Mikhail[5], Moskaev Anton[4], Fedorova Valentina[3] and Stegniy Vladimir[2], [1]Department of Entomology, Virginia Polytechnic and State University, Blacksburg, United States, [2]Laboratory of Ecology, Genetics and Environment Protection, Tomsk State University, Tomsk, Russia, [3]Laboratory of Ecology, Genetics, and Environment Protection, Tomsk State University, Tomsk, Russia, [4]Moscow Region State University, Russia, [5]Moscow Region State University, Russia, [6]Tomsk State University, Russia, [7]VirginiaTech, United States

Abstract: Development of high-resolution chromosome maps is an important step in genomic studies. Anchoring genomic supercontigs to the chromosome positions is required for the development of chromosome-based genome assemblies. Cytogenetic maps are also important for identification of chromosome positions of genes, chromosome segments or chromatin proteins. Physical mapping of inversion breakpoint regions is necessary for studying chromosomal rearrangements. For example, physical mapping of the genomes of Anopheles gambiae, An. atroparvus and An. albimanus revealed near-whole arm chromosome translocation during mosquitoes evolution. Despite the development of long-read sequencing techniques, such as PacBio and Oxford Nanopore, as well as application of the Hi-C technology for scaffolding of genome assemblies, chromosome maps are still useful in guiding the genome assembling process. Malaria mosquitoes have six chromosomes in the diploid complement. Due to the small number of chromosomes and perfect-quality polytene chromosomes, about 100 chromosome maps are available for Anopheles mosquitoes. The technology of cytogenetic mapping evolved from simple drawn chromosome maps to high-resolution digital photomaps that are currently available for 10 most important malaria vectors. Some of these chromosome maps have been used for the physical mapping of the reference genomes for An. gambiae, An. stephensi, An. albimanus, An. atroparvus, and An. sinensis. Here we present a high-resolution chromosome map of An. messeae s.l., the member of the Maculipennis subgroup. This species is an important malaria vector in Europe and Russia and it occupies a large territory of Eurasia. The species has well developed inversion polymorphism located on four chromosome arms including the X chromosome. The application of region-specific microdissected DNA-probes is demonstrated as a useful approach for precise mapping of inversions breakpoints.

Geographic distribution and inversion polymorphism in natural population of cryptic species Anopheles messeae and Anopheles daciae in Eurasia

Authors: Sharakhova Maria[1], Sharakhov Igor[8], Brusentsov Ilya[4], Gordeev Mikhail[7], Yurchenko Andrey[3], Moskaev Anton[6], Karagodin Dimitriy[5] and Baricheva Elina[2], [1]Department of Entomology, Virginia Polytechnic and State University, Blacksburg, United States, [2]Laboratory of Cell Differentiation, Institute of Cytology and Genetics, Novosibirsk, Russia, [3]Laboratory of Evolutionary Genomics of Insect, Institute of Cytology and Genetics, Novosibirsk, Russia, [4]Laboratory of Evolutionary Genomics of Insect, Institute of Cytology and Genetics, Novosibirsk, Russia, [5]Laboratory of Evolutionary Genomics of Insects, the Federal Research Center Institute of Cytology and Genetics, Siberian Branch of the Russian Academy of Scienc, [6]Moscow Region State University, Russia, [7]Moscow Region State University, Russia, [8]VirginiaTech, United States

Abstract: Anopheles messeae Falleroni is geographically widespread and genetically diverse Eurasian species, which was the major vector of malaria transmission over this territory in the past. Five highly polymorphic inversions associated with the geographical distribution have been reported in this species. A cryptic species A. daciae, Linton, Nicolescu & Harbach was first discriminated from A. messeae in 2004 by five nucleotide substitutions in ITS2. However, distribution of A. daciae in Eurasia and inversion polymorphism in this species remain poorly understood. In this study, mosquito larvae and adults were collected from eight geographically distant regions in Eurasia from Russia and Latvia. ITS2 sequences were analyzed in 1465 specimens of Anopheles, of which 993 were karyotyped. Our study supports a previous observation that among the five described nucleotide substitutions in ITS2 only two have fixed differences between A. messeae and A. daciae. We observed varying species composition among the collected samples, which ranged from the complete absence of A. messeae in Voronezh and Sevastopol (Russia) to the complete absence of A. daciae in Irkutsk (Russia). Both species were found in equal proportions in Riga (Latvia), Moscow, Ufa, and Novosibirsk (Russia). Interspecies hybrids were rare and were identified only in Tomsk and Novosibirsk. Three other species A. maculipennis, Meigen, A. atroparvus, Van Thiel, and A. beklemishevi, Stegniy, Kabanova were found in several locations. A cytogenetic comparison of A. daciae and A. messeae samples demonstrated that the two species significantly differ from each other by the frequencies of polymorphic inversions. Previously described inversion X0 fixed in A. messeae was found in this species at an extremely low frequency. Inversions X2 and X4 were found only in A. messeae. Principal Component Analysis based on the frequencies of autosomal inversions in the populations studied clearly distinguished two species and demonstrated much higher diversity between the populations of A. messeae. Average Fst value between species was 0.147 with highly significant values for the majority of inter-species population comparisons. Nested AMOVA analysis indicated that significantly more variation was accumulated between the species than between their geographical populations. Overall, our study demonstrated that A. daciae prevails in the western locations and is absent in the Eastern Siberia. This study also uncovered genetic differentiation between A. messeae and A. daciae associated with chromosomal inversions. Understanding the species composition of malaria vectors in Northern Eurasia and their genetic divergence will be instrumental for developing an adequate strategy for the vector control.

Sequencing and statistical analyses were supported by the Russian Science Foundation grant 19-14-00130 to MVS.
Karyotyping was supported by the Russian Foundation for Basic Research 20-54-04017.

Relationship of characters of the propodeal-metapectal complex and ovipositor to host use in Ichneumonidae

Authors: Sharanowski Barb, University of Central Florida, Department of Biology, Orlando, FL, United States of America, United States

Abstract: A recent hypothesis by Li et al. (2015) suggested there are four main types of propodeal-metasomal articulations in parasitoid wasps related to distinct oviposition postures adapted for different types of hosts and host habitats. Here we test this hypothesis by examining covariation among morphological features of the propodeal-metapectal complex and ovipositor along with host in extant Ichneumonidae.

Estimating the number of global insect species extrapolating data from Costa Rica: Erwin was right!

Authors: Sharkey Michael[1], Janzen Dan, Hallwachs Winnie, Pook Victoria and Baker Austin, [1]University of Kentucky, United States

Abstract: Employing recently generated data from reared and Malaise-trapped, barcoded specimens from Área de Conservación (ACG) in north-western Costa Rica, we generate estimates for the total number of Microgastrinae in ACG's 125,000 terrestrial hectares of dry forest, cloud forest and rain forest. This is accomplished by comparing the number of microgastrine COI BINs (Barcode Index Numbers) from reared caterpillars with those of Malaise-trapped BINs. Entire samples from dozens of Malaise-trap years have been barcoded and this allowed us to compare the relative species-richness of microgastrines with other braconids, ichneumonids, Hymenoptera, and other insects. With these estimates for ACG, we extrapolate estimates for these taxa for Costa Rica and the world. These broader estimates were generated by using the number of tree species in ACG, Costa Rica, and the world as a template. Our results indicate that Terry Erwin's (1980) estimate of 30 million insect species is a reasonable approximation.

Overcoming the taxonomic impediment: A radical solution for an intractable problem

Authors: Sharkey Michael[4], Smith Alex[3], Brown Brian[2], Janzen Danial[5], D. N. Hebert Paul[1] and Hallwachs Winnie, [1]Centre for Biodiversity, University of Guelph Guelph, ON, Canada, [2]Natural History Museum of Los Angeles County, United States, [3]University of Guelph, Canada, [4]University of Kentucky, United States, [5]University of Pennsylvania, United States

Abstract: The magnitude of the taxonomic impediment is outlined using data collected from decades of biodiversity research in Costa Rica. We demonstrate that, given the current rate of species descriptions, it will take thousands of years to treat all extant species. The solution proposed is a DNA (COI) barcode approach to characterize species, similar to that published in Deutsche Entomologische Zeitschrift by Meierotto et al. in 2019. Each species treatment consists of a diagnosis based on the information contained in the barcode region of the COI gene, an image of the specimen, and some details necessary to conform with the International Code of Zoological Nomenclature. An example using hundreds of new species from Costa Rica is presented. It will emphasize that these treatments are not meant to be the final step in species-level taxonomy for hyper-diverse taxa, but rather a necessary first step that will facilitate more comprehensive treatments when warranted and to be integrated with classical morphology-based descriptive taxonomy in an efficient manner.

Towards a new infrageneric structure of the genus Copelatus Erichson, 1832 using the Australasian species as an example

Authors: Shaverdo Helena[3], Hájek Jirí[2], Hendrich Lars[1] and Balke Michael[1], [1]The Bavarian State Collection of Zoology, Germany, [2]The National Museum, Prague, Czech Republic, [3]The Natural History Museum Vienna, Austria, Austria

Abstract: With its 454 described, mostly tropical species, Copelatus Erichson, 1832 is the largest genus in the family Dytiscidae. The genus remains poorly studied, being one of the taxonomically most challenging dytiscid clades. Creating and using a species group system for large genera has been proved to be a very useful in taxonomic studies, although such species groups are informal, artificial units. However, application of molecular analyses and more detailed investigations of morphological characters allow us to suggest natural species groups, i.e. monophyletic groups. Copelatus is traditionally divided into 15 groups, following Sharp's (1882) species group classification based on the number of elytral striae. Recently, several studies on African, Neotropical and Oriental species showed that the numbers of these striae could strongly vary and, therefore, the present infrageneric system of the genus is in need of revision. Since nine of the known Copelatus species groups include Australasian species, and the species of this region are the most poorly studied, we initiated a project on their systematics with one aim being the revision of the species group classification.

We studied in details the morphology of the species from Australia, New Guinea, and Solomon Islands. We chose shape and setation of the male genitalia as a set of key characters for the new Copelatus species group structure. Two main development tendencies of the median lobe were discovered. Using them, as well as shape and setation of paramere, we proposed 12 new species groups for more than 100 species in Australasia, approximately 90 of which are new. A weak correlation of the groups with the number of the elytral striae was noted. Results of our preliminary phylogenetic analysis based on molecular data confirmed monophyly of most of the groups. Further examination with involving of the larger species number from the different regions is planned to verify our preliminary results on the new infrageneric structure of the genus Copelatus.

BMSB Economic Impact Survey (Republic of Georgia)

Authors: Shavgulidze Rati[1], Namichaishvili Louisa[1], Inasaridze Nino[2], [1]CNFA Georgia, [1]CNFA Georgia, [2]I. Javakhishvili Tbilisi State University, Georgia; CNFA Georgia, Georgia

Abstract: The emergence of the Brown Marmorated Stink Bug (BMSB) in the Western part of Georgia has left visible damage across the agricultural sector. This study served to analyze and determine the economic impact of the BMSB on Georgia's hazelnut sector. In particular, this study calculated the foregone export earnings, utilizing secondary data sources, as well as descriptive statistics. In addition to calculating the foregone foreign exchange earnings, the study also analyzed the household composition, farming practices and alternative income sources of hazelnut farmers to provide a more holistic analysis. The result shows that actual yield levels in MY2016-17, MY2017-18, MY2018-19, MY2019-20, and MY2020-21 were 63%, 40%, 26%, 50% and 70% of growers' expectations, respectively. The unrealized export earnings in MY 2016-17, MY2017-18, MY2018-19. MY2019-20, and MY2020-21 amounted $US 4 million, $US 36 million, $US 74 million, $US 50 million and $US 11 million. The study found that the proportion of damaged kernels (blank, shriveled, mouldiness) has increased from 14 % in MY 2016-17 to 28 % in MY 2018/19, followed by a decline to 10% in 2020/21. Hazelnut output projection for MY2021/-22 is less positive than those during the last two years, given that reportedly plant protection measures have been implemented on a limited scale in 2020-21 and fall 2021. However, projections could be revised given intensive plant protection campaign already initiated by the MEPA/ NFA during the current production season and favorable weather conditions.

Findings and results of this study do not suggest that losses in yield and quality of hazelnut during the 2016/17-2020/21 production season were solely due to the BMSB. Rather, Georgia's reduction in hazelnut production and quality is also due to the combination of negative factors that include increased pressure from the BMSB as well as an increased presence of fungal diseases and unfavorable weather conditions. These factors, coupled with farmers' failure to adhere to proper production practices, contribute to the total foregone revenue of farmers and processors. The joint efforts made by different stakeholders (government, development agencies, local authorities, professional associations) during the last few years including awareness raising campaign on monitoring and control of BMSB may play critical role in improvement of yield levels and reduction of unrealized export earnings.

"beesofcanada.com": A resource of assisting in the conservation of bees in Canada, and the current status of our bees

Authors: Sheffield Cory S.[2] and Heron Jennifer M.[1], [1]British Columbia Ministry of Environment and Climate Change Strategy, Canada, [2]Royal Saskatchewan Museum, Canada

Abstract: In Canada, species at risk are assessed using two methods: 1) broad assessments for all species of a given taxa (e.g., all bees) at the national scale via "Wild Species: the General Status of Species in Canada" (Wild Species), and 2) at the individual species level via assessments done through the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). Wild Species assessments are done every five years using NatureServe methodologies, and assessments include species that are not at risk as well as those considered potentially at risk. COSEWIC assessments for individual species use International Union for the Conservation of Nature (IUCN) Red List procedures and are only done on select candidate species. However, both methods require species data, and for the ca 900 bee species in Canada, such data is not readily available. The website "beesofcanada.com" was developed to provide users with an easy to use resource for all things bees in Canada, including a filterable species list generator for each jurisdiction, a complete catalogue with synonymies and type information, summaries of ecological information, and detailed point maps for each species. Though the website is currently being populated with data, information was recently used to assess bees for Wild Species; the results of this assessment will also be summarized.

Bacterial Communities of Artificial and Natural Mosquito Breeding Sites in Taiwan and the Search for Microbial Insecticides

Authors: Shelomi Matan, National Taiwan University, Taiwan

Abstract: This presentation covers three separate experiments done as part of a three-year project on mosquito-microbe interactions in Taiwan.

1) Container-breeding mosquitoes detect the presence of certain microbes in the water, stimulating oviposition. We hypothesized that the presence or absence of certain microbes in containers thus drives the differential attraction of different mosquito species to different container types, and that these relationships could be detected via metagenomics. We focused on Aedes aegypti and Ae. albopictus, both of which coexist in artificial containers in Southern Taiwan, and sought to see if these species' presence or absence in a container correlated with that of certain microbes.

2) Artificial containers are attractive to Aedes, but other mosquitoes prefer natural, plant-based water containers, or phylotelmata. These include large axils, tree hollows, and bamboo tubes. We sampled from such containers in Northern Taiwan, in the autumn and the spring, to compare the microbiota over time and across species, and to once again see if mosquito presence or absence correlates with microbiota.

3) We cultured many microbes during our collecting trips. Did any of these have effects on mosquitoes that could be detected in the laboratory? We present the results of our larvicidal assays on environmental microbes, as well as on known but terrestrial entomopathogenic microbes, in the hopes of finding a possible biocontrol.

Antimicrobial Peptides of the Phasmatodea

Authors: Shelomi Matan[4], Vogel Heiko[1], Vilcinskas Andreas[2] and Jacobs Chris[3], [1]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [2]Institute of Insect Biotechnology, Justus-Liebig University, Germany, [3]Max Planck Institute for Chemical Ecology, Germany, [4]National Taiwan University, Taiwan, Taiwan

Abstract: The Phasmatodea, or stick and leaf insects, are an understudied clade of insects whose pathology is of interest to cultivators and conservationists. Part of an insect's innate immunity are antimicrobial peptides (AMPs), which have therapeutic potential in human and veterinary medicine. We exposed stick insects to a mixture of pathogens to induce an immune response, and used RNA-Seq to identify subsequently differentially and/or highly expressed genes in Peruphasma schultei. AMPs were identified in the attacin, coleoptericin, defensin, thaumatin, and tachystatin families. We also found C- and i-lysozymes and several pattern recognition proteins [gram-negative bacteria-binding proteins and peptidoglycan recognition proteins]; as well as a large group of short, cysteine-rich, secreted peptides, many of which were highly induced and predicted to potentially have AMP activity. We also found 45 different sequences of hemolymph lipopolysaccharide-binding proteins, which is an unusually large number for insects. This is the first work to look at AMPs and immunity in stick insects, with implications for Phasmatodea conservation and pathology.

Ovarian specifically expressed genes of rice pest brown planthopper and theirs contributions for the reproduction.

Authors: Shen Yan, Zhejiang University, China

Abstract: The vast majority of insects, reproduction requires not only monitoring of internal physiological stimuli, but also depends on complex physiological responses to the external environment. We learned that most of female insects are oviparous. In a general way, ovulation is followed rapidly by fertilization and then oviposition. The regulation of insect reproduction are poorly known in insects, especially compared with knowledge of vertebrate reproduction.

The brown planthopper (BPH), Nilaparvata lugens, a phloem-feeding hemipteran insect, has emerged as a major pest of rice plants in Asian countries. Robust capacity for fecundity is one of the main causes of the serious economic losses inflicted by BPH. As there are so many genes participating in the reproductive events. We thoroughly searched and analyzed the genomes of BPH at both genomic and transcriptomic levels, and selected genes who were almost exclusively expressed in ovary of BPHs. They account for more than 1% of the total N. lugens genes encoded in the genome. We supposed these ovarian specifically expressed genes may be associated to female reproduction and even play significant roles in fecundity. To determine their functions, we conducted RNAi experiments in 0- to 2-h female adult BPHs. Here, we select three representative and interesting examples in our recent study:

1. The very first process in the reproductive success of oviparous species is the biosynthesis of vitellogenin (VTG, Vg). Here, we identi?ed a Vg and two Vg-likes from BPH. We found NlVg is a conventional insect Vg that is involved not only in reproductivity and embryogenesis, but also in nymphal development; NlVg-like1 is related to hatching; NlVg-like2 is associated with oocyte nutrition absorption.
2. A pair of healthy oviducts is important for female adults. We identi?ed a novel neuropeptide-like protein, Nl851, is specifically expressed in female's oviducts. We found more than one eggs were stuck in oviducts simultaneously during spawning. TEM showed the epithelial cells of lateral oviducts were loosely and irregularly arranged, which increasing the difficulty of female reproduction.
3. Eggs are compressed during passage down the narrow oviducts in spawning, so eggshell's elasticity facilitates oviposition. We identified an eggshell-related protein, Nl6565, who was essential for egg maturation in BPH. All oocytes appeared concavity in the middle portion with thin and rough endochorion layers after the injection of dsNl6565. Some developed oocytes had even entered the hypertrophied bursa copulatrix, causing the inability of reproduction.

Our findings help to better understanding of the ovarian specifically expressed genes in the phloem-feeding species and reveal a new angle for finding potential targets at BPH management based on RNAi technology. However, there are much still to learn about the genes associated with reproduction.

Impact of the Nagoya Protocol on biological control activities in Australia

Authors: Sheppard Andy[1], Sathyamurthy Raghu[1], [1]CSIRO, Australia

Abstract: Australia is a signatory, but has not ratified the Nagoya Protocol (NP) since it came into effect in 2010. There have been a number of publications explaining the implications of the NP for classical biological control activities some of which have described procedures to ensure biological control activities address the requirements of the Nagoya Protocol. While Australia undertakes a wide range of classical biological control programs against mainly weeds, vertebrate and invertebrate pests, Australian biological control research agencies have not formally developed or applied any such procedures to their practices when engaging with native range countries. Addressing the NP has largely involved understanding the implications of it for classical biological control programs and developing close working relationships within native range countries to work within the spirit of the agreement. This includes signed agreements with local research agencies including certain levels of Australian investment and paid collaboration. Obtaining all the relevant local permits for collection and shipping, being explicit about the activities being undertaken, and making sure that all the biological control activities resulting from these interactions remain within the public good not-for-profit basis under which most classical biological control programs are undertaken. The NP has certainly had an impact on the capacity to collect and ship potential biological control agents from some jurisdictions, but these jurisdictions appear to be operating under local legislation and regulatory mechanisms that go well beyond those relevant for the standard implementation of the NP. In such instances Australian research agencies do engage consular services from the relevant AU embassies to help with negotiations, but this has not always led to easier access to potential biocontrol agents. Part of the issue is the diversity of ways in which countries that have ratified the NP are implementing it within their jurisdictions and given this, the reluctance of research agencies within Australia to get bogged down in formal NP based negotiations with all native range countries Australia needs to access for fear this would grind biological control programs to a halt. Australia as far as possible continues to work within the spirit of the NP using the principles developed in the published guidelines for classical biological control activities.

Molecular characterization of pars lateralis neurons relevant to diapause control in the blow fly, Protophormia terraenovae

Authors: Shiga Sakiko, Graduate School of Science, Osaka University, Japan

Abstract: Many insects anticipate the arrival of an unfavorable season by sensing photoperiod to enter diapause. Although endocrine mechanisms underlying diapause induction have been studied in many species, neural mechanisms mediating environmental control of diapause have not been understood well. Adult females of the blow fly Protophormia terraenovae develop the ovary in long days, whereas ovarian development is inhibited via suppression of juvenile hormone (JH) biosynthesis in the corpus allatum (CA) to enter reproductive diapause in short days. Brain surgery and neuroanatomy showed that neurons with somata in the pars lateralis (PL) and fibers in the posterior lateral tract in the brain, termed PL neurons, are necessary for diapause under short days. However, PL neurons are heterogenous in their neurochemistry and in fiber projection, and it is not known which types of PL neurons are important for diapause control. Location of clock protein PERIOD-immunoreactive dorsal neurons (DNs) seems to be close to the PL in P. terraenovae. It is possible that some PL neurons may correspond to DNs themselves. In this study, we characterized PL neurons by single cell PCR and immunohistochemistry to discuss relevant neurons to diapause control. After fluorescent dye filling through the nervi corporis cardiaci, labelled PL somata were individually collected for nested-PCR to examine gene expression of neuropeptides and circadian clock proteins which had been localized either in P. terraenovae PL neurons or in Drosophila melanogaster DNs. Of 24 PL somata (females, N=6) 75 % expressed at least 3 clock genes (clock-gene expressing PL somata). Two kinds of neuropeptide genes expressed in more than 60% of the clock-gene expressing PL somata. Antibodies against these neuropeptides labeled PL neurons extending fibers in the CA, and receptor genes of both neuropeptides expressed in the CA. Quantitative PCR revealed that one of the receptor genes tended to express higher under short days than under long days in the CA. These results show a possibility that some PL neurons function as circadian clock DNs and also as neurosecretory cells releasing the neuropeptide to control the CA for diapause under short days. We are investigating effects of the candidate neuropeptide on JH production or release by the CA, and comparing activities of the PL neuron under different photoperiods in near future.

Morphological analysis of Pigment-dispersing factor immunoreactive neurons and pars lateralis neurons in the larval brain of the flesh fly Sarcophaga similis

Authors: Shiga Sakiko[2], Ohe Yutaro[1], [1]Department of Biological Science, Graduate School of Science, Osaka University, Japan, [2]Graduate School of Science, Osaka University, Japan

Abstract: Many insects in the temperate zone alter physiological states according to day or night length to develop or enter diapause, in order to survive unfavorable seasons. This response is called photoperiodism. The mechanism underlying photoperiodism consists of three components: “photoreceptors”, “photoperiodic clocks” and “endocrine systems”. Responsible organs and molecules about the photoreceptors and endocrine systems have been studied in many species, but little is known about which neurons are responsible for the photoperiodic clocks.
The flesh fly Sarcophaga similis enter pupal diapause in short days (SD), but S. similis reared under SD are destined from diapause to non-diapause pupae when they receive only 4 or 5 long days (LD) in the larval stage. Pupal diapause is caused mainly by suppression of ecdysteroids. In many lepidopteran species, prothoracicotropic hormone (PTTH) secreted from neurosecretory cells in the pars lateralis (PL) of the brain is important for synthesis of ecdysteroids. In addition, endogenous circadian clocks have been considered being involved in the photoperiodic clocks. Brain neurons expressing a neuropeptide pigment-dispersing factor (PDF) are known as circadian clock cells in several dipteran species. In this paper, to explore neural mechanisms underlying photoperiodism in S. similis, we examined projections of PDF neurons and PL neurons which have cell bodies in the PL. We hypothesized that PDF neurons may store photoperiodic information. Then additionally we examined whether PDF neurons change the morphology between SD and LD.
First, we performed immunohistochemistry using an antiserum against PDF combined with backfill staining of PL neurons using neurobiotin with the third instar larval brain. Three to 6 PDF-immunoreactive (-ir) cells were shown in a hemisphere. Fibers extended from the somata were found at dorsal protocerebrum, and many immunoreactive varicosities were found along the terminal arborizations to the PL. Furthermore, we compared the number of PDF-ir varicosities between diapause (SD) and non-diapause destined larvae (exposed to only 5 days of LD in SD). Although there was no significant difference, the number of varicosities in SD was slightly less than that in LD. By unilateral backfills from a third from the distal end of the ring gland, 6 cells in the ipsilateral PL (PL-i) and 2 cells in the contralateral PL (PL-c) were labeled. Many fine fiber branches were labeled around the neurite from PL-i and PL-c cells. Since PTTH neurons are generally 2 pairs and terminate contralateral ring gland in D. melanogaster, the PL-c neurons are probably PTTH neurons. In addition, double staining of PL and PDF-ir neurons shows that PDF-ir fibers are close to fibers of PL-i and PL-c neurons. These results suggest that PDF neurons have interaction to PTTH neurons. PDF neurons may store photoperiodic information and send it to PTTH neurons.

Nutritional niches reveal domestication tradeoffs in fungus-farming ants

Authors: Shik Jonathan, Department of Biology, University of Copenhagen, Denmark

Abstract: During domestication, human farmers traded greater crop productivity under cultivation for lower yields outside these specialized conditions. We found similar domestication tradeoffs across the phylogeny of fungus-farming attine ants. We first defined the fundamental nutritional niches (FNNs) of fungal cultivars and discovered they transitioned from broad and variable in loosely domesticated fungi to narrowed and specialized across millennia of domestication. We next tested whether ant farmers strategically harvest realized nutritional niches (RNNs) of nutritionally defined substrate mulches and found that colonies strictly regulated protein harvest to target their cultivars’ FNNs. We then combined molecular inference and extensive field studies to reveal that neighboring attine colonies often farm different fungal haplotypes with different growth properties. However, ant farmers can also navigate landscapes of nutritionally variable substrates to harvest broad RNNs and target their cultivar’s specific FNN. We finally explain how this integrative approach can unify the study of diverse farming systems around ecological niche and evolutionary mutualism principles.

Import and release of invertebrate biological control agents: regulation in Brazil

Authors: Shimbori Eduardo Mitio[3], Mascarenhas Matosinhos de Sousa Izabela[1], Sousa Domingues Vitor[1], Gradiz Nascimento Paulo Augusto[3], Penteado-Dias Angelica Maria[2], [1]IBAMA, [2]UFSCar, [3]USP/ESALQ

Abstract: Import and release of exotic invertebrate biological control agents are potentially extremely beneficial or harmful. Proper research and regulation may help tip the balance in favor of its benefits. We will present the current status of Brazilian regulations.

Improvement of insect nets: Red-colored nets most effectively suppress the onion thrips, Thrips tabaci (Lindeman) invasion

Authors: Shimoda Masami[1], Tokumaru Susumu[2] and Ito Shun[2], [1]Institute of Agrobiological Sciences, NARO, Japan, [2]Kyoto Prefectural Agriculture, Forestry and Fisheries Technology Center, Japan

Abstract: Onion thrips, Thrips tabaci Lindeman, is distributed worldwide, and caused serious damage to Welsh onion, onion (Imai et al., 1988), persimmon (Morishita and Oue, 2001) and Citrus (Tsuchiya, 2001). T. tabaci is also known as a vector of Tomato spotted wilt virus (TSWV) (Zawirska, 1976) and Iris yellow spot virus (IYSV) (Doi, et al., 2003). In Welsh onion cultivation in Japan, T. tabaci is mainly controlled by insecticides. However, the pyrethroid resistance of T. tabaci has been reported in Japan, the USA, Canada, and Australia (Morishita and Oue, 2001; Allen et al., 2005; Shelton et al., 2006; Herron and James, 2008; Morishita, 2008).

Insect net is one of the physical control methods. Although the control effects of mesh size of the net on the insect invasion have been reported, there are few reports about the effects of the net color. Oya et al. (2011) reported that the density of T. tabaci on cabbage covered with the red-colored nets was very low. However, there are lots of unclear points about the behavioral response characteristics of this species against the red-colored nets. In this study, therefore, we examined the behavioral response characteristics of T. tabaci against the red-colored nets, and the control effects by covering Welsh onion with the red-colored nets under field condition, as one of the physical control methods.

1.Behavioral response characteristics of Thrips tabaci on Welsh onion against the red-colored nets

To evaluate the control effects of the red-colored nets against T.tabaci, we investigated the invasion rates of the thrips into the nets and the number of damage spots by the thrips on Welsh onion fully covered with six types of colored nets under laboratory condition. As a result, the invasion rates of T.tabaci into the nets were significantly lower by fully covering with the red-colored nets (red-white, red-red, and red-black type) than by fully covering with the white-colored nets (white-white type). In addition, the number of damage spots by the thrips on Welsh onion fully covered with all types of the red-colored nets was suppressed from approximately one-ninth to one-third of that with the white-colored nets.

2.The control effects by covering with the red-colored nets against Thrips tabaci

The control effects by covering Welsh onion with the red-colored nets (red-red type) on the populations of T. tabaci were investigated in the commercial fields in Kyoto Prefecture, Japan. The populations of T. tabaci on the plants fully covered with the red-colored nets were reduced to approximately one-tenth of those without nets covering. Furthermore, even only surrounding the fields by the red-colored nets, T. tabaci populations on Welsh onion were suppressed to approximately one-half of that without the red-colored nets.

These results indicated that the red-colored nets are effective and economically efficient measure for controlling T. tabaci.

Seasonal adaptations of the blister beetle, Epicauta gorhami, a hypermetamorphic insect

Authors: Shintani Yoshinori[1] and Terao Misato[1], [1]Minami Kyushu University, Japan

Abstract: The bean blister beetle, Epicauta gorhami (Coleprtera: Meloidae), is distributed in Japan. The adults are polyphagous herbivores and occur in summer to autumn. In contrast, the larvae feed only on grasshopper eggs in soil. As is common with other species in Meloidae, E. gorhami larvae undergo hypermetamorphosis, with four distinctive larval stages in the typical meloid life cycle: the planidium, first grub, coarctate (pseudopupa), and second grub stages. The pseudopupa (fifth instar in the case of E. gorhami), a form characteristic of hypermetamorphosis for meloid beetles, is a dormant stage that is adapted for diapause. First, we have found that larval development of E. gorhami is controlled by temperature and photoperiod: at 25ºC all larvae enter diapause at the fifth instar as pseudopupae under short-day conditions, whereas substantial part of larvae pupate directly from the fourth instar under long-day conditions. At lower temperatures larvae enter pseudopupal diapause, whereas at higher temperatures they pupate directly from the fourth instar under any photoperiodic conditions. We have also observed that E. gorhami larvae metamorphose precociously if they encounter food shortages during the fourth instar. These larvae pupate or pseudopupate earlier with a smaller body size (precocious metamorphosis) compared to those supplied with sufficient food. The incidence of precocious pupation is influenced by the food supply: larvae under a food shortage tend to pupate even under short-day conditions at 25ºC. Consequently, the reaction norm is modified by the feeding conditions. The post-feeding period (11-12 days) before pupation is unchanged, irrespective of feeding conditions, and thus larvae in the face of food shortages may undergo normal physiological processes. In nature, large variation of food availability may exist among individual larvae of E. gorhami because the size of grasshopper egg pods available to the first-instar larvae varies greatly depending on the grasshopper species. In the face of food shortages, larvae are unlikely to find a new food resource because those at the feeding stage (i.e. first grub) are less mobile. Under such circumstances, it appears that an adaptive response occurs, in which larvae control metamorphosis in response to food availability. Finally, we examined how the reaction norm of food-deprived E. gorhami larvae functions in nature by rearing insects outdoors in different seasons with manipulation of the food supply. The results indicated that most fully-fed larvae entered pseudopupal diapause, whereas food-deprived larvae tended to pupate precociously without entering diapause, especially early in the season. The resulting smaller adults reproduced early in the autumn and their progeny attained the pseudopupal stage before winter, indicating that the reaction norm may have an adaptive role in controlling seasonal development in the face of food shortages, producing a bivoltine life cycle.

Eating for Winter – Diet Macronutrients Affect Caterpillar Diapause

Authors: Short Clancy[2], Dos Santos Izailda B.[2], Deans Carrie[3], Behmer Spencer T.[1], de Paula-Moraes Silvana V.[2] and Hahn Daniel A.[2], [1]Texas A&M University, [2]University of Florida, [3]University of Minnesota

Abstract: Surviving winter is a severe challenge for many insects. Diapause allows insects to become dormant during harsh seasonal conditions like winter, thus synchronizing their growth, development, and reproduction with favorable seasonal conditions. Diapause may last many months and is often accompanied by the cessation of feeding, representing a substantial nutrient cost. However, many insects live in nutrient limited or risky foraging environments, so may struggle to obtain the nutrients needed for diapause. How might nutrient intake affect an insect's likelihood of diapause? Furthermore, how might an insect's feeding preferences change if it is destined for the resource intensive diapause program? We are investigating these questions in the corn earworm, Helicoverpa zea, using the geometric framework for nutrition to examine the relative roles of carbohydrate and protein nutrition. Overall, diapause and nutrition are mutually linked. Our experiments lay the groundwork for future studies to test the relative importance of nutrient intake and nutrient stores, or test the extent to which nutritional differences in agricultural crops may delay diapause and affect overwintering survival in the field. Our findings may contribute to IPM recommendations in agriculture landscapes with host plants predicted to cause different diapause incidence and overwintering survival in H. zea.

Landscape-scale consequences of nutritional heterogeneity in a major agricultural insect pest, Helicoverpa zea (Lepidoptera: Noctuidae)

Authors: Short Clancy[4], Sword Gregory[3], Tessnow Ashley[1], Deans Carrie[2] and Black Joseph[1], [1]Department of Entomology Texas A&M University College Station, Texas, United States, [2]Entomology Department University of Minnesota St. Paul, Minnesota, United States, [3]Texas A&M University Department of Entomology Interdisciplinary Research Program in Ecology and Evolutionary Biology College Station, United States, [4]University of Florida, Department of Entomology and Nematology, United States

Abstract: The corn earworm/cotton bollworm, Helicoverpa zea, is a major generalist crop pest in North and South America. In the United States, H. zea typically shifts from utilizing corn as a host early in the growing season to cotton where it is an important mid-late season pest. Nutrition can have profound effects on insect growth, survival, and the ability to deal with environmental stressors. Corn and cotton vary substantially as nutritional resources for developing H. zea larvae, with corn being a very carbohydrate-biased nutritional resource whereas cotton offers a slightly protein-biased ratio of the two major macronutrients. When reared on carbohydrate-biased diets mimicking corn, H. zea larvae were more susceptible to both Bt toxins and nuclear polyhedral virus (NPV) infection relative to larvae reared on protein-biased diets that reflected the macronutrient profile of cotton. These results suggest that (i) selection for resistance to transgenic and biological control strategies whose efficacy can be affected by nutrition such as Bt toxins and NPV should be stronger for larvae utilizing corn as a host earlier in the season, and (ii) cotton provides a favorable nutritional environment that further facilitates their survival later in the year.

The Potential of Fluorescence Imaging to Distinguish Insect Species

Authors: Shortall Chris[3], West Jon[1], Halsey Kirstie[2] and Perryman Sarah[2], [1]Biointeractions and Crop Protection. Rothamsted Research. Harpenden, United Kingdom, [2]Computational and Analytical Sciences. Rothamsted Research. Harpenden, United Kingdom, [3]Rothamsted Research, United Kingdom

Abstract: We demonstrate a fluorescence analysis technique for discriminating between species of insect. Fluorescence was measured using a fluorescent stereomicroscope imaging system using violet and GFP filters. The imaging system recorded the emission of fluorescence, following excitation at various wavelengths (between 405-500nm) and emission in the ranges 460-700+nm. The set-up was successfully used to photograph a suite of pest and non-pest species in laboratory conditions. Several species exhibited fluorescence, which increases the scope for their detection and identification with implications for automated pest monitoring and early detection. This set-up can easily be adapted for field use increasing the scope for early detection and identification of insects with implications for automated monitoring

Anatomical differences between leaf galls of European Diplolepis eglanteriae (Hymenoptera: Cynipidae) introduced into Canada on exotic roses and galls of the endemic Diplolepis nebulosa on wild roses

Authors: Shorthouse Joe[2] and Fenwick Brandy[1], [1]Department of Biology Laurentian University Sudbury, Ontario, Canada, [2]Laurentian University, Canada

Abstract: The accidental introduction into Ontario, Canada of the European cynipid Diplolepis eglanteriae provided an opportunity to compare the structure and development of its gall with what appears to be an identical gall of the endemic species Diplolepis nebulosa. Both galls are spherical, about the size of a small pea, single-chambered, and with a smooth surface. Not only do galls of D. eglantariae occur on the adaxial (upper) surface of rose leaves whereas those of D. nebulosa occur on the abaxial (lower) surface of rose leaves, there are differences in the site of initiation, growth patterns and structures. Galls of D. eglanteriae are initiated from palisade cells, retain an epidermis, and when mature, have larval chambers lined with a thin layer of nutritive cells and a weak sclerenchyma layer within their walls. Galls of D. nebulosa are initiated from mesophyll cells, develop without an epidermal layer, have a thick layer of nutritive cells and a prominent sclerenchyma layer with cells filled with phenolics. These findings are consistent with the generally accepted observation that each species of Diplolepis induces structurally distinct galls.

Diversity and distribution of Protura in the world

Authors: Shrubovych Yuliya, Institute of Systematics and Evolution of Animals, Poland State Museum of Natural History, UNAS, Ukraine. Institute of Soil Biology, BCCAS, Czech Republic, Poland

Abstract: Protura, known also as coneheads, are soil-dwelling microarthropods, wingless, eyeless, with slender, elongate bodies ranging in size between 0.7–2 mm. Due to their minuteness and cryptic edaphic lifestyle they were discovered relatively late in the history of entomology. Since their first description in 1907 up to 835 valid species belonging to 76 genera and three orders (Acerentomata, Eosentomata and Sinentomata) have been described worldwide. The proturan fauna of the northeastern Palearctic (59 species), Africa (60 species), Australia (32 species), North America (76 species) and South America (60 species) may be assumed to be poorly known in relation to the size of these areas as well as in comparison to the species diversity of the proturan fauna of Europe (187 species), China (217 species) and Japan (89 species). Analysis of the distribution patterns of proturans only a few cosmopolitan genera: the most diverse in the world comprise the genus Eosentomon (Eosentomidae), four genera of the Acerentomidae and the genus Proturentomon (Protentomidae). The members of the order Sinentomata are distributed exclusively in the Far East (China and Japan). Among the members of the Acerentomidae practically all genera of the Nipponentominae and some genera of the Acerentominae are distributed in the eastern Palearctic and North America. Members of the Berberentulinae, which are characterized by reduction of some morphological characters, instead are distributed mainly in the Pantropical region and the western Palearctic.

Recent faunistic analysis of the Arctic region at the northernmost border of Protura distribution showed that Arctic proturans are not species-rich (23 in total) but quite diverse: in addition to the cosmopolitan genus Eosentomon they are represented by eight genera of Nipponentominae as well as five genera of Acerentominae. The occurrence of proturans in Arctica is limited to Beringia. Some genera are known from both the American Arctic and Siberia, but the majority of their species have restricted distributions, and none has been found in both the American Arctic and Siberia. The higher number of Asian-North American genera confirms the generally accepted theory that northeastern Asia was the main center of speciation of Holarctic species, with the Bering land bridge serving as the most important exchange route from west to east and vice-versa.

Carcasses as caring nurseries: carrion preservation by the burying beetles and their microbiome

Authors: Shukla Shantanu, Max Planck Institute for Chemical Ecology, Germany

Abstract: Carrion is an ephemeral resource, which is highly nutritious but susceptible to rapid microbial degradation. Despite carrion's susceptibility to putrefy and quickly turn unpalatable, the burying beetle Nicrophorus vespilloides is seemingly immune to any ill effects of feeding on decaying carcasses. Carrion is the sole source of nutrition for the larvae, and the maintenance of its quality is important for larval survival and development. Carcasses support a wide diversity of life forms including bacteria, fungi, nematodes, and mites that can affect carcass quality as well as compete with larvae for nutrients. How do the burying beetles cope with a challenging resource such as carrion, despite burying it in the microbe-rich environment of soil?

We demonstrate that the burying beetle successfully manages the carrion microbiota by preventing microbial succession typically associated with putrefaction. Instead, beetles inoculate their own gut microbes containing specialist, symbiotic bacteria and fungi on the carrion, which prevents carrion degradation. By comparing beetle-tended carcasses with untended carcasses, we show that the beetles' gut microbes reduce concentrations of putrefactive polyamines and modify the levels of digestive enzymes. This regulation of the carcass' biochemical and microbial properties is adaptive for beetles, for when disrupted, it reduces larval growth. The study demonstrates how insects modify their habitats to enhance fitness and regulate microbial competitors on an ephemeral resource such as carrion.

From Species Delimitation to Novel Vector Surveillance Tools in Culicoides

Authors: Shults Phillip[2], Eyer Pierre-Andre[1], Vargo Edward[1] and Cohnstaedt Lee[3], [1]Texas A&M University, United States, [2]United States Department of Agriculture, [3]USDA-ARS-NBAF-FABADRU

Abstract: A multifaceted approach to species delimitation can often add clarity to issues such as cryptic species or species complexes. In North America, the main vector species is Culicoides sonorensis which belongs to a complex of species that have both morphological and molecular similarities. Single nucleotide polymorphism (SNP) data from individual Culicoides collected across the US and Canada identified an additional two cryptic species within the existing three species of this complex. The inability to differentiate these from the vector species in the past has undoubtedly affected vector competency estimates, species distribution maps, and vector surveillance efforts. Interestingly, there was also discordance between the SNP and mitochondrial data which explains why barcoding these species has had limited success. Based on these molecular identifications, we highlight subtle morphological and overt ecological differences that support these species designations. The larval habitats within this species complex are vastly different and could be evidence of speciation through ecological niche partitioning. Finally, species-specific microsatellite markers were developed to rapidly, and economically, differentiate the non-vector species from C. sonorensis. Continued study of the speciation of closely related vector and non-vector species will produce valuable evolutionary insights into vector competency as well as improve current surveillance programs.

Evaluation of Hook-SWD for Management of Drosophila suzukii in Low Pressure Systems

Authors: Sial Ashfaq[1], Liburd Oscar[3], Rodriguez-Saona Cesar[2], Rhodes Elena[3], LaTora Gabrielle[3] and Spies Janine[3], [1]Department of Entomology, University of Georgia, Athens, United States, [2]Rutgers University, United States, [3]University of Florida, United States

Abstract: Attract-and-kill tactics work well in low pressure systems where the population of Drosophila suzukii rarely exceeds 20 flies per trap per week. The HOOK trade name encompasses a suite of attract-and-kill products, each formulated for a specific target pest and manufactured by ISCA Technologies. The effect of attract-and-kill product HOOK SWD, containing a proprietary fruit volatile-based attractant, a red dye, and 0.25% spinosad, on D. suzukii infestation was measured in conventional and organic commercial blueberry systems in north central Florida. Treatments included: 1) HOOK® applied every 7 days + grower's standard (suite of pesticides and practices), 2) HOOK® applied every 14 days + grower's standard, and 3) grower's standard only. Adult SWD population density was measured using Scentry® traps and lures, and adult emergence was measured by allowing adults to emerge from decomposing fruit. Trap catches revealed that there was no difference in treatments for adult density. However, larval counts as a result of adult emergence was significantly different among treatments. There was also a treatment-by-week interaction indicating reduced emergence later in the season. There was no difference between Hook applied at 7 d versus 14 d. These findings support the potential use of attract-and-kill as an additional IPM tool for D. suzukii management in low pressure systems.

Integrated and novel management strategies for Drosophila suzukii

Authors: Sial Ashfaq[5], Isaacs Rufus[8], Rendon Dalila[6], Bezerra Da Silva Cherre[1], Dalton Daniel[9], Park Kyoo[9], Walton Vaughn[6], Miller Betsey[6], Ryan Chave[6], Kaiser Clive[6], Jiang Duo[7], Ballman Elissa[4], Pfab Ferdinand[11], Drummond Francis[12], Tait Gabriella[9], Loeb Gregory[2], Bal Harit[4], Hunter Jamal[5], Collins Judith[10], Xue Lan[7], Valerio Rossi-Stacconi Marco[9], Serhan Mermer[9], Rachele Nieri[6], Fanning Phillip[8], Hesler Stephen[3], Van Timmeren Steve[8] and Walton Vaughn[7], [1]Brazilian Agricultural Research Corporation, Embrapa, Brasília, Brazil, Brazil, [2]Cornell University Geneva, New York, United States, [3]Department of Entomology, Cornell University, Cornell AgriTech, New York Agricultural Experiment Station, Geneva, NY, United States, [4]Department of Entomology, Michigan State University, United States, [5]Department of Entomology, University of Georgia, Athens, United States, [6]Department of Horticulture, Oregon State University, United States, [7]Department of Statistics, Oregon State University, United States, [8]Michigan State University, United States, [9]Oregon State University, United States, [10]School of Biology and Ecology, University of Maine, United States, [11]University of California, United States, [12]University of Maine, United States

Abstract: Spotted-wing drosophila, Drosophila suzukii, is a worldwide pest of soft-skinned, stone and small-fruit. This species is able to utilize different habitats and substrates for both nutrition and reproduction. This capacity can be attributed to a significant capacity for adaption, a topic of multiple investigations. Here we will discuss seasonal biology, overwintering survival strategies, the use of population models, cultural, behavioral and chemical management options within the context of a whole-production management system.

Practitioners affected by this insect are currently largely dependent on agrochemicals in order to maximize yields and maintain quality standards. In some cases these crops have agrochemical input costs that are 61 times higher than non-specialty crops, in part because of this damaging insect. D. suzukii management costs can comprise up to 1/6th of the production costs of fruit production. These inputs however result not only on economic costs. Additional costs include those to the environment, pesticide resistance, and secondary pest outbreaks. The introduction of new control strategies including agrochemicals can be slow and corporate consolidations have reduced the number of organizations investing in R&D, which negatively affects the availability of novel control strategies. The goal of this talk is to provide a perspective of how season-long coordinated, novel, and conventional management strategies can result in significant savings to practitioners.

Non-target effects of insecticides labelled for organic use for management of Drosohila suzukii in berry crops

Authors: Sial Ashfaq[1], Liburd Oscar[3], Roubos Craig[4], Rhodes Elena[3], Rufus Isaacs[2], Spies Janine[3], Sarkar Nupur[3] and Fanning Phillip[2], [1]Department of Entomology, University of Georgia, Athens, United States, [2]Michigan State University, United States, [3]University of Florida, United States, [4]University of Georgia, United States

Abstract: Drosophila suzukii is an invasive pest of soft fruits in North America, South America, and Europe. This destructive pest has led to the disruption of berry IPM programs due to the increase use of insecticides to manage this pest. Thus far, only one insecticide, spinosad (Entrust®) labelled for organic use has proven effective against D. suzukii populations. As more insecticide products become available for organic growers it is important to evaluate their residual effects on key natural enemies in the system. Here, we evaluate the effects of six organic insecticides alone and in combination with three adjuvants and two phagostimulants on three common natural enemies including two predators, Orius insidiosus and Chrysoperla rufilabris, and a parasitoid wasp, Aphidius colemani in laboratory bioassays. Sabadilla alkaloids caused mortality to O. insidiosus equal to that of spinosad. All insecticides evaluated were slightly toxic to A. colemani. The adjuvant, polyether-polymethylsiloxane-copolymer polyether caused mortality that was not significantly different from spinosad. When the sublethal effects of the two predatory species were examined by measuring eggs laid and % egg hatch, minimal sublethal effects were observed in C. rufilabris. Alternatively, all insecticides resulted in a reduction in egg hatch in O. insidiosus compared with the control.

Status of Insecticide Resistance in Drosophila suzukii in the United States

Authors: Sial Ashfaq[2], Burrack Hannah[1], Isaacs Rufus[4], Chiu Joanna[3], Hamby Kelly[10], Liburd Oscar[7], Rodriguez-Saona Cesar[5], Gress Brian[6], Drummond Francis[9], Zalom Frank[6], Disi Joseph[8], Spaulding Nathan[8] and Van Timmeren Steve[4], [1]Department of Entomology and Plant Pathology, North Carolina State University, United States, [2]Department of Entomology, University of Georgia, Athens, United States, [3]Dept. of Entomology and Nematology, University of California Davis, United States, [4]Michigan State University, United States, [5]Rutgers University, United States, [6]University of California Davis, United States, [7]University of Florida, United States, [8]University of Georgia, United States, [9]University of Maine, United States, [10]University of Maryland, United States

Abstract: Drosophila suzukii is an invasive pest of small and stone fruits in the United States. Females oviposit into ripe or ripening fruit and larvae feed and develop inside the fruit. Due to very low tolerance for infested fruit in the market, preventative insecticide applications are made to control this pest which is not a sustainable approach and may lead to resistance development in field populations of D. suzukii. It is therefore extremely important to monitor field populations for resistance and implement resistance management strategies proactively. This presentation will provide information on protocols developed for rapid screening of field populations and results of a survey conducted to assess status of resistance against commonly used insecticides in D. suzukii field populations in the United States.

Effects of DEHP on development, ecdysteroid pathway, and reproduction of the moth Spodoptera littoralis

Authors: Siaussat David[4], Aviles Amandine[2], Maria Annick[5], Goutte Aurélie[3], Alliot Fabrice[3], Bozzolan Francoise[2], Boulogne Isabelle[1], Massot Manuel[2], Maibeche Martine[2] and Dacher Matthieu[2], [1]Normandie University, UNIROUEN, Laboratory Glyco-MEV EA 4358, France, [2]Sorbonne University - Institute of ecology and environmental sciences of Paris, France, [3]Sorbonne University - UMR METIS, France, [4]Sorbonne University, INRA, CNRS, IRD, UPEC, Univ. P7, Institute of Ecology and Environmental Sciences of Paris (iEES-Paris) 75005 Paris, France, [5]Sorbonne University, Institute of Ecology and Environmental Sciences (iEES) - Paris, France

Abstract: Bis(2-ethylhexyl) phthalate (DEHP) is a widely produced plasticizer considered as an endocrine disrupting chemical in vertebrates. Indeed, many studies have shown that DEHP alters hormonal levels, reproduction and behaviour in vertebrates. Few studies have focused on the effects of DEHP on insects while DEHP is found almost everywhere in their natural habitat, in particular soils and plants. Here, we investigated the effects of DEHP on sexual behaviour and physiology of a pest insect, the noctuid moth Spodoptera littoralis. In this nocturnal species, olfaction is crucial for sexual behaviour and ecdysteroids at the antennal level have been shown to modulate sex pheromone detection by males. In the present study, larvae were fed with food containing different DEHP concentrations, then DEHP concentrations were measured in resulting adults (males and females). Hemolymphatic ecdysteroid concentrations, antennal expression of genes involved in the ecdysteroid pathway (nuclear receptors EcR, USP, E75, E78 and calmodulin) and sexual behaviour were then investigated in adult males. The success and latency of mating as well as the success of egg hatchings were also studied from couples with one DEHP male versus one uncontaminated female or couples with one DEHP female versus one uncontaminated male. We also studied the offspring obtained from couples with contaminated females to test transgenerational effect of DEHP. Our results showed a general downregulation of nuclear receptors and calmodulin gene expression for the higher concentration of DEHP, suggesting a peripheral olfactory disruption. We found some effects on male behaviour, but without alteration of their mating rate. Effects on offspring mortality and developmental rate at the N+1 generation were also found for the highest doses of DEHP. Altogether, the study shows for the first time that larval exposure to DEHP could induce delayed endocrine disruptive effects in adults of a terrestrial insect as well as effects on the next generation.

Influence of insecticides on diurnal locomotor activity of Hylobius abietis L. (Coleoptera: Curculionidae)

Authors: Sibul Ivar[1], Ploomi Angela[1], [1]Estonian University of Life Sciences, Tartu, Estonia

Abstract: The large pine weevil, Hylobius abietis, is an economically harmful insect pest in reforestation areas in boreal coniferous forests. The adults cause damage by feeding on the tender bark of stems of young conifer plants. Various methods have been attempted to control H. abietis. The use of pesticides (synthetic pyrethroids, neonicotinoids) in critical areas for environmental and health reasons should be minimised or banned. Many alternative repellents (botanical insecticides) are implemented to protect transplants against weevils. Application of new alternative control methods and introduction of biological insecticides require profound knowledge on the ecology and behaviour of forest pest insects. Little information in known about the diurnal rhythms of locomotor activity.

The aim of current research was to determine how industrially manufactured botanical insecticide karanja oil (a.i. karanjin) and neonicotinoid insecticide Actara 25 WG (a.i. thiametoxam) influence the adult pine weevils locomotor behaviour in laboratory contitions.

The experiments were carried out in an video tracking arena. Ethovision XT 11 (Noldus, The Netherlands) was used to record and analyze the movement of insects.

The results can be summarised as follows:

- In constant laboratory conditions the locomotor activity of the adults of H. abietis began to increase prior to the beginning of experimental darkness, revealing a peak during several hours of darkness, and decreased only some time after the end of the scotophase. In daylight, the beetles were relatively inactive. These rhythms appear to be of endogenous origin.
- Lethal concentration (0.2%) of Actara 25 WG influenced strongly female and male beetles` diurnal locomotor activity. In first hours after treatment beetles had locomotor disturbance and high activity. After 4 hours locomotor activity lowered and persisted low until the end of experiment. On beetles treated with thiametoxam endogenous rhytms disappeared.
- Karanja oil (10.0%) reduced beetles locomotor activity but natural diurnal movement dynamics of insects persisted.

Lethal and mobility effects of insecticides on the beneficial Pterostichus niger Schall. (Coleoptera: Carabidae)

Authors: Sibul Ivar[3], Ploomi Angela[2], Jõgar Katrin[2] and Aru Kristiina[1], [1]Estonian Agricultural Board, Pärnu, Estonia, [2]Estonian University of Life Sciences, Tartu, Estonia

Abstract: Carabid beetles (Coleoptera: Carabidae) are biological indicators in agricultural landscapes. The aim of current research was to determine the food-related effect of industrially manufactured botanical insecticides NeemAzal-T/S, neem oil (a.i. azadirachtin), karanja oil (a.i. karanjin) and neonicotinoid insecticide Actara 25 WG (a.i. thiametoxam) on the mortality and mobility of the adult carabid beetles Pterostichus niger Schall.

The results can be summarised as follows:

- Reduced concentration (0.14%) of Actara 25 WG was the most toxic, causing the death of 43% of P. niger adults within 10 days.
- As a result of a dosage 10 times smaller than the recommended concentration of Actara 25 WG (0.02%), as many (19%) of P. niger died due to this within 10 days, as due to NeemAzal-T/S (12%) and neem oil (12%).
- Considerably less (9%) of P. niger died as a result of karanja oil compared to the reduced concentrations of Actara 25 WG. The preparations of neem (NeemAzal-T/S, neem oil) had similar effect on P. niger as karanja oil.
- Reduced concentrations of Actara 25 WG (0.14% and 0.02%) influenced the mobility of P. niger – 24 h after eating, the mobility of some insects were disturbed or they became immobile. Part of the immobile and insects with limited mobility recovered within 10 days.

Future studies should explain the influences of thiamethoxam and neem preparations to predatory carabid beetles and other beneficial arthropods behaviour and mortality. So far less studied karanja oil known to have insecticidal activity needs more comprehensive studies.

Dynamic interactions between the symbiont Candidatus Erwinia dacicola and its olive fruit fly host Bactrocera oleae

Authors: Siden-Kiamos Inga[3], Koidou Venetia[2], Skoufa Evangelia[3], Papadogiorgaki Sevasti[4], Papadakis Stefanos[4], Chalepakis George[4], Vontas John[1], Livadaras Ioannis[1] and Ioannidis Panagiotis[1], [1]Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology Hellas, Heraklion, Crete, Greece, [2]Department of Biology, University of Crete, Voutes University Campus, Heraklion, Crete, Greece .Institute of Molecular Biology & Biotechnology, Founda, Greece, [3]IMBB, FORTH, [4]UOC

Abstract: The olive fly, Bactrocera oleae, is the most important pest of olive orchards worldwide. The ability of olive flies to utilize olives for their development appears to be rare and unique in nature and has been associated with interactions with symbiotic bacteria. In the current study we reveal critical aspects of this unique symbiotic relationship between the olive fly and bacteria of the genus Candidatus Erwinia dacicola. These new insights presented here may stand as the basis for the future development of novel olive fly control approaches targeting the symbiont, by using molecular and classical tools in smart applications.

The determination of the relative abundance of Ca. E. dacicola with real time quantitative PCR analysis during the life cycle of the olive fly revealed a significant fluctuation between different developmental stages. With the use of microscopy, the localization of the the symbiont and the morphology of the gastric caeca between different larval stages were studied. Second instar larvae appeared with distended gastric caeca, filled with the bacterial mass, while during the third instar stage they were smaller and convoluted. We showed that the bacteria reside extracellularly in the gastric caeca and during the transition to late third instar stage, they are discharged into the midgut accompanied by a change in caeca size and morphology due to the contraction of the muscles surrounding the caeca.

Furthermore, a comparative transcriptomics analysis of gastric caeca dissected out of second and third instar larvae collected from the field, in comparison to samples obtained from a laboratory strain devoid of Ca. E. dacicola was carried out. Two pairwise comparisons were set; gastric caeca from second and third instar larvae, in order to identify genes potentially involved in this developmental transition and gastric caeca from second instar larvae developing in olives and in artificial diet, in order to identify olive fly genes potentially involved in the establishment and regulation of the symbiotic relationship, since wild-type animals contain huge numbers of the symbiont while the laboratory-reared not. Significant changes in transcript expression were noted and genes associated with the developmental changes revealed by the microscopic analysis as well as responses to microorganisms were highlighted.

Entomortierella and red wood ants - candidates for a yet undescribed symbiosis?

Authors: Siedlecki Igor[4], Kochanowski Michał[1], Reszotnik Gabriela[2], Majchrowska Maria[3], Błocka Zuzanna[3], Pawlicka Matylda[1], Płaskonka Barbara[1] and Wrzosek Marta[1], [1]Botanic Garden, Faculty of Biology, University of Warsaw, [2]Faculty of Agriculture and Ecology, Warsaw University of Life Sciences, Nowoursy, [3]Institute of Evolutionary Biology, Faculty of Biology, University of Warsaw, [4]University of Warsaw Botanic Garden, Poland

Abstract: Entomortierella is one of the fungal genera recently determined in the study of the Mortierellaceae phylogeny1. The etymology of the name: entomon- refers to a frequent isolation of this genus representatives from insects. However, a determination of any explicit insect-Entomortierella interaction is still missing. In our studies on the mycobiota of Formica polyctena, we have isolated species of Entomortierella from the ants' environment. Precisely, we have isolated those strains from: the ants' cadavers3, infrabuccal pellets, and mound material. Moreover, preliminary results of our study suggest Entomortierella as a characteristic taxon for the F. polyctena mound material compared with the surrounding forest litter. Finally, in our preliminary behavioral studies, we have observed F. polyctena workers feeding on E. beljakovae hyphae and a tendency of ants to prefer this hyphae over soil-borne M. alpina. A nutritional value of E. beljakovae for the ants still remains unknown, however this species produces a great abundance of enlarged cells filled with oil droplets, which could possibly work as a supplementary food source. Observed presence of Entomortierella representatives in the F. polyctena environment and ants' interest towards the fungi suggest an occurrence of a previously unknown ant-fungal interaction, which needs further research to be fully understood.

Designing pest-resilient sustainable apple orchards using simulation models

Authors: Sigsgaard Lene, University of Copenhagen Department of Plant and Environmental Sciences, Denmark

Abstract: Simulation modeling is a highly useful approach when the goal is to predict, quantify, and compare outcomes for a range of complex input variables. There are numerous examples of successful integrations of simulation modeling used to develop sustainable crop management practices and to quantify the downstream effects on pest populations. The API-Tree research team experimentally and observationally gathered data on diverse plants' effects on insect communities in European apple agroecosystems. Using these data as inputs, we use simulation models to evaluate field designs for pest resiliency. We hypothesize these simulations will result in new, location-specific hypotheses for optimal pest-resilient field designs.

Round table. Proposal 1: The system approach to work on lever combination against pests

Authors: Sigsgaard Lene, University of Copenhagen Department of Plant and Environmental Sciences, Denmark

Abstract: Pest management is complex and dynamic and must be able to accommodate changes. In a system approach to pest management, it must rely on combining and integrating pest control methods to keep pest populations below the economic threshold. In integrated pest management –IPM, preventative measures are essential and include conserving and augmenting the natural enemies in and around the crop, choosing healthy cultivars and on crop management decisions, including physical management, use of fertilizers or irrigation and any biological or chemical control. Field experiments allow us to assess, in a real field context, the effect of different levers of action including management practices and lever combinations. In experimental fields, replication of treatments and controls can provide data with less variation and guide what should be tested in more realistic on-farm trials. In on-farm trials cropping system performances can be assessed. Results from experimental fields and on-farm experiments, provide a basis for developing management and testing novel field designs, such as the introduction of intercrops or flower strips.

Proposal 3: Participatory approaches as a way to tackle complexity towards the design of agroecological orchard

Authors: Sigsgaard Lene[2] and Simon Sylvaine[1], [1]INRAE Gotheron, UERI, France, [2]University of Copenhagen Department of Plant and Environmental Sciences, Denmark

Abstract: Perennial systems such as orchards are complex agroecosystems that encompass spatial (i.e., multi-layer design) and temporal (i.e., carry-over effects across consecutive years) dimensions. The design of such systems and/or their dissemination require various types of knowledge, from basic, to applied and empirical knowledge, thus involving a range of stakeholders in a participatory approach to tailor agroecological orchards.

Beside various types of experiments and modelling approaches to evaluate combinations of levers of action against pests and explore scenarii, co-design is a powerful way to innovate and tailor solutions adapted to farmers' context. Co-design permits creativity and to collect, mobilize, organize and hybridize knowledge from various sources in the design of complex agroecosystems. Participative approaches also permit farmers to appropriate experimental systems or parts of experimental systems to design their own ones on their farm. In system experiments, the way levers of action against pests are experimented and decisional systems formulated are key-elements to produce both generic and localized knowledge to feed the agroecological transition and face uncertainties. This advocates for more and renewed interactions among farmers, advisors, researchers and other stakeholders in the foodchain to innovate in a co-design process.

Fungi are more transient than bacteria in caterpillar gut microbiome

Authors: Šigutová Hana[2], Šigut Martin[2], Pyszko Petr[6], Višnovská Denisa[3], Drozd Pavel[5], Kostovcík Martin[1], Kolarík Miroslav[4], Kotásková Nela[2] and Dornák Ondrej[6], [1]Charles University; Institute of Microbiology of the Czech Academy of Sciences, Czech Republic, [2]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic, [3]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic; Microbiology Institute, Academy of, Czech Republic, [4]Microbiology Institute, Academy of Science of the Czech Republic; Department of Botany, Faculty of Science, Charles University, [5]University of Ostrava - Faculty of Science, Czech Republic, [6]University of Ostrava, Czech Republic

Abstract: Despite a massive increase of studies on caterpillar gut microbiota (Insecta: Lepidoptera), there has been an emphasis on bacteria, neglecting the fungal component. Therefore, we lack data on whether are fungal microbiotas resident or transient, and shaped by similar factors as those of bacteria. Moreover, negligible attention has been paid to the role of microbiota in determining the host specificity. We sampled nine polyphagous caterpillar species from several tree species at multiple sites to determine factors shaping leaf and gut bacterial and fungal microbiota. We also investigated to which extent caterpillars acquire their microbiota from the diet. We performed 16S and ITS2 rDNA metabarcoding of leaves and guts to determine composition and richness of the respective microbiotas. Leaf bacteria and fungi were shaped primarily by spatial variables; however, in the guts, they affected only fungi. Gut bacteria were shaped primarily by caterpillar species, with some species harboring more specific assemblages. There were significant differences between leaf and gut microbiotas; in bacteria, this difference was more pronounced. Moreover, the leaf–gut similarity of bacterial but not fungal component differed significantly among caterpillar species, suggesting that some species have more transient bacterial microbiota than others. Our results suggest that the factors shaping caterpillar gut microbiota are complex, and highlight great interspecific differences in microbiota residency within the same insect functional group.

Optimal habitat matching in (semi)aquatic insects: A privilege of specialists?

Authors: Šigutová Hana[2], Harabiš Filip[3], Šigut Martin[2], Dolný Aleš[1] and Choleva Lukáš[4], [1]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic, [2]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic, [3]Department of Ecology, Faculty of Environmental Sciences, Czech University of Life Sciences Prague, Czech Republic, [4]The Czech Academy of Sciences, Institute of Animal Physiology and Genetics, Laboratory of Fish Genetics; Department of Biology and Ecology, Faculty of Science, University of Ostrava

Abstract: Habitat selectivity and its effects on fitness remain poorly understood, especially in relation to specialization. We studied habitat selectivity and its consequences in selected taxa of aquatic insects (Hemiptera: Notonectidae, Coleoptera: Dytiscidae). From each group, we chose one habitat generalist (Notonecta glauca, Dytiscus marginalis) and one species specialized to fishless habitats (Notonecta obliqua, Acilius sulcatus). In a series of mesocosm experiments we quantified their responses to the vegetation type (no macrophytes, only floating macrophytes, floating and littoral macrophytes) and the presence/absence of fish predator (Carassius auratus), both at population and individual levels. To verify the preference–performance relationship, we investigated the survival of two selected species (Notonectidae: Notonecta glauca, Dytiscidae: Graphoderus cinereus) under the same experimental setting. At the population level, no differences were found between specialists and generalists, but similar preferences were found within individual groups. Both species of backswimmers showed a clear preference for pools without fish with floating macrophytes, while in both species of diving beetles it was impossible to determine the preferred habitat type. In backswimmers, at the level of individuals, no differences were found between the preferences of males and females; the decisions of both species were relatively consistent, and were governed by conspecific attraction. Contrarily, the selection of diving beetles was primarily density dependent, regardless of the presence of fish or vegetation structure. Their consistency in habitat selection decisions was generally lower than in backswimmers, and sex-related differences were found; males more often opted for the same habitat type, while female choices were rather random, probably due to male harassment. The survival rate was significantly higher in fishless pools with macrophytes, which was the preferred habitat type for both studied species. Therefore, optimal habitat matching is not a privilege of specialists but is rather a result of intra- and interspecific interactions and life- history strategies. In intensive fishponds with high fish stock density and altered vegetation structure, mismatch of cues for optimal habitat selection may lead to altered structure and composition of aquatic communities. Such ponds, ubiquitous in European agricultural landscape, may either deter many insect taxa from colonization and oviposition, or act as ecological traps through fish predation.

This research was supported by the Czech Science Foundation (GA-18-24425S).

Diversity and phenology of hoverflies (Diptera: Syrphidae) in pine forests (Pinus halepensis Miller) of Algeria

Authors: Sihem Djellab[2], Haroun Chenchouni[1], Nadjoua Mebarkia[1] and Souad Neffar[1], [1]Department of Natural and Life Sciences, Faculty of Exact Sciences and Natural and Life Sciences, Larbi Tebessi University, Tebessa, Algeria

Abstract: Hoverflies are good indicators of ecosystem integrity, especially in drylands. However, the key factors explaining hoverfly diversity in North African forest ecosystems are still not addressed. The current study provides data on the diversity, structure and functional trophic groups (FTG) of the hoverfly community in Aleppo pine forests under a semi-arid climate in northeastern Algeria. Using an entomological net, hoverflies were sampled weekly during 2008–2009. Alpha and beta-diversity of hoverflies and functional trophic group (FTG) were analyzed using several parameters and indices (e.g. species composition, richness, occurrence, diversity, estimations, similarity, etc.). In total, 602 individuals of 21 species were collected with a constant species (Eupeodes corollae)

and four common species (Episyrphus balteatus, Chrysotoxum intermedium, Eristalis arbustorum and Eristalis tenax). Most species (17) occurred accidentally or very accidentally in samples. The highest diversity was recorded during spring, corresponding to the flowering season of most understory plant species. Seasonal rarefaction and extrapolation curves indicated that the expected species richness would be higher in autumn and spring compared to summer and winter. The spectrum of FTG ranked predators first with 52.4% of species, followed by saprophagous (42.8%) and then phytophagous (4.8%) species. Hoverfly communities showed high taxonomic richness and alpha-diversity all over the year, with peaks during spring that coincides with flowering period of most plant species of the forest understorey and favourable climatic conditions.

The Near infrared spectroscopy technique for surveillance of disease vectors; Lessons learnt in the past 12 years

Authors: Sikulu-Lord Maggy[3], Azambuja Gabriela[2], Dowell Floyd [4], Wirtz Bob [1], Mayagaya Valeriana, Ferreira Aline, Lord Anton and Maciel de Freitas Rafael, [1]CDC, [2]Instituto Oswaldo Cruz, [3]The University of Queensland, [4]USDA

Abstract: Vector control programs need high throughput, rapid and cost-effective surveillance tools to estimate the impact of interventions, determine exposure risk and direct interventions to disease hotspots. Traditional surveillance tools such as those that estimate insect survival or those that detect infections in insects are either laborious, technically demanding, or costly for operational use. Our team has been assessing the applicability of the near infrared spectroscopy (NIRS) technique as an alternative surveillance tool for vector control programs. It is a non-destructive one stop shop technique that can be used to measure multiple characteristics of an insect sample such as infection, species identity and age with just a single, 3-second reading of the insect. The technique does not require reagents to operate therefore hundreds of samples can be scanned and analyzed immediately.

We have collected over 20,000 NIR spectra from insects around the world. Our main goal is to be able to use these spectra and machine learning algorithms to predict the age, species, infection status and insecticide status of disease vectors. We will present results on the development and refinement of the technique over the past decade, challenges, lessons learnt and plans underway to successfully facilitate its incorporation into surveillance programs

Chemical composition of Tenebrio molitor (Fabricius, 1798) (Coleoptera: Tenebrionidae) reared on organic waste

Authors: Silva Luciana[1], Lopes Elainy[1], Dourado Leilane[1], Cavalcante Mariana[1], Gomes Reneton[1], Silva Sandra[1] and Lima Stelio[1], [1]UFPI, Brazil

Abstract: The objective of this study was to evaluate the chemical composition of insect meals from Tenebrio molitor (MT) rearing in poultry litter (PL). A total of 250 T. molitor larvae were distributed in a completely randomized design with 5 treatments and 5 replications of 50 larvae per experimental unit. The larvae were placed in plastic containers (30cm x 15cm x 10cm) and arranged in bookshelf metal. The control diet (0%) was based on chicken feed (300g), wheat bran (475g), milk powder (125g), oats (475g) and barley (125g), and the other diets were 25, 50, 75 and 100% replacement of the control diet by PL. The PL used was rice husk base. Each repetition received 300g of feed, and the rearing moisture was controlled with the use of chayote (Sechium edule), which was checked every two days and replaced when it was senescent in appearance. At the end of the experiment, the larvae were accounted for, dehydrated in a greenhouse and ground for meals production. The meals T. molitor were evaluated for their bromatological and mineral composition: Dry matter (DM), mineral matter (MM), crude protein (CP), ether extract (EE), calcium (Ca), magnesium (Mg), phosphorus (P), potassium (K), zinc. (Zn), copper (Cu), manganese (Mn) and iron (Fe). All variables analyzed were subjected to analysis of variance, SNK (Student-Newman-Keuls) test. The values of Ca (0.58e, 21.56d, 25.32c, 28.73b e 30.57a), Mg (2.07d, 6.06c, 10.23b, 9.45b, 12.17a), P (8.360c, 3.44d, 9.29b, 9.88b e 10.39a) and Zn (100.30e, 121.70d, 130.30c, 136.30b e 145.50a) presented linear increase with the addition of PL in the diet; the K (30.27c, 45.87a, 29.90c, 40.73b, 23.83d) and Fe (56.78b, 62.07a, 35.07c, 5.75d, 5.65d) obtained higher values in MT when used 25% of PL and lower with use of 100% of PL; the Cu (10.50a, 11.75a, 2.28b, 1.70b, 1.83b) had higher values for the larvae reared with 0 to 25% of PL and Mn (10.79 c, 7.05d, 15.93b, 20.57a, 3.313e) to 75%. The DM of MT (meals) increased with the addition of PL (86.71b, 86.76ab, 85.98ab, 87.69ab, 88.48a) and CP decreased (48.16a, 45.89a, 46.08a, 47.31a, 40.26b) with the addition of 100% PL. The EE values were higher in the diet with 25% of PL (31.97bc; 34.25a, 31.30c, 27.22d, 32.88b). Larval development was better for the treatment with addition of 50 and 75% of PL (1,020b, 1,009b, 1,458ab, 1,705a, 1,058b), differing from the others, showing satisfactory development of the insects created in the residue. The results indicate that the used PL can influence the meal composition of T. molitor larvae without compromising the nutritional quality and larval development of the insect.

Temporal dynamics of Bemisia tabaci (Gennadius) (Hemiptera: Aleyrodidae) in commercial soybean cultivation

Authors: Silva Luciana[3], Pavan Bruno[4], Oliveira Lorrana[2], Cavalcante Mariana[2], Sobrinho Neurandir[2] and Rodrigues Raimundo[1], [1]UFC, Brazil, [2]UFPI, Brazil, [3]UFPI, Brazil, [4]UNESP, Brazil

Abstract: The objective of this research was to evaluate the temporal dynamics of adults and nymphs of B. tabaci on commercial Bt soybean crops. In the 2017/2018 harvest, the planted varieties were Brasmax BônimoIPRO® and BRS 9180IPRO®, and in the 2018/2019 harvest the varieties sown were Brasmax BólioIPRO® and Brasmax ExtremaIPRO®. The area for each variety was 16,000 m2, divided into 160 sample units of 100 m², in a 10 x 10 m experimental grid. The third trefoil counting from top to bottom was used for sampling of whitefly adults and nymphs. Counting of whitefly adults was done with care to avoid agitating the insects, with the help of a mirror to reflect the leaf's abaxial surface and facilitate counting in three plants per sampling point (4 evaluations/point and 3 plants/evaluation). The number of nymphs was determined by counting the insects on the leaflet's abaxial surface with the aid of a manual magnifying glass, on four leaflets per sample point (4 evaluations/point and 4 leaflets/evaluation). The sampling of nymphs and adults of B. tabaci was carried out in all 160 points previously georeferenced, in which at each sampling point four evaluations were made, 2 m equidistant from the central point (4 repetitions/sampling point). B. tabaci adults were recorded in the crops beginning 56 and 45 days after emergence (DAE), in the varieties Brasmax BólioIPRO® and BRS 9180IPRO®, respectively. In the 2017/2018 crop, nymphs were observed on both cultivars between 70 and 73 DAE. However, it is noteworthy that there was a progressive increase in the number of whitefly adults and nymphs on both varieties evaluated according to the days after emergence, even with the application of insecticides aimed at the control of B. tabaci adults and nymphs. In the 2018/2019 harvest, the beginning of the infestation in the Brasmax BonusIPRO® variety was approximately 64 DAE for adults and nymphs. In the same harvest at around 58 DAE, the onset of infestation by adults and nymphs of B. tabaci in the Brasmax ExtremaIPRO® variety was recorded. In the 2017/2018 and 2018/2019 crops, the number of adults and nymphs of B. tabaci on the Brasmax BônimoIPRO® variety remained close to one adult/plant and one nymph/leaflet. Regarding the BRS 9180IPRO® variety, in the 2017/2018 harvest there was a population abundance of almost ten adults/plant, and about two nymphs/leaflet, at 101 DAE. In the following harvest at 92 DAE the population peak of adults and nymphs of B. tabaci on the variety Brasmax ExtremaIPRO® was observed, with about five adults/plant and four nymphs/leaflet. Considering the stages of development of the plant, in general in both seasons, the infestation started between V8 and R2 and the peak population of adults and nymphs of B. tabaci was between R5 and R7. However, it can be seen that late cycle cultivars presented a greater infestation by B. tabaci adults and nymphs.

Genomics through the lens of pest management: how reference-quality assemblies are bringing the sterile insect technique to the 21st century

Authors: Sim Sheina[2], Geib Scott[1], [1]USDA-ARS Daniel K. Inouye U.S. Pacific Basin Agricultural Research Center, United States, [2]USDA-ARS Daniel K. Inouye US Pacific Basin Agricultural Research Center, Tropical Crop and Commodity Protection Research Unit, Hilo, Hawaii, United States

Abstract: The sterile insect technique (SIT) is a concept devised by Knipling in the 1950s for the genetic control of pestiferous insects. Through the release of sterile males, SIT provides an approach that is a species-specific with few off-target effects but relies on damaging irradiation and manual sorting for mass-release of sterile male-only agents. Through the development of novel genomic techniques, reference-quality and chromosome-scale genome assemblies are accessible to investigators of non-model systems and can now be applied to make advancements in SIT. In our research, we employ single-molecule sequencing, linked-read sequencing, HiC mapping, and linkage mapping to identify genes and loci which can be exploited to produce conditional lethal sex-specific phenotypes that will facilitate male-only releases which could cut programmatic costs of SIT in half. These results are currently being applied in CRISPR microinjection and rearing projects to create a new genetic sexing strains in tephritid fruit flies that pose a threat to specialty-crop agriculture worldwide.

CTL4 gene-knockout to block Plasmodium infection in the vector mosquito

Authors: Simoes Maria L.[1], Dimopoulos George[2], Mlambo Godfree[1] and Dong Yuemei[1], [1]Johns Hopkins Malaria Research Institute, Johns Hopkins Bloomberg School of Public Health, Johns Hopkins University, United States, [2]Johns Hopkins University, United States

Abstract: The development of genetically modified (GM) mosquitoes for malaria control has gained strength through the recent advances in gene-drive technology and an increased understanding of vector-parasite interactions. While most work aiming at the development of GM malaria resistant mosquitoes, suitable for population replacement, has focused on the over-expression of anti-parasitic genes, here we have explored a strategy relying on CRISPR/Cas9-based inactivation of mosquito encoded Plasmodium agonists. During its sexual cycle inside the mosquito vector, Plasmodium engages in intimate interactions and relies in numerous Anopheles derived host factors, which act as facilitators of infection. The C-type lectin CTL4 has been identified as a Plasmodium agonist (Osta et al., 2004). In our recent work we showed that the C-type lectin-mediated protection against parasite melanization in the African vector A. gambiae is dependent on the intensity of infection, rather than the mosquito-parasite combination (Simões et al., 2017). RNA interference (RNAi)-based silencing of CTL4 resulted in melanization and reduction of live parasites, albeit RNAi results in only partial gene silencing. We hypothesized that the knockout (KO) of CTL4 would result in complete melanization of the parasites, and consequently a complete halt of P. falciparum's development inside the mosquito. We are currently using CRISPR/Cas9
technology for targeted CTL4-KO in A. gambiae. We generated gRNA overexpressing A. gambiae transgenic lines that were crossed with the Vasa::Cas9 strain, to generate CTL4-KO A. gambiae mutants. These CTL4-KO GM mosquitoes are being evaluated for parasite blocking of total Plasmodium-agonist disruption. The effects of CTL4-KO on bacterial and fungal development inside the mosquito are also being screened.

Niche conservatism and functional traits of invasive Leaf-beetles

Authors: Simoes Marianna[2], Krull Marcos[1] and Nuñez-Penichet Claudia[3], [1]Leibniz Centre for Agricultural Landscape Research, [2]Senckenberg Research Institute, [3]University of Kansas

Abstract: Non-native invasive insects have major impacts on ecosystem function, agricultural production, and human health. To predict the geographical distributions of these species, correlative ecological niche models are typically used. Such methods rely on assumptions of niche conservatism, although there is increasing evidence that many species undergo niche shifts during invasions. However, knowledge regarding niche conservatism and functional traits related to invasion dynamics remain incipient for many insect groups, in particular to Coleoptera – largest clade of Animalia. We compiled a novel database of 66 globally invasive beetle species, tested for niche expansion, unfilling across this group, and examined if factors such as human influence, climate, feeding habits, and body size may be associated with observed niche changes. Here we present results with a special focus on the family Chrysomelidae.

Mechanisms underlying plant specialization in the pea aphid complex

Authors: Simon Jean-Christophe, INRAE

Abstract: While the vast majority of insect herbivores feed on a few host plants belonging to a single or closely related taxonomic families, the molecular mechanisms underlying plant specialization remain poorly understood. The pea aphid Acyrthosiphon pisum forms a complex of biotypes, each specialized to one or few species of cultivated or wild legumes. This system offers a unique opportunity to study the molecular basis of plant specialization in the complex and to test whether the same or independent gene set determines plant specificity. Using a genome scan approach of pooled individuals from different biotypes of A. pisum, we first revealed hotspots of genomic differentiation that contain several genes of the chemosensory system and the salivary system, two functions respectively involved in host selection and exploitation by the aphid. Using functional tools, we validated the role of specific salivary genes as effectors in the aphid-legume interactions. Finally, using a GWAS approach on a large panel of pea genotypes, we identified resistance factors that may govern the outcome of plant-aphid interactions. Identification of aphid effector targets and the molecular basis of resistance factors in legumes will provide a better understanding of the mechanisms that determine host specificity in A. pisum.

Effects of intercropping aromatic plants with apple trees on aphid control

Authors: Simon Sylvaine[1], Gautier Hélène[2], Morel Karine[3] and Gomez Laurent[2], [1]INRAE Gotheron, UERI, France, [2]INRAE Avignon, PSH, France, [3]INRAE Gotheron, UERI, France

Abstract: In fruit tree production, the development of alternatives to chemical control is a major lever for solving the problems caused by the intensive use of pesticides. Compared to a monoculture, several studies have shown the benefits of introducing companion plants (CPs) with crops to repel pests and attract their natural enemies. However, the field evaluation of candidate CPs has not been carried out in orchards, which is a bottleneck for the use of this strategy by farmers. We hypothesized that some aromatic plants (Rosmarinus officinalis, and Tagetes patula) can affect the performance of aphids favoring their biocontrol, and can promote the action of their natural enemies and improve orchard productivity. Repellent aromatic plants intercropped with apple trees have been tested in a field experiment at the INRAE Gotheron experimental station and compared to grass ground cover as control. We studied the impact of the presence of aromatic plants in orchards on the abundance of the rosy apple aphid (Dysaphis plantaginea), a major pest of apple orchards. Our analytical approach was also based on observations of the abundance of natural enemies and measures of their efficacy in the bioregulation of the pest. This agroforestry system can offer an alternative or a complementary approach to optimize apple pest management and can produce aromatic plants answering the growing demand for these products.

Multifaceted impacts of resin use by honey bees for social immunity and colony health

Authors: Simone-Finstrom Michael[2], Rinkevich Frank[2], Shanahan Maggie[1], Spivak Marla[1], [1]University of Minnesota, Twin Cities, United States, [2]USDA, Agricultural Research Service, Honey Bee Breeding, Genetics and Physiology Research, United States

Abstract: Honey bees are constantly dealing with threats from pathogens, pests, pesticides and poor nutrition. It is critically important to understand how honey bees' natural immune responses (individual immunity) and collective behavioral defenses (social immunity), can improve bee health. One form of social immunity in honey bee colonies is the formation of a propolis envelope, made up of bee-collected plant resins, within the nest that acts as an important antimicrobial layer. Previous research has indicated that honey bees (Apis mellifera) use these resins as both and indirect and direct defense against various microorganisms. Further, a resin-rich environment effects individual physiological immune responses and resin foraging behavior can be influenced by pathogen exposure. The intricate role of propolis on individual bee and colony health is further compounded by other environmental conditions including resource availability, pesticide exposure and the microbiota of the colony. A large-scale effort examining these different factors will be discussed under the context of the impact of increased resin use of colonies involved in a commercial beekeeping operation and those maintained in stationary apiaries in Minnesota and Louisiana.

Gryllus veletis: a model for insect freeze tolerance

Authors: Sinclair Brent, The University of Western Ontario, Canada

Abstract: Freeze tolerance, the ability to survive internal ice formation, was first described in insects more than 250 years ago. However, we still have only a limited understanding of the mechanisms underlying this ability, perhaps because of a paucity of suitable model systems. Here, I introduce a new model freeze tolerant species, the spring field cricket, Gryllus veletis. Gryllus veletis can be reared en masse in the laboratory, and acclimated to induce freeze tolerance. When freeze tolerant, it can survive 7 days at -8°C or 1.5 h at -12 °C. G. veletis is large enough to allow us to dissect and study individual tissues ex vivo. My lab has assembled a transcriptome, characterised the gut microbiome, are embarking on genome sequencing, and are close to developing a functional RNAi protocol for gene knockdown. There are additional untapped resources, including (likely) genetically differentiated populations from its broad geographic range. I will then give two examples of how we have already used G. veletis to show that there is a metabolic cost to recovering from freezing, and that different cryoprotectants in a multi-component system have different functions in cellular protection.

The physiology and functional genomics of invasiveness in the Asian longhorned beetle

Authors: Sinclair Brent[3], Torson Alex[3], Roe Amanda[2] and Doucet Daniel[1], [1]Natural Resources Canada, [2]Natural Resources Canada, Canadian Forest Service, Great Lakes Forestry Centre, Canada, [3]The University of Western Ontario, Canada

Abstract: For many invasive insects, the ability to survive winter can dictate success of establishment and therefore influence the risk they impose on naïve environments. To cope with low temperature stress during temperate winters, many insects enter diapause and become more stress tolerant. The Asian longhorned beetle (Anoplophora glabripennis) is an invasive species whose native range spans both subtropical and temperate climates that likely drive variation in overwintering capacity among populations. Therefore, introduced A. glabripennis could pose variable invasion risk based on their source population. The objectives of this study were to identify transcriptomic and metabolomic markers of diapause and cold tolerance using established, invasive populations of A. glabripennis from North America. Overwintering larvae from these invasive populations enter diapause, suppress their supercooling point using cryoprotectants, and are partially freeze tolerant. These phenotypic changes correlate with significant transcriptomic changes including those functioning in the heat-shock response, epigenetic modification, and insulin signalling. Ultimately, these data will be used to identify population-level differences in the genomic regulatory regions associated with variation in diapause and cold tolerance phenotypes and therefore allow us to develop genomic markers correlated with invasion risk.

Role of Heat Shock Proteins in Aedes aegypti to cope up with high temperature exposure

Authors: Singh Poonam[2], C Dhiman Ramesh[2], Pande Veena[3] and Kumar Virender[1], [1]All India Institute of Medical Sciences, Delhi, India, [2]ICMR- National Institute of Malaria Research, Delhi, India, [3]Kumaun University, Nainital, Uttarakhand, India

Abstract: INTRODUCTION
Dengue is one of the major public health problems in India. Studies have shown that insecticides exposure also imposes stress on mosquitoes' physiology. The present study was carried out to understand the role of Heat-Shock Proteins in response to temperature exposure and the identification of new physiological markers under combined exposure of temperature and insecticides in Aedes aegypti.
METHODOLOGY
Exposure experiments were carried out in Percival Incubator. Survival and exposure experiments were ranged from 5-45°C Temp & 65-75%RH. To optimize the expression of HSPs Quantitative real-time PCR was carried out for detailed analysis. Further, 1H-NMR spectroscopy-based metabolomic analysis was carried out to determine the impact of temperature on physiology along with insecticide exposure (4% DDT/5%Malathion/0.05% Deltamethrin) following the standard procedure. For tissue extract preparation 6% PCA and D20 for spectral acquisition were used. TSP was added as a chemical shift reference.
RESULTS
The results of experiments show a decreasing trend of adult emergence with increasing temperature. The impact of temperature on survival showed that at 36°C and 38°C vector could survive for 12±3.2 and 9±0.81 days only. Enhanced up-regulation of HSP70 was evident at all exposure ranges of temperature. HSP70 & HSP26 showed a significant up-regulation of 219 and 2580 folds at 40ºC for 1-hour exposure while HSP90 up to 18259 fold at 1-hour post-exposure at 35ºC. Actin was used as a control gene. 1H-NMR spectra of Aedes aegypti under temperatures and insecticides exposure revealed the presence of aliphatic, alcohol, vinyl, carbohydrate and aromatic low/ high mol. wt metabolites. The majority of the signals were found between the 0-9ppm part of the spectra. Of identified peaks, the maximum was in the aliphatic region of the spectrum as compared to the aromatic. The generated spectra show that the metabolites composition is highly variable between control & exposed groups (Temp./Insecticide+ Temp./Insecticide). The conc. of ßHOB, Lac, Acetoacetate, Chol, Hist, and Glu were fluctuating between control & exposed groups.
DISCUSSION
The study indicates that the varying exposure of Aedes aegypti to temperature affects longevity and survival. The up-regulation of HSP70, 90 & 26 for 1-hour exposure suggests that the vector is able to withstand the extremes of temp. and reduction in their longevity will not occur as expected. Metabolite profiling revealed the presence of dynamic metabolites and changes in the concentration under stressed exposure. The presence of HSP constituent's amino acids supports the role of HSPs in coping with environmental stress. The changes in the histidine are important as they play a crucial role in enzymatic catalysis and ligand binding. The generated Aedes aegypti metabolite profile appears to be a step forward to understand the impact of temperature in different scenarios of exposure. The detailed results will follow.

Role of Collembola in recycling of nutrients: a case study of Kathara coalmine area of Jharkhand, India

Authors: Sinha Brajkishore[1], Kumari Vidya[1] and HEMBROM AMITA[2], [1]PKRM College, Dhanbaad, India, [2]Yogda Satsang Mahavidyalaya, Jagarnath Nagar, Ranchi Jharkhand, India

Abstract: Collembolans – soil and litter apterygotes play an important role in the carbon cycle and have role in flux of soil biotic carbon pool. An experiment was carried out in the reclaimed over burden dumps (ROBDs) of Kathara coalmine area, Jharkhand, through 2007 – 2009 (early) to analyze the pedosphere arthropod mesofauna in general and Collembola in particular. Three ROBDs along with one disturbed ecosystem system with natural succession (DESWNS) were selected for the study. Through Berlese-Tullgren funnel method field trash were shorted and analyzed in the laboratory. It was observed that from five years old reclaimed over burden dump (ROBD) 305 soil mesofauna arthropod (SMA) were collected, whereas from fifteen years old ROBD 291 SMA, from thirty years old ROBD 407 SMA and from 50 years old DWNS 364 SMA were collected. The diversity index (DI) for five years ROBD was 1.7953, fifteen years ROBD was 1.8258, for thirty years was 1.7846 and for 50 years old DESWNS was 1.8183. In all the four selected sites the percentage occurrence of Collembola was higher with higher diversity index among all other soil mesofauna - Acari, Protura, Diplura, Symphyla, Pseudoscorpion, Enchytraeids and others – collected from the four study sites. Implicitly, collembolans are hard species and thrive in adverse situations. They have succeeded over the other mesofaunal arthropods and support the decay processes for nutrient cycling via micro flora and fauna of pedosphere eventually help in above ground floral succession.
Keywords: Collembola, soil mesofaunal arthropod, Berlese-Tullgren apparatus, reclaimed, ROBDs, pedosphere.

Omnivorous wasps as mobile samplers of particulate matter

Authors: Skaldina Oksana[1] and Leskinen Jari[2], [1]Postdoctoral researcher, Finland, [2]SIB Labs Unit, University of Eastern Finland

Abstract: Insects can be used in biomonitoring as mobile samplers of airborne particulate matter (PM). However, current knowledge on their susceptibility to PM is limited to pollinators. We investigated the capability of two omnivorous wasp species (Vespula sp.) in external accumulation of coarse (PM10) and fine (PM2.5) particles. The internal accumulation of particles in wasps' gut tissues was also assessed considering heavy metals acquisition. Female individuals of V. vulgaris and V. germanica were sampled with a hand-netting near to Harjavalta Cu-Ni smelter and in the reference areas in southwestern Finland. They were analyzed with microscopy (LM, SEM, TEM) and X-ray spectroscopy (EDX) methods. Near to the smelter wasps trapped significantly more particles, which were of bigger size and which surface density was higher. V. vulgaris accumulated larger particles than V. germanica, but that wasn't associated with morphological characteristics such as size or hairiness. In both areas, accumulated surface PM carried clays and silicates. Only in polluted environments wasps consistently carried heavy metal particles (from high to moderate weight %) of Fe, Ni, Cu, and S – major pollutants emitted from the smelter. External PM contamination in wasps is suggested as a qualitative descriptor of industrial emissions.

Target Enrichment Phylogeny of Pipunculidae (Diptera)

Authors: Skevington Jeffrey[2], Moran Kevin[4], Motamedinia Behnam[3], Kelso Scott[1] and Kehlmaier Christian[5], [1]Agriculture and Agri-Food Canada, [2]Canadian National Collection of Insects, Arachnids and Nematodes, Canada, [3]Carleton University, [4]Carleton University, Canada, [5]Senckenberg Natural History Collections

Abstract: Using over 1300 targets developed for Syrphidae phylogenetics, we were able to develop the first large-scale genomic phylogenetic hypothesis for big-headed flies (Diptera, Pipunculidae). We show that the syrphid targets are widely applicable beyond the target family that they were developed for and that resulting topology is similar to a 5-gene analysis published in 2021 but with higher support values. Big-headed flies are primarily parasitoids of leafhoppers and their relatives (Auchenorrhyncha) and we hope that this analysis will lead to a greater understanding of host relationship and morphological evolution while providing a robust comparative framework for future ecological questions.

Recent Advances in Auchenorrhynchan Phylogeny: Insights from Transcriptomic and Genomic Sequencing

Authors: Skinner Rachel K.[2], Dietrich Christopher H.[1] and Walden Kimberly K.O.[3], [1]Illinois Natural History Survey, [2]Purdue University, [3]University of Illinois Urbana-Champaign

Abstract: The hemipteran suborder Auchenorrhyncha, comprising cicadas (Cicadoidea), planthoppers (Fulgoroidea), spittlebugs (Cercopoidea), and leafhoppers and treehoppers, (Membracoidea) is an insect group for which a stable evolutionary hypothesis has been difficult to achieve. In a previous study, we reconstructed auchenorrhynchan phylogeny using 84 auchenorrhynchans representing 27 families. Despite this extensive sampling, several regions of the tree still suffered from lack of support and several biologically important families were not represented. We used transcriptome sequencing or targeted ortholog assembly from genome skimming to obtain data from 44 additional auchenorrhynchan species, including representatives of previously missing families as well as several key lineages from regions of the tree with poor support or unexpected placements. While many of the deep relationships obtained within Auchenorrhyncha were well-supported and retained across data types and analytical methods, others remain unstable; thus, we used partitioned coalescence support scores and four-cluster likelihood mapping to explore putative sources of phylogenetic conflict in this group. Additionally, incorporation of transcriptome and targeted assembly of genomic data are shown to have utility for phylogenetic investigation of some lineages within Auchenorrhyncha, which may benefit future evolutionary and comparative studies in these groups.

Characterization of the Kenyan honey bee (Apis mellifera) gut microbiota

Authors: Slippers Bernard[1], Hamba Tola Yosef[2], Herren Jeremy[3], Paredes Juan[4] and Lattorff Michael[5], [1]FABI, University of Pretoria, South Africa, [2]International Centre of Insect Physiology and Ecology, Nairobi, Kenya; Department of Biochemistry, Genetics and Microbiology, University of, [3]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [4]research scientist, Kenya, [5]University of Nairobi; Martin-Luther-University Halle-Wittenberg

Abstract: Pollinators including honey bees have a major impact on food security worldwide. Their gut microbiota plays important roles in host physiology such as digestion, protection, detoxification and development of immune responses, among others. The honey bee (Apis mellifera) has emerge as model for gut-microbiota host interaction studies due to its high conservation and simplicity. In this study we have characterized for the first time the honey bee gut microbiota in the tropics and in Africa, using 16S rRNA library sequencing. In contrast to other latitudes, we found that the most abundant genera are three bee specific bacterium: Gilliamella, Snodgrassella and Frischella but not Lactobacillus. This suggest that they might play a key role in the tropical African continent and helps to do further analysis on their potential functions in the host.

Selection of resistance in Aedes aegypti by exposure to an essential oil spatial repellent

Authors: Smartt Chelsea[3], Lord Cynthia[1] and Chen Tse-Yu[2], [1]Florida Medical Entomology Lab University of Florida, United States, [2]Florida Medical Entomology Laboratory University of Florida, United States, [3]Florida Medical Entomology Laboratory University of Florida, United States

Abstract: Wide spread insecticide resistance has increased interest in development and use of alternative control strategies. One alternative strategy that has increasing interest is the use of spatial repellents as a means of limiting human exposure to mosquitoes by controlling their access to dwellings. Pyrethroid-based spatial repellents have been shown effective against a variety of biting insects however their popularity may contribute to the spread of resistance to permethrin, one of the most commonly used insecticides worldwide. Mosquitoes with resistant genotypes may have altered phenotypes for life history traits along with reduced mortality after exposure. Thus new products, including spatial repellents, should be investigated and adapted for mosquito control. It is unknown how rapidly resistance may develop to spatial repellents nor the consequences to other mosquito life history traits, but this information is key to effective reduction of human-mosquito contact. This study investigates the efficacy of using essential oils as spatial repellents against Aedes aegypti, with a focus on development of resistance to essential oils and subsequent effects on mosquito life history traits.

Simulated impacts on vectorial capacity from resistance and exposure to insecticides and repellents in Aedes aegypti

Authors: Smartt Chelsea[3], Lord Cynthia[1], Henneberg Austin[2], Light Jebidiah[2] and Chen Tse-Yu[2], [1]Florida Medical Entomology Lab University of Florida, United States, [2]Florida Medical Entomology Laboratory University of Florida, United States, [3]Florida Medical Entomology Laboratory University of Florida, United States

Abstract: High levels of resistance to commonly used insecticides have been documented in many populations of Aedes aegypti, resulting in increased interest and use of alternative chemicals and spatial repellents. Mosquitoes carrying resistance genes to insecticides or repellents may have other changes in their physiology, affecting fitness and vector competence for arboviruses. Exposure to chemicals, whether sub-lethal doses of insecticides or spatial repellents, may also alter physiology. Vectorial capacity, the entomological components of the basic reproduction number of a vector-borne arbovirus, is a useful way to integrate these varied effects to estimate impact on pathogen transmission. Relatively little is known about the relationships between resistance and exposure and mosquito physiology traits (survival, biting rate) and virus interaction traits (infection and transmission rates, extrinsic incubation period). Using an individual based model, we are integrating net effects on vectorial capacity under different assumptions about relationships between traits and resistance or exposure (e.g. increasing, decreasing and no effect). Individual estimates are summed for population level vectorial capacity estimates. We will compare population vectorial capacity across traits, relationships, resistance levels and exposure to assess which are most influential and where better estimates will have the strongest effect on prediction of outcomes. These results will inform mosquito control strategies in an environment of increasing resistance and use of alternative chemicals, and identify regions of parameter space where risk of transmission may increase with exposure.

Host plant based variation in virus load in white peacock caterpillars

Authors: Smilanich Angela[1] and Watanabe Amy[1], [1]University of Nevada, Reno, United States

Abstract: Secondary metabolites in plants serve as a defense mechanism against herbivorous insects. However, some specialist species have evolved to sequester these secondary metabolites and use the compounds to their own advantage. Our study focused specifically on the role of iridoid glycosides (IGs) on virus load in Anartia jatrophae larvae infected by a Junonia coenia densovirus (JcDNV). Larvae were randomly assigned to either the novel host plant of high IG-content (P. lanceolata) or the native host plant, which lacked any IGs (B. monnieri). Quantitative PCR was used to observe viral replication by measuring virus load each day post-inoculation of three different doses. We hypothesized that IGs assist the specialist insect herbivores in fighting off pathogenic infections. Supporting this idea, our study showed a consistently lower viral load in individuals reared on P. lanceolata compared to individuals fed on B. monnieri. Other variables tested revealed a significantly greater viral load in individuals inoculated with a high dose over those given a medium or low dose, and no significant difference in viral load through days sacrificed post-inoculation. Interestingly, there was no significant interaction between host plant and dose given, suggesting that the pattern with host plant was consistent regardless of viral dose given to the larvae. There was also no significant interaction between host plant and day sacrificed. However, even though viral replication progressed consistently through the different days between the two host plants, there was a consistently lower viral load with a slightly steeper viral load decrease in larvae reared on the introduced host plant with high IG content than those reared native host plant lacking any IGs. This suggests that IGs help larvae defend against pathogens by decreasing overall load, possibly by allowing more of the virus to be suppressed or cleared. The mechanisms for how IGs benefit specialist insects still requires further investigation.

Novel immunological interactions as an overlooked aspect of global change: insights from the host range expansion of Lycaeides melissa

Authors: Smilanich Angela[1], Yoon Su'ad[1] and Forister Matthew[1], [1]University of Nevada, Reno, United States

Abstract: The emerging field of ecological immunology seeks to understand how ecological variation may contribute to immunological variation in the wild, and how these levels of variation can contribute to evolutionary processes. My dissertation research has focused on how different components of ecological variation such as novel resource use may impact the immune response of a specialist Great Basin butterfly, Lycaeides melissa, the Melissa blue butterfly. L. melissa has colonized the exotic legume Medicago sativa in the past 200 years; L. melissa frequently utilizes M. sativa throughout its range despite the fact that L. melissa larvae suffer both reduced survival and decreased adult fecundity on this host, compared to development on a common native host Astragalus canadensis. This interaction with the novel, exotic host plant represents a novel immunological interaction due to the fact that nutritional variation is tightly linked with immunological variation in plant feeding insects, an interaction which I sought to quantify in this study. Specifically, I investigated how L. melissa responds to experimental infection with a highly virulent insect pathogen, Junonia coenia densovirus (JcDNV), and whether resistance to this pathogen is affected by host plant use. I asked the following questions: (1) Does host plant quality affect the ability of Lycaeides melissa larvae to resist JcDNV infection? and (2) Will population of origin affect the ability of Lycaeides melissa larvae to resist JcDNV infection? Preliminary results show that L. melissa larvae are less able to resist JcDNV infection when feeding on the novel, exotic host plant.

Field-evolved resistance to Bt crops in Canada

Authors: Smith Jocelyn[1], Farhan Yasmine[1], Hallett Rebecca[1] and Schaafsma Art[1], [1]University of Guelph, Canada

Abstract: Since the introduction of Bt crops in North America over 25 years ago, their use has become integrated into corn production systems as standard practice, typically regardless of the levels of pest populations they were designed to control. Patterns of insect resistance to Bt corn in Canada have generally followed those of the United States; however, in recent years, novel situations have been observed in Canada, including the first instance of field-evolved resistance to Cry1F in Ostrinia nubilalis Hübner (Lepidoptera: Crambidae). This case will be highlighted along with a review of Bt corn resistance in Diabrotica spp. LeConte (Coleoptera: Chrysomelidae) and Striacosta albicosta Smith (Lepidoptera: Noctuidae) in Canada. The implications and challenges to mitigating these resistance cases will be discussed.

Bringing Back the River of Grass: Gauging Melaleuca (Melaleuca quinquenervia) Biological Control Success in Florida's Everglades

Authors: Smith Melissa[4], Allen Dray F.[3], LaRoche Francois[2], Buckingham Gary[3], Wheeler Gregory[3], Rodgers Leroy[2], Purcell Matthew[1], Rayamahji Min[3], Pratt Paul[3], Tipping Philip[3] and Center Ted[3], [1]Australian Biological Control Laboratory, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia, [2]South Florida Water Management District, United States, [3]USDA Agricultural Research Service, United States, [4]USDA Agricultural Research Service, United States

Abstract: The southern tip of North America coalesces into one of the world's largest freshwater wetlands, the Everglades. Though this region is much like an island, home to high biodiversity and endemism, it is also the site of a century of development and landscape scale engineering to control the vast quantities of water. Melaleuca quinquenervia, a tree native to tropical Australia, was planted extensively throughout South Florida as street trees, levee stabilizers and later to reduce standing water in marshy areas. Millions of seeds and seedlings were planted during the first half of the 20th century, resulting in far ranging monocultures of melaleuca trees throughout native sawgrass and tree island habitats. The latter third of the last century saw the start and formation of a collective effort to restore the ecological integrity and function of Florida's vast Everglades, including reducing invasive species, notably melaleuca. Through extensive cooperation with the USDA's Australian Biological Control Laboratory in Brisbane, three biological control agents were released and later successfully established. To further capitalize on the efficacy of these agents, a multi-year, multi-agency areawide project was funded to determine best practices for integrating management techniques. Now fifteen years out from the start of the TAME (The Areawide Melaleuca Eradication) Project, melaleuca populations have contracted significantly from their maximum. Land managers now consider melaleuca "under control" in most areas and resources and attentions have been diverted to more immediately pressing plant invasions. Melaleuca control is an example of successful agent prioritizing and integration of biological control to produce long lasting positive impacts on an ecosystem wide invasive species.

Automatic quantification and classification of honey bee comb and its contents

Authors: Smith Michael[2], Koger Benjamin[1], [1]Department of Collective Behavior, Max Planck Institute of Animal Behavior, Germany; Centre for the Advanced Study of Collective Behaviour, University of Konsta, [2]Department of Collective Behavior, Max Planck Institute of Animal Behavior, Germany; Centre for the Advanced Study of Collective Behaviour, University of Konsta, Germany

Abstract: The ecological dominance of the social insects is due, in part, to their ability to allocate tasks among workers. In honey bee colonies, task allocation is also spatial, because the organization of the nest dictates where certain tasks occur. The spatial configuration of the nest itself changes and develops during a colony's lifetime, reflecting both the current state of the colony, and its environment. Studying comb use and nest development, however, is unfortunately understudied, partly because quantifying the nest requires time-consuming manual tracing. These tedious traditional methods make it intractable for large-scale data acquisition, which limits our understanding of how nests develop. Here, we present a system for automatic, high-precision honey bee comb quantification. We built an affordable imaging box for taking high-resolution images of comb, with uniform lighting, even in field settings. Then, using a deep convolutional neural network for image segmentation (U-Net), we designed software that quickly and accurately quantifies the amount of comb, and the contents of the comb, specifically: capped brood, uncapped brood, honey, pollen, and empty comb. We tested our method in varied environmental conditions, showing that the system is robust across multiple colonies and hive designs. This new method is faster and more accurate than previous manual methods, now making it possible to understand how environmental and biological stressors impact colony health and development.

EFLa-type neuropeptide mRNA trans-splicing in hemimetabolous insects

Authors: Smykal Vlastimil[3], Wu Bulah Chia-Hsiang[1], Chvalova Daniela[1], Hejnikova Marketa[4], Lichy Martin[1], Chen Ping[4] and Dolezel David[2], [1]Biology Centre CAS, Institute of Entomology, Ceske Budejovice, Czech Republic, [2]Biology Centre CAS, Institute of Entomology, Ceske Budejovice, Czech Republic, [3]Biology Centre CAS, Institute of Entomology, Czech Republic, Ceske Budejovice, Czech Republic, [4]Faculty of Science, University of South Bohemia, Ceske Budejovice,Czech Republic

Abstract: EFLa-type neuropeptides are present in many arthropods, including several insect orders. Besides EFLa elusive function, the way how the mature EFLa-encoding transcripts are formed is also enigmatic, as EFLa exons spliced to exons of Proh-4 gene were found in Pyrrhocoris apterus (Heteroptera), Bemisia tabaci (Sternorrhyncha) and Locusta migratoria (Orthoptera). Presence of intergenic Proh-4/EFLa fused transcripts can be theoretically explained by canonical cis-splicing, cis-splicing of adjacent genes (cis-SAG), or even by trans-splicing, a rare molecular mechanism in insects. We focused on P. apterus, where Proh-4/EFLa transcripts represent about 1/10 of Proh-4 expression, EFLa pre-mRNAs lack in-frame translation start site, and where gene-linkage and genome analyses excluded cis-splicing and cis-SAG mechanism of Proh-4/EFLa generation. Trans-spliced Proh-4/EFLa transcripts were detected by full-length mRNA sequencing using Oxford Nanopore technology with isoform-specific resolution. In-silico analysis of 3' splice site (3'ss) strength predicted weak 3'ss of Proh-4 intron 2, permitting trans-splicing with 10-fold stronger EFLa outron 3'ss. Analogous analysis in L. migratoria found less profound Proh-4 to EFLa 3'ss strength difference, reflected in 10-fold lower Proh-4/EFLa trans-splicing, determined by quantitative real-time PCR. We conclude that although the exact trans-splicing mechanism generating Proh-4/EFLa transcripts stays elusive, it can represent conserved and sound gene expression mechanism.

Pursuing proactive approaches to identifying insecticide resistance in blood feeding arthropods (Diptera: Muscidae)

Authors: Smythe Brandon, New Mexico State University, United States

Abstract: Identification of insecticide resistant field populations of horn flies (Haematobia irritans) has historically been reactive. Initial indicators of insecticide resistance are largely based upon consumer observations of decreased efficacies or overall failure of commercial products across time. At which time, researchers can confirm the presence of resistant using available molecular or bioassay techniques. However, the confirmation of insecticide resistance in field populations following ineffective product performance does little to maximize producer profit. Currently, researchers at New Mexico State University are re-evaluating existing confirmational techniques to develop proactive solutions for cattle producers. Modifying existing techniques to provide proactive horn fly management programs will be discussed within the context of developing sustainable animal production solutions.

Phenotypic variability of life-history traits and voracity of Macrolophus pygmaeus (Hemiptera: Miridae) in two populations of Portugal: Mainland and Azores

Authors: Soares António Onofre[1], Borges Isabel, [1]University of the Azores, Portugal

Abstract: Tuta absoluta (Meyrick, 1917) (Lepidoptera: Gelechiidae) is a major pest attacking tomato that may lead to 60-100% of crop losses. This invasive pest species native to South America landed in Europe in 2006, in Spain, and 3 years later it spread to Portugal. In 2012, it was recorded for the first time in the Azores archipelago. Macrolophus pygmaeus Rambur (Hemiptera: Miridae) is a predator used as biological control agent against the tomato leaf miner. The biological characteristics of two populations of M. pygmaeus, one collected in the mainland Portugal and the other collected in the Azores Isalands (Portugal), were studied on single diets of a potential natural prey (T. absoluta eggs) and of a substitute prey (Ephestia kuehniella Zeller (Lepidoptera: Pyralidae) eggs) used for predator mass rearing in biofactories. The comparations included life history traits, including immature development and reproductive performances, population growth parameters, voracity of immature stages and ovipositing females. The most noticeable differences between the biology of populations were in the reproductive performances, in which reproductive performance of the Azorean populations were higher.

Evidence of Lumpy skin disease virus transmission from subclinically infected cattle by Stomoxys calcitrans

Authors: Sohier Charlotte[2], Haegeman Andy[1], Mostin Laurent[1], De Leeuw Ilse[1], Van Campe Willem[1], De Regge Nick[1] and De Clercq Kris[1], [2]Sciensano, Belgium, [1]Sciensano

Abstract: Lumpy skin disease virus (LSDV) is a vector-transmitted capripox virus that causes disease in cattle. Stomoxys calcitrans flies are considered as major vectors and were recently shown to be able to transmit virus from LSDV infected cattle showing typical clinical signs to naïve cattle. Currently no conclusive data is available whether subclinical or preclinical infected cattle play a role in virus transmission. Therefore an in vivo transmission study with 13 donor and 13 acceptor bulls was performed. S. calcitrans flies were placed either on subclinical or preclinical infected animals. Subclinical and preclinical lumpy skin disease (LSD) was characterized by the absence of nodules and detection of LSDV genome. LSDV transmission from vectors fed on subclinical donors was evidenced in 2 out of 5 acceptor animals. One of these acceptor animals developed clinical disease while the other remained subclinical. No proof of LSDV transmission from vectors fed on preclinical donors was observed in the 8 acceptor animals. Our results show that subclinical animals can contribute to virus transmission. Therefore, stamping out of only clinical diseased LSD animals seems insufficient and will possibly lead to reappearance of LSD.

Flower-insect interactions and biodiversity in the Eastern Ghats forest, India

Authors: Solomon Raju Aluri Jacob, Department of Environmental Sciences Andhra University Visakhapatnam, India

Abstract: Insects visit flowers for their sustenance. They use pollen as protein source and nectar as energy source. The pollen they inevitably lose in going from flower to flower is important to plants for pollination. Different insects have different pollinating abilities depending on the floral density and floral morphological and functional characteristics. The interactions between insects and flowers appear to have led to the evolution of certain traits in them for mutualistic benefits. Insects require food throughout the year. Perennial, annual and ephemeral plants play a vital role in sustaining insects. These plants flower at different times and thus provide food to insects throughout the year. Among different plants, perennials, especially trees are very important to sustain insect diversity. In return, plants receive the benefit of self or cross-pollination. Among the insects, bees, wasps and butterflies were observed on different plant species that flower at different times of the year. The field work coupled with lab work indicated that both generalist and specialist pollination syndromes exist. Certain plants use all available insects for pollination while certain other plants have specialized floral traits that are adapted to particular classes of insects. In the eastern ghats forest, dry season is very crucial for the local insects due to the dearth of forage, this is because a few tree species flower at this time and serve as keystone plant species for the structural and functional integrity of the ecosystem. Further, in the study, some self-incompatible and obligately out-crossing endemic and endangered plant species have been recorded and they are obligately dependent on certain categories of insects for their fruit/seed set. The studies indicated that insect-flower interactions are mostly mutualistic and their relationships are the basis for the continued existence of biodiversity in this forest ecosystem. Therefore, it is imperative to take measures for the conservation and management of pollinator fauna in order to ensure the sustainability of plant taxa and the pollinators dependent on them.

Wood ants prefer conifers to broadleaved trees in mixed temperate forests

Authors: Sondej Izabela[1], Finér Leena[3], Domisch Timo[3] and Czechowski Wojciech[2], [1]Department of Natural Forests, Forest Research Institute, Poland, [2]Museum and Institute of Zoology, Polish Academy of Sciences, Warsaw, Poland, [3]Natural Resources Institute Finland (Luke), Natural Resources, Joensuu, Finland

Abstract: Wood ants (species of the subgenus Formica s. str.) are one of the most important groups of insects in forest ecosystems due to their high abundance and activity. Their mutualistic interactions with tree-dwelling aphids can affect tree growth. The Białowieża Forest is widely regarded as the best example as a forest with limited anthropogenic impact in the temperate zone in Europe. We assessed the preference of host trees for Formica polyctena and Formica rufa, the two dominating wood ant species in this ecosystem. In addition, we compared coniferous and mixed stands. In 2017, we chose 15 wood ant mounds of the Formica rufa group: F. rufa (8 mounds) and F. polyctena (7 mounds) based on an earlier wood ant nest inventory, conducted in 2016 in the Białowieża Forest. In March 2017, all trees within the study plots were mapped and their species, diameter at breast height (130 cm above soil level) and distance from the ant mound were measured. In our study we used term 'host trees' and 'non-host trees" as trees foraged upon by the ants and trees not visited by the ants. Around each mound a circular study plot with a radius of 20 m was established. During 2017 and 2018, all trees on the study plots were monitored for ant activity from May to September (twice a month in 2017 and monthly in 2018). If ants were present on the tree trunk, their number was counted on a 50 cm stretch at breast height, representing a snapshot method at the time of assessment.

In mixed stands F. polyctena visited more trees per plot than F. rufa. Formica polyctena might forage a larger area due to higher population sizes, which further confirms higher foraging pressure of F. polyctena in comparison to F. rufa.

In our study area, host trees of the ant-aphid mutualism were larger in diameter than non-host trees. The ants also preferred trees situated closer to their nests. Both in mixed and coniferous stands, the most visited tree species was Norway spruce. The Białowieża Forest is experiencing a massive bark beetle outbreak. This outbreak started in 2012 and already killed approx. 1.4 million m3 of spruce. Outbreaks are likely to further increase in extent and severity in the future due to climate change. As wood ants seem to have concentrated on using spruce as a host tree, it is possible that wood ant colonies are endangered. The decline of living spruce in the Białowieża Forest may endanger their food source and impact on the vitality of ant colonies.

Invasion and control of Lycorma delicatula in the Republic of Korea

Authors: Song Myung Kyu, Chungbuk Agricultural Research and Extension Services(CBARES), South Korea

Abstract: The spotted lanternfly(SLF) or Lycorma delicatula(order Hemiptera, family Flulgoridae) is a planthopper native to China, India, and Vietnam. Although it has two pairs of wings, it jumps more than it flies. Its host plants are grapes, pines, stone fruits, and Malus spp. It was accidentally introduced in Korea in 2006.

The damage by L. delicatula : grapes(The ratio of grapes' commercial value was 19.2% with no paper bag in organic farming because of L. delicatula's nectar. And there was the sucking damage.) and other plants. The hosts of the spotted lanternfly are ailanthus, poplar, grape vine and so on. Total 41 trees are known in Korea.

The ailanthus branch and leaves were withered. The lanternfly spot the sweet dew very much on the fruit, leaves, grape's bag and all of place. The sweet dew became the sooty mold. Because of the sooty mold, the vine truck was infected secondary, the commercial value of grapes was fell down. This grape didn't be sold. The leaf photosynthesis was interrupted by the sooty mold.

In Korea, we used monitoring, spraying the chemicals, physical method to control L. delicatula. The media supported the control time and the government's managing strategy was done.

Time is required to balance the density of the newly introduced pest. Lycorma delicatula does harm to the vine. To reduce the damage of L. delicatula, the governments, Institutes, farmers and all people should strive to pest control.

Neuropeptide bursicon homodimers-induced prophylactic immunity in Tribolium castaneum

Authors: Song Qisheng[1] and Li Jingjing[1], [1]University of Missouri

Abstract: Bursicon is a cystine knot family neuropeptide, composed of bursicon (burs) and partner of bursicon (pburs) subunits. It can form heterodimers to regulate cuticle sclerotization and wing maturation in insects. Recent studies show that bursicon subunits can also form homodimers to mediate midgut stem cell proliferation and prophylactic immunity. However, the underlying molecular mechanism of bursicon homodimer-regulated immune response remains unclear. Using the red flour beetles, Tribolium castaneum, as a model organism, we have shown that burs and pburs were expressed throughout larval-adult development. Knockdown of burs or pburs decreased the expression of antimicrobial peptide (AMP) genes, including Attacin 1-2, Coleoptericin 1 and Defensin 3, in the larvae. Treating larvae with recombinant pburs (r-pburs) protein led to up-regulated expression of these AMP genes in a dose dependent manor. Bacterial infection resulted in increased expression levels of burs and pburs in the larvae. Silencing burs or pburs increased larval mortality upon bacterial infection while injection of r-pburs protein facilitated bacterial clearance. Furthermore, r-pburs protein activated the transcription factor Relish. We infer that bursicon homodimers-induced AMP gene expression is via Relish in T. castaneum.

Current Status and Control Strategies of Lanternfly in Korea

Authors: Soo Kang Wee, Crop Protection Division, National Institutes of Agricultural Science, South Korea

Abstract: Introduction: Since 2000th so many sporadic insect pests have invaded to Korea from abroad. They are Lantern fly (Lycorma delicatula, 2004, from China), citrus flatid planthopper (Metcalfa pruinosa, 2009, from USA), the Ricaniid Planthopper (Ricania shantungensis, 2010, from China) etc. And they are doing great damage to crops. Among them, Lantern fly has been shown to be incomparable with the other two species in terms of spreading rate and damage since it was first discovered in Seoul and Cheonan in 2004. Since the first inflow of L. delicatula into Korea, the area of occurrence is as follows; 1ha(‘06) ? 7ha(’07) ? 91ha(‘08) ? 2,765ha(2009) ? 8,738ha(2010) ? 7,400ha (2011) ? 6,905ha(2012) ? 3,433ha(2013) ? 1,800ha(2014) ? 1,176ha(2015) ? 2,561ha(2016) ? 2,852ha(2017) ? 2,107ha(2018) ? 1,091ha(2019), Since 2011, the occurrence area of Lantern fly has been gradually decreasing.
Methods: In Korea, various techniques have been developed and used for controlling Lantern fly. Through the development of trap plants that attract and kill Lantern fly, sticky traps, registration of various insecticides, wintering survey, early hatching nymph density survey, spawning adult survey, etc. In addition, farmers have jointly controlled joint efforts to reduce the area of occurrence and damage. Currently, a kinds of parasitoid, Anastatus sp. is imported from China and multiplyed and released in large quantity in areas with high density of Lantern fly.
Results/Conclusion: The incidence of Lantern fly invaded in 2004 has been increasing by 2011, and since then, the area has gradually decreased. The most important factor is attributed to the result of close monitoring of pest control personnel in the city and county centers and the joint efforts of the central and local governments.

What alligator weed distribution models in its native and invaded ranges tell about its invasion story and biological control

Authors: Sosa Alejandro[2], Sánchez Restrepo Andrés[3], Reche Vanina A.[1], Cabrera Nora[1], Pratt Paul[4], [1]Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata, [2]Fundación para el Estudio de Especies Invasivas (FuEDEI), Hurlingham, Ar, [3]Fundación para el Estudio de Especies Invasivas (FuEDEI), Hurlingham, Ar, Argentina, [4]USDA, ARS, WRRC, Invasive Species and Pollinator Health Research Unit

Abstract: Biological invasions are one of the most important drivers of biodiversity losses around the world. Weed biological control has a history of more than 100 years, with good examples of success. One example is the introduction of the flea beetle Agasicles hygrophila to control alligator weed (Alternanthera philoxeroides), an amphibious aquatic plant native to Southern South America and has invaded several countries around the world, including Australia, Italy, China and USA. Other potential control agents include beetles Disonycha and Systena. In this work, occurrence records of the weed and control agents were compiled from multiple sources. Ecological niche models were made to establish the potential areas of current and future distribution. Alligator weed future scenarios show an increase in potential and climatically favorable areas towards northern South America compared to the current model. For Agasciles and the other potential agents, models did not show the same trend; on the contrary, the future scenarios are not very different from the current potential areas. Agasciles model was the best matched the most suitable areas of the current Alligator weed. This study allowed us to understand the current distributions as well to estimate future scenarios that will allow us to improve control strategies.

The Apterostigma auriculatum species group: Phylogenomic species delimitation and taxonomy

Authors: Sosa-Calvo Jeffrey[2], Schultz Ted[2] and Rabeling Christian[1], [1]Arizona State University, [2]National Museum of Natural History-Smithsonian Institution

Abstract: The fungus-farming ant genus Apterostigma, occurring in the Neotropics and the Caribbean, is divided into three species groups based on morphological and molecular data: the auriculatum group (13 spp), the pilosum group (30 spp), and the megacephala group (1 sp). Associations between Apterostigma species and their fungal cultivars are strongly correlated with phylogeny. Species in the auriculatum group cultivate agaricaceous fungi, the ancestral fungal cultivar of all fungus-farming ants. Species in the pilosum group cultivate pterulaceous fungi, presumably as a result of a transition from a leucocoprineaceous to a pterulaceous cultivar in their most recent common ancestor. Finally, the single species in the megacephala group is the only lower fungus-farming ant known to cultivate the highly modified and most recently evolved higher cultivar, cultivated by most leaf-cutter ants. To study the associations between the ants and their fungi, Apterostigma species need to be properly delimited. Our dataset includes 142 taxa (58 belonging to the auriculatum group), including eleven paratypes (5 belonging to auriculatum group), and ~2300 UCE loci. Preliminary results suggest that major clades within the auriculatum group originated very rapidly around 10–12 Ma and that the group contains at least nine new species.

Management and Insecticide Resistance of Stink Bug Populations (Hemiptera: Pentatomidae) in Commodity Crops

Authors: Sosa-Gómez Daniel Ricardo[2], Pasini Amarildo[1], Kraemer Beatriz[1], Spalding Correa-Ferreira Beatriz[2], E. D. Vieira Carlos[7], B. R. Martinez Cláudia[5], O. N. Lopes Ivani[3] and E. Husch Patrícia[4], [1]Department of Agronomy, Universidade Estadual de Londrina, Londrina, PR, Brazil, [2]Department of Entomology, Embrapa Soja, Londrina, PR, Brazil, [3]Department of Statistics, Embrapa Soja, Londrina, PR, Brazil, [4]Department of Zoology, Universidade Federal do Paraná, Curitiba, PR, Brazil, [5]Laboratory of Animal Ecophysiology, Department of Physiological Sciences, Universidade Estadual de Londrina, Londrina, PR, Brazil

Abstract: Pest management of stink bugs (Hemiptera: Pentatomidae) on soybean [Glycine max (L.) Merr.], corn (Zea mays L.), and cotton (Gossypium spp.) agroecosystems is of major concern in several countries of the Americas. Euschistus spp., Dichelops spp., Nezara viridula (F.), and Piezodorus guildinii (West.), are the most abundant species. In this presentation we will review their distribution, damaged caused, and methods used to control the most important pest species in the Americas, with emphasis on those occurring in Brazil. We will also present and discuss the implications of the trends toward decreased susceptibility of stink bug populations to insecticides, and the current difficulties to manage these pests. Currently, Euschistus heros (F.) is less susceptible to organophosphate insecticides than in the past. Reduction in E. heros susceptibility to pyrethroids and, to a lesser extent, to neonicotinoids, has also been observed. Metabolic detoxification is involved in organophosphate, neonicotinoid and pyrethroid reduced susceptibility. Use of insecticides with similar mode of action may have favored selection of resistant phenotypes in stink bug populations. Considering the restricted number of insecticides with different modes of action against stink bugs, a defined program of insect resistance management is needed. Some strategies to reach this goal are recommended, and include: 1) Avoid chemical control of overwintering populations. During overwinter, E. heros populations are in diapause and natural enemies are prevalent. Therefore, chemical application is useless to reduce populations and adds pressure to select insect resistant individuals. 2) Use selective insecticides (nucleopolyhedroviruses, Bacillus thuringiensis based products, insect growth regulators, etc.) to control caterpillars with different modes of action from the products used against stink bugs. 3) Check out on fixed times stink bug resistance rates to organophosphates, neonicotinoids, and pyrethroids, and use a proper insecticide. 4) Avoid problems with application technology. 5) Apply integrated pest management measures when action threshold is reached. 6) Do not increase the insecticide dose when control fails, but instead use a product with a different mode of action; and 7) Control weeds and volunteer plants that may host stink bugs. Monitoring and mapping areas of resistance could be useful in insecticide management of stink bug populations. Since their control relies exclusively on chemicals, actions should be taken to reduce selective pressure. Educational programs to train growers to use insecticides wisely should be implemented to improve chemical control. Although large areas (> 2,000 ha) hinder stink bug population monitoring and proper control time, growers should be aware of the consequences of inadequate management of these pests. Ideally, insecticide applications should be restricted to areas where the action threshold has been reached.

From lab to field: Biological control of the Japanese beetle (Popillia japonica) with entomopathogenic fungi

Authors: Sostizzo Tanja[1], Scheibler Franziska[3], Grabenweger Giselher[2], [1]Agroscope, Switzerland, [2]Agroscope, Zurich, Switzerland, [3]ETHZ

Abstract: The Japanese beetle Popillia japonica is an invasive scarab and listed as quarantine organism. Originating from Japan, it invaded North America, the Azores and recently mainland Europe. The gregarious beetle threatens agri- and horticulture by feeding on leaves, fruits and flowers of a wide range of valuable crops and ornamental plants. Larvae feed belowground mainly on grass roots and damage golf courses, football fields and other areas covered with turf. An efficient but environmentally friendly control strategy is pending.

In Switzerland, larval populations of damaging native scarab species, such as Phyllopertha horticola or Melolontha melolontha, are controlled by applying registered products containing the entomopathogenic fungi Metarhizium brunneum or Beauveria brongniartii. The goal of our research is to adapt this control strategy to the invasive pest. In laboratory experiments and large-scale field trials, we assessed the control effects of those registered fungal strains against Japanese beetle larvae and adults.

Inoculation experiments in the laboratory showed that adult beetles are highly susceptible to fungal attack, while larvae resist infection with fungal spores applied by topical spraying. However, when injected directly into the hosts' hemolymph, the fungi were able to infect and kill the larvae. This gives evidence that the cuticle of the larvae plays a major role in the defense against entomopathogenic fungi.

In two field experiments, barley kernels colonized with M. brunneum strain BIPESCO 5 were applied to infested meadows with a no-till seeder. When applied in September, we found no effect of the fungus on the larval population, while the application in spring slightly reduced the number of larvae per square meter. Furthermore, we sprayed M. brunneum conidia dissolved in water against P. japonica adults on a soybean field with an air-supported trail sprayer. While we found an effect on beetles collected after the spray treatment, we did not detect a clear control effect on the field. Hence, a screening for more virulent strains and research on more efficient application methods might help to increase efficacy of fungal treatments against Japanese beetle adults and larvae.

Evolution of sexual conflict in scorpionflies (Mecoptera)

Authors: Soszynska-Maj Agnieszka[6], Perez-de la Fuente Ricardo [5], Wang Ji-Shen [1], Skibińska Kornelia[3], Kopec Katarzyna[3], Krzeminski Wieslaw[3], Szpila Krzysztof[2] and Krzeminska Ewa[4], [1]College of Agriculture and Biological Sciences, Dali University, Dali, China, [2]Department of Ecology and Biogeography, Nicolaus Copernicus University, Torun, P, [3]Institute of Systematics and Evolution of Animals, PAS, Krakow, Poland, [4]Institute of Systematics and Evolution of Animals, Polish Academy of Sciences, Krakow, Poland, [5]Oxford University Museum of Natural History, Oxford, United Kingdom, [6]University of Lodz, Faculty of Biology and Environmental Protection, Poland

Abstract: Scorpionflies (Mecoptera) are one of the oldest holometabolous insects, known since the Permian. They flourished in the Mesozoic but most of their lineages rapidly declined during the Cenozoic. Mecoptera are models in sexual conflict study as their mating practices are very diverse, including coercive behaviour and nuptial gift provisioning. The male behaviour towards the female may be coercive in such a degree that the expression 'rape' has been used in the past for describing their mating rituals. The role of palaeontology in sexual conflict studies remains negligible, namely due to the paucity of well-preserved fossils. Mecoptera were very abundant insects in the past, so their fossil evidence is abundant enough to trace the evolution of their mating behaviour. Three exceptional scorpionflies from three different Cretaceous and Eocene ambers deposits, each belonging to a distinct panorpoid lineage allow us to extrapolate trends observed among extant relatives. Fossil evidences suggest that panorpoid mecopterans had accordingly disparate mating strategies in the past. The forcing mating strategy in this group is secondary derived and did not evolve prior to the Eocene. However, extreme coercive mechanisms did not survive until today among scorpionflies. Our data provide first steps toward gaining a deep-time perspective able to inform discussions on the evolution of mating-related sexual conflict over mating among insects.

Importance of mobility of plant pests across borders

Authors: Soto Antonia[1], Benito Marco[2], Puig Javier[2], Romero Elena[2], Martinez-Blay Victoria[2], [1]Universitat Politècnica de València, Spain, [2]UPV. Instituto Agroforestal Mediterraneo. Spain

Abstract: The increase in international trade over the recent decades has risen the number of exotic insect species that cross borders, and with this, the invasion of plant pests. Invasive species are a very important issue, they cause significant losses on agricultural production and have intense impact on the environment. The entry of these organisms produces an enormous economic expense in the public sector to be able to carry out the official management and the private sector sees it yields greatly reduced.

The group of mealybug insects are typical invasive pests due to their small size and cryptic behaviour. These population outbreaks are frequent when mealybugs are introduced into new areas without their specific natural enemies. The invasive condition of the family pseudococcidae and the difficulty to control them by chemical methods have made this group of insects a target of this problem. In recent years we have several examples in Europe, Delottococcus aberiae De Lotto species is one of them in citrus crops in eastern Spain. This species of mealybug is native to southern Africa and was recorded for the first time in Spain in 2009. It is an invasive citrus pest that cause different types of direct fruit damage, mainly protuberances around fruit calyx or size reduction. A large percentage of the distorted fruit loses completely its commercial value. At present, chemical control is the main strategy used to management the populations of this pests.

To avoid these problems, it is necessary to implement tools that make these invasions difficult. It would be very appropriate to give a globalization perspective to this type of problem. For example, well-done Pests risk analysis can be highly beneficial, can be an important tool that can limit the impact of harmful exotic species. On the other hand, mealybugs are a target of biological control strategies, for this reason, establishing agile classic biological control programs, based on the introduction and release of exotic natural enemies from the native area of the pest, seems another good management tool. It is essential to detect the mobility of plant pests and reduce the risk of invasive pests through the increasingly globalization of measures.

Diversity, transmission mode, and evolution of symbiosis in an insect community

Authors: Souza Beraldo Camila[1], Duplouy Anne[1], [1]The University of Helsinki, Finland

Abstract: Species communities are shaped by a wide diversity of ecological interactions, including symbiosis. Defined as a long-term interaction between dissimilar species, symbiotic interactions range on a continuum between costly and beneficial, depending on the host-symbiont system considered. For instance, the symbiotic bacterium Wolbachia, which is estimated to infect about 60% of all insect species, can either benefit its host in presence of pathogens, or negatively affect its host fecundity. Consequently, symbionts have been suggested to play an important role in the dynamics of the host species populations, and of their host interactions with competitors, predators or preys. Despite this, most eco-evolutionary studies of natural insect communities rarely consider the insects' symbiotic partners. Hence, we lack a comprehensive view on how important symbionts are in the ecology and evolution of natural host communities. I propose to investigate this topic using the insect community associated to the ribwort plantain (Plantago lanceolata) in the Åland islands. This system is particularly well described, and includes several species that have been studied for over 30 years (e.g. the glanville fritillary butterfly Melitaea cinxia and its associated parasitoids). I aim (i) to characterize the occurrence, abundance and distribution of symbionts in this unique insect community; (ii) to investigate the transmission modes of the symbionts within and between hosts in the field; and (iii) to study whether these different symbiotic interactions have played major roles in the evolutionary history of their insect host species. In order to address these questions, I will combine fieldwork across the Åland islands with experiments in the laboratory, and phylogenetic analyses. My research will contribute to the better understanding of various host-symbiont interactions, and unravel the important role of symbionts in shaping host species interactions in natural communities.

Storage of Trichogramma pretiosum Riley, 1879 at low temperatures and different relative humidity levels to improve Applied Biological Control programs

Authors: Souza Mikaela[3], Coelho Jr. Aloisio[2], P. Parra José Roberto[1], [1]Department of Entomology and Acarology, Luiz de Queiroz College of Agriculture (ESALQ)/University of São Paulo (USP), Brazil, [2]ESALQ-University of São Paulo, Brazil, [3]Luiz de Queiroz College of Agriculture, University of São Paulo, Brazil

Abstract: Biological control (BC) is increasingly important in Brazil as a component of Integrated Pest Management (IPM). With the increase in BC utilization, commercial companies are now selling biological control agents such as the parasitoid wasp Trichogramma pretiosum Riley (Hymenoptera: Trichogrammatidae). One problem encountered is the logistics of storing and transporting these insects, considering that they may need to be stored during periods of low usage or transport from one region to another. If the insects are stored without protocols based on their biology, they may emerge before the scheduled time, be less efficient as pest control agents, or die. The techniques currently used in Brazil have not been tested scientifically, and the low temperatures currently used can affect biological parameters of T. pretiosum and therefore the wasps' performance in the field. The present study evaluated the effect of low temperatures and relative humidity on biological characteristics of different life stages of T. pretiosum. The pupal stage proved to be the most suitable for storage. At a temperature of 10°C, pupae survived for up to 10 days with no deleterious effect on the emerged parasitoids, whereas longer storage periods reduced pupal viability in relation to a control group (insects reared at 25°C). Trichogramma pretiosum females emerged from pupae stored at 10°C showed reduced parasitism capacity after 20 days of storage. The effect of air relative humidity (RH) on T. pretiosum pupae in eggs of A. kuehniella stored at a temperature of 10°C (based on the previous study) was evaluated, using RH levels of 30, 50, 70 or 90 ± 10% and periods of 5, 10, 15 or 20 days. The optimum relative humidity for storage of T. pretiosum was 90%, for up to 20 days at 10°C; the parasitism, pupal viability and sex ratio were not affected. Parasitoids emerged from immatures kept at 10°C and RH of 90% showed a reduction of parasitism capacity just at 20 days of storage. Low RH affected the parasites' viability after 10 days of storage. These data show that pupae of T. pretiosum can be stored up to 15-20 days at 10°C and 90% RH without affecting the biology/quality of immature and adult parasitoids.

How many genes do we need, and which ones?

Authors: Spasojevic Tamara, Natural History Museum Basel, Switzerland

Abstract: Sequencing technologies advanced at great speed in the last years and have made the cost-effective assembly of very large datasets feasible even for non-model taxa. Datasets with hundreds to thousands of genes promise to resolve phylogenetic problems that have previously been deemed unsolvable. However, the allure of big data does not come without its pitfalls, mainly because analysis methodologies have not yet caught up with the growth in dataset size. We investigate how data filtering approaches can help strike a better balance between the number of genes and the rigor of the analytic approach. Filtering criteria such data completeness, evolutionary rate, clocklikness and model mismatch were tested and show differing performance in improving tree resolution. We discuss how these methods allow us to investigate the reliability of the current hypothesis of the evolution of hymenopteran families, especially with respect to the Eusymphyta hypothesis.

Challenges and potentials of total-evidence dating: a case study of hyperdiverse Darwin wasps

Authors: Spasojevic Tamara[1] and Klopfstein Seraina[1], [1]Natural History Museum Basel & University of Bern

Abstract: Total-evidence dating (TED) is currently the most comprehensive approach for estimating divergence times, which integrates extant and fossil taxa, and molecular and morphological information in a Bayesian framework. Along with applying TED to date Pimpliformes, one of the most diverse groups of parasitoids belonging to Darwin wasps (Hymenoptera, Ichneumonidae), we explore the impact of taxon sampling and missing morphological information on the age estimates. Based on newly compiled molecular data from ten nuclear genes and a morphological matrix that includes 222 characters, we show that age estimates become both older and less precise with the inclusion of more distant and more poorly sampled outgroups. In addition, we discover an artefact that might be detrimental for TED: "bare-branch attraction," namely high attachment probabilities of certain fossils to terminal branches for which morphological data are missing. Our analysis recovers a Jurassic origin for Pimpliformes and Darwin wasps, an older origin than previously thought but also that diversification of the crown group happened well before the Cretaceous-Paleogene boundary. Our case study demonstrates that to obtain robust age estimates, total-evidence dating studies need to be based on a thorough and balanced sampling of both extant and fossil taxa.

How old is the association between PDVs and Darwin wasps?

Authors: Spasojevic Tamara[2] and Spasojevic Tamara[1], [1]National Museum of Natural History, Washington, DC, United States, [2]Natural History Museum Basel, Switzerland

Abstract: The age of the association between parasitoid wasps and their adopted viruses can provide insights into the environmental and co-evolutionary context in which it occurred. The oldest known fossil Darwin wasps (Ichneumonidae) date back to the Cretaceous (~130 Ma), but their taxonomic placement remains unclear. The oldest fossils described in Campopleginae and Banchinae – the two subfamilies currently known to harbour PDVs – only date back to the Eocene (~50 Ma). To bridge the gaps in the fossil record, we used a molecular tree of the group, combined with a new method to calibrate the molecular clock that integrates fossils directly into the analysis ("total-evidence dating"). We found that the origin of the family lies deep in the Jurassic (~180 Ma), and that Banchinae and Campopleginae split in the Cretaceous. However, more extensive taxon sampling is needed to pinpoint the more recent gains and losses of virus associations in this group, and it should be coupled with an intensified study of the Darwin wasp fossil record, which still holds many undescribed species.

Compounds without borders: quantifying scent pollution of complex odor blends

Authors: Sprayberry Jordanna, Muhlenberg College, United States

Abstract: Bumblebees are critical pollinators whose populations have been experiencing troubling declines over the past several decades. Successful foraging improves colony fitness, thus understanding how anthropogenic influences modulate foraging behavior may aid conservation efforts. Previous work has demonstrated that pollution of a learned odor signal with the scent of non-insecticidal agrochemicals resulted in modulation of bumblebee foraging behavior. Additional work on diesel exhaust, petrol exhaust, and ozone degradation of floral blends indicates that modulation of floral-odor signals may be a pervasive issue that many pollinators contend with. However, given the vast array of potential odor pollutants, individually testing candidates is an ineffective approach. The ability to quantitatively measure how much scent-pollution of a floral-odor bumblebees can tolerate and subsequently predict responses to novel odor pollutants would represent a paradigm shift in odor-pollution studies. Existing statistical methods for analyzing complex odors have poor predictive power because statistically-derived odor-spaces are rewritten when new odors are added. This study presents an alternative method of analyzing complex odor blends based on the encoding properties of insect olfactory systems. This “Compounds Without Borders” (CWB) method vectorizes odors in a multidimensional space representing the relevant functional group and carbon characteristics of their component odorants. A single vector can be built for any scent, which allows the angular distance between any two odors to be calculated – including a learned odor and its polluted counterpart. The data presented here indicate that CWB-angles are capable of both describing and predicting bumblebee odor-discrimination behavior: odor pairs with angular distances in the 20-29° range are generalized, while odor pairs over 30 degrees are differentiated. Given that the neurophysiological properties underlying CWB-vectorization of odors are not unique to bumblebees, this method of characterizing complex scents likely has applications to other species. Indeed, CWB-angle analysis of published data on a hawkmoth supports the idea that this method may be broadly applicable.

Multicomponent interactions involving insect-transmitted plant viruses: presumed norms, deviations, and spillover effects

Authors: Srinivasan Rajagopalbabu, University of Georgia, United States

Abstract: Insect vectors transmit plants viruses in multiple modes across the transmission spectrum ranging from non-persistent to persistent-propagative fashion. In the process, these microbes (plant viruses) either directly or indirectly (plant modulation) affect the fitness of their insect vectors. The general assumption being that fitness benefits to vector insects are more robust and obvious in the case of persistent viruses as opposed to non-persistent viruses. While this assumption is based on experimental evidence, recent studies with diverse plant viral pathosystems seem to challenge such an assumption. The driving factors seem to be the susceptibility status of the plant to the microbe, the resulting phenotype, and the temporal stability of such a phenotype. Antithetical to the original assumption, the resulting interactions on insect fitness are more favorable in the case of some non-persistent viruses and less obvious in the case of some persistent viruses. At times, the effects of plant-microbe interactions on their vector herbivores are accompanied by a very high degree of fidelity and are so very specific. However, at times, there seem to be spillover effects extending to non-vectors in the same and different feeding guilds. These effects will also be discussed with multiple plant virus-based pathosystem studies. Further, the spillover effects of plant-microbe interactions on the next-trophic level on entomophagous insects with relevance to biological control is also documented. A few relevant papers published by our group are listed below; the presentation in the symposium would revolve around these studies as well as ongoing studies pertaining to impacts of plant-virus-vector interactions on biological control.

Macro- and micro-level impacts of a plant-infecting orthotospovirus on its thysanopteran vector

Authors: Srinivasan Rajagopalbabu[1], Culbreath Albert[1], Shrestha Anita[1], Champagne Donald[1] and Abney Mark[1], [1]University of Georgia, United States

Abstract: Thrips-transmitted orthotospovirus, tomato spotted wilt virus (TSWV), affects several agriculturally important crops resulting in billions of dollars worldwide. Thrips maintain intricate interactions with orthotospoviruses such as TSWV, and transmit such viruses in a persistent and propagative manner. Using a peanut-tobacco thrips (Frankliniella fusca (Hinds))-TSWV pathosystem, we evaluated the component interactions at macro and micro levels via preference bioassays, biology studies, and next generation sequencing. Macro-level assays indicated that TSWV infection altered thrips fitness positively by enhancing egg production, and negatively by reducing survival and increasing developmental time. Next generation sequencing with three life stages of TSWV-infected and non-infected thrips revealed substantial differential gene regulation between infected and non-infected thrips. Differentially expressed contigs pertaining to thrips development, and vector-virus interactions including virus reception and multiplication, and immune responses were annotated. Small RNA sequencing also indicated the virus is being processed differently in thrips than in plant hosts, and demonstrated that there is extensive upregulation of SiRNAs pertaining directly to viral genes. These results show that though there were positive effects on thrips following virus infection (primarily induced by modulation of plant biochemistry), there also were substantial virus-induced negative fitness effects on the vector itself. TSWV is structurally akin to many animal infecting bunyavirales' members, and there seem to be similarities in vector-virus interactions between plant- and animal-infecting members of bunyavirales. All the above-stated results have been published and will be discussed in depth.

Differences in transcriptomes between an orthotospovirus vector and non-vector thrips species

Authors: Srinivasan Rajagopalbabu[1], Culbreath Albert[1], Shrestha Anita[1], Champagne Donald[1] and Abney Mark[1], [1]University of Georgia, United States

Abstract: Thrips function as important pests of numerous agricultural crops Worldwide via directly feeding on them and/or indirectly by transmitting devastating plant viruses such as orthotospoviruses (Order: Bunyavirales). Even though hundreds of species have been recorded as agricultural pests, only a handful of species have been recorded as vectors of orthotospoviruses. Species within the same genus function as vectors and non-vectors of orthotopsoviruses. Thrips-transmit these important group of plant viruses in a persistent-propagative manner, likely resulting in complex and intricate interactions. It is not clear as to which transmission determinants differentiate a vector and a non-vector. To understand this phenomenon, the transriptomes of a vector thrips species (Frankliniella fusca Hinds) and that of a non-vector (Frankliniella tritici Fitch) were synthesized de novo and compared. Gene ontology-based annotations revealed several differences across the functional categories. Transcripts associated with vector-virus interactions in both species were further examined in depth. Results revealed important differences between vector and non-vector thrips. For instance, transcripts of an important ubiquitous cell surface receptor (heparan sulfate) that is known to facilitate virus entry was identified only in the vector species transcriptome, but was conspicuously absent in the non-vector transcriptome. Differences in other transmission determining factors such as virus replication inhibitors (belonging to an important enzyme superfamily known as Viperin), and various immune pathways were also observed between vector and non-vector species. Overall, the immune pathways were more robust in the non-vector as opposed to the vector. The roles of these putative molecular determinants are yet to be functionally validated. Nevertheless, differences in key molecular transmission determinants observed in this study enhance our understanding and offer plausible explanation of why some thrips alone are able to function as vectors of orthotospoviruses. The information included here has recently been published and will be discussed in depth.

Vector-virus interactions in non-persistently- and persistently-transmitted plant viruses

Authors: Srinivasan Rajagopalbabu[2], Gadhave Kiran[1], [1]North Carolina State University, United States, [2]University of Georgia, United States

Abstract: The vector-mediated transmission is obligatory for majority of plant viruses. We studied vector-virus interactions in two diverse pathosystems involving a non-persistent Potyvirus, Papaya ringspot virus (PRSV), and a persistent and circulative bipartite Begomovirus, Cucurbit leaf crumple virus (CuLCrV). Our findings revealed that PRSV differentially altered the vector; melon aphid (Aphis gossypii Glover) and the non-vector; silverleaf whitefly (Bemisia tabaci Gennadius) biology through host plant quality manipulation. CuLCrV transmission studies revealed that B. tabaci transmitted CuLCrV vertically and horizontally with low frequency and accumulation, and showed no transmissibility to non-infected squash plants. These interactions highlight complex and context-specific interactions between Hemipteran vectors and the viruses they transmit- each with significant implications for virus transmission and spread.

Intra-specific host associated morphometric and genetic variability in Helicoverpa armigera (Hübner) populations from India

Authors: Srivastava Chandra[2], Chakravarty Snehel[1], [1]Department of Entomology and Agricultural Zoology, Institute of Agricultural Sciences, Banaras Hindu University, India, [2]Professor, Department of Entomology and Agricultural Zoology, Institute of Agricultural Sciences, Banaras Hindu University, India

Abstract: The Old World Bollworm, Helicoverpa armigera (Hübner) is one of the most prominent polyphagous species of Heliothinae pest complex of worldwide occurrence, including India. In India, this pest species attacks around 96 different crops and thereby causes huge monetary losses. In addition to it, Indian populations of H. armigera occurring on different host plants and at different geographical locations also exhibit differential responses to various selection pressures, thereby rendering its management more difficult in our country. Detailed understanding of the morphometric and genetic differences in different host associated populations of H. armigera can be very useful to know about its population structure. Thus in the present study, we conducted morphological studies and DNA barcode analyses using cytochrome oxidase I (COX-1) gene, which unraveled the mystery of H. armigera breeding on different host plants. The insect cultures collected from eight major crop plants of India, namely chickpea, pigeonpea, pea, okra, tomato, chilli, wheat and cotton were maintained in laboratory on artificial diet up to two filial generations. Phenotypic traits such as body colour patterns, larval and pupal length, length of femur, fore wings and genital organs in adult moths were recorded. For molecular characterization of different host associated populations, the COX-1 gene sequences of H. armigera obtained in FASTA format were imported into the MEGA 6.0 software package and multiple sequence alignments were performed with the ClustalW algorithm using default parameters. The results revealed that populations differed significantly for most of the morphometric traits studied at larval, pupal and adult stages. Significant differences were also observed among the different host associated populations with respect to occurrence of green or brown colour morphs, pigmentation patterns on lateral band and frequency as well as intensity of black pigmentation on larval body. Besides external phenotypic traits, attributes of genital organs like aedeagus and valval length in males and length of bursa copulatrix and bursa seminalis in females also differed significantly among populations. Thirty four polymorphic sites were observed in the COX-1 gene sequences of the studied populations, showing both transitional and transversional substitutions. The pair-wise genetic distance ranged from 0.000 to 0.037 with highest evident between cotton and chilli populations. The neighbour-joining tree also showed clustering of the populations into two distinct clades. Differences based on morphometry and genetic analysis clearly indicates the possibility of existence of different host specific races in H. armigera populations of India. Such information will be very helpful for the development and deployment of appropriate integrated management strategies for this pest species in the region.

Evolution of filter-feeding in aquatic insects dates back to the middle Triassic: new evidence from fossil stemgroup mayflies (Insecta: Ephemerida)

Authors: Sroka Pavel[1] and Staniczek Arnold H.[2], [1]Biology Centre of the Czech Academy of Sciences, Institute of Entomology, Czech Republic, [2]State Museum of Natural History Stuttgart, Department of Entomology

Abstract: Within aquatic insects, mayfly nymphs have developed a remarkable diversity of life strategies and feeding habits. However, early evolution of these strategies and the role of mayfly nymphs in freshwater palaeoecosystems remain largely unknown. We investigated fossil mayfly nymphs of the Grès à Voltzia Formation from the middle Triassic, France, which represents the oldest known outcrop including a diverse mayfly fauna. We focused on three species, namely Mesoplectopteron longipes, Vogesonympha ludovici and Triassoephemera punctata, and investigated both original type material and numerous previously unstudied specimens. As a result, we provide a new interpretation of their morphology, life histories, and systematics. The nymphs of M. longipes, V. ludovici and T. punctata were aquatic and at least the former two species undoubtedly lived in flowing water as passive filter-feeders. This finding represents the so far earliest occurrence of this feeding strategy in aquatic insects. The most obvious morphological adaptations to this lifestyle are long filtering setae arranged in rows on forelegs, analogous to some modern mayfly nymphs.

Is pomegranate a superfood for Leptoglossus zonatus? - Fall hosts and overwintering of a polyphagous insect pest in California

Authors: Stahl Judith[1], Wilson Houston[2] and Daane Kent[1], [1]University of California Berkeley, California, United States, [2]University of California Riverside, United States

Abstract: The leaffooted bug Leptoglossus zonatus (Hemiptera: Coreidae) is a key pest in many California specialty crops. Feeding causes damage in almond early in the season, followed by damage in pistachio around April to mid-May when L. zonatus moves between crops. In fall, large populations of L. zonatus have been observed on pomegranate before migration into overwintering habitats. The location of a suitable fall host for nymphal development of the third and final generation before overwintering may be a key element in developing a successful control program, which also includes improved monitoring of overwintered adults migrating into nut crops in spring.

In this study, the influence of the potentially excellent fall host pomegranate on L. zonatus population build-up is evaluated. Additionally, migration into and out of overwintering habitats is monitored.

Fall survival of caged L. zonatus nymphs and developing adults of the third generation was higher in pistachio than in pomegranate, walnut, and citrus. Surprisingly, a fourth generation was completed in pistachios and walnut, which could be added to the list of L. zonatus host plants. Migration from pomegranate into the overwintering host citrus was observed from beginning of October onwards.

The results will contribute to the development of successful IPM programs for this polyphagous pest in California.

Phylogenetic relationships of true bugs (Hemiptera: Heteroptera)

Authors: Standring Samantha[3], Weirauch Christiane[2], Allen Julia[4] and Johnson Kevin[1], [1]Illinois Natural History Survey, University of Illinois, United States, [2]UC Riverside, [3]UC Riverside, United States, [4]University of Nevada

Abstract: With ~45,000 species, the true bugs (Heteroptera: Hemiptera) are ecologically and behaviorally diverse, including diurnal and nocturnal species as well as herbivores and predators. Additionally, many heteropterans are of economic importance, as several are agricultural pests, disease vectors and beneficial biological control agents. Likely in part due to their economic importance, in recent years a large number of analyses have explored relationships among the seven infraorders. While the relationships between infraorders are largely resolved, relationships between superfamilies and families remain uncertain for many groups, and in some cases have yet to be tested. Previous phylogenetic studies have been limited in their scope primarily by low taxonomic sampling, not enough molecular data to resolve relationships, or no molecular data in some cladistic analyses of morphological characters. Using the new alignment-based sequence extraction software (ALiBaSeq) we extracted loci from a combined transcriptomic and genomic dataset, covering over 80% of heteropteran families. We used the 2395 orthologous loci set from Johnson et al. 2018 as our baits and performed reciprocal blast to test for paralogy. We then generated a phylogenetic hypothesis in IQtree and tested relationships between infraorders, superfamilies and families.

Phylogenomics of Thrips (Thysanoptera)

Authors: Stanford-Beale David[3], Johnson Kevin[5], Sweet Andrew[1], Stanford-Beale David[4] and Mound Lawrence[2], [1]Arkansas State University, United States, [2]Australian National Insect Collection, Commonwealth Scientific and Industrial Research Organisation, Canberra, ACT, Australia, [3]Department of Entomology, Purdue University West Lafayette, Indiana, United States, [4]Dept. of Entomology, Purdue University West Lafayette, Indiana, United States, [5]Illinois Natural History Survey, University of Illinois, United States

Abstract: Members of the order Thysanoptera (Paraneoptera), commonly named thrips, amount to over 6,000 described species. A small number of species are responsible for extensive damage to agriculture and horticulture directly through mechanical feeding damage and indirectly through the spread of tospoviruses, a damaging plant virus group. Previous studies on the phylogenetic relationships of this order lacked the resolution of family and subfamily relationships, especially in the Thripinae subfamily which has previously been shown to be paraphyletic.

We investigated intraordinal relationships between families and used fossils to time calibrate their divergence from one another. Monophyly was tested for the suborders, families, recognized subfamilies, and proposed lineage groups. We built phylogenies using 2050 known orthologs assembled using aTRAM 2.1. We sampled 57 thysanopteran species including representatives of five of the nine families, 51 genera and all Phlaeothripinae lineage groups. The two suborders, Tubulifera and Terebrantia, are recovered as monophyletic. The two most speciose families, Thripidae and Phlaeothripidae, as well as Aeolothripidae, were also recovered as monophyletic. The inferred phylogeny has strong nodal support across the tree, clarifying relationships between families, subfamilies, and the relationships between the lineage groups within Phlaeothripidae. Further sampling is needed to test the relationships of Uzelothripidae, Stenurothripidae, and Fauriellidae; families missing from both the current analysis and previous studies.
We will show examples of how this phylogeny has already impacted thrips research and share results of two downstream studies that rely on the inferred phylogeny: cophylogenetic analysis of Tospoviruses and their Thrips vectors; and the pattern of rapid mitochondrial genome rearrangements in Thysanoptera.

Biodiversity and systematics of jumping plant-lice of the subfamily Liviinae (Hemiptera: Psylloidea: Liviidae) with particular focus on the Neotropics

Authors: Štarhová Serbina Liliya[3], Malenovský Igor[2], Petráková Lenka[2], Queiroz Dalva L.[1], Percy Diana[5] and Burckhardt Daniel[4], [1]Embrapa Florestas, Estrada da Ribeira, Colombo, PR, Brazil, [2]Faculty of Science, Masaryk University, Brno, Czech Republic, [3]Free University of Bozen-Bolzano, Italy, [4]Naturhistorisches Museum, Basel, Switzerland, [5]University of British Columbia, Vancouver, BC, Canada

Abstract: Psyllids constitute a predominantly tropical taxon, characterised by narrow host ranges. The Neotropics house arguably the most diverse and, at the same time, the least studied psyllid fauna. Recent targeted field work in Brazil supports this claim. Only two species of Liviinae, referred to Diclidophlebia, have been reported from Brazil, while over 60 undescribed species are represented in the recent collections. For analysing the host patterns of the Brazilian species, phylogenetic analyses of the world Liviinae were performed using seven mitochondrial and nuclear gene regions (COI, cytb, 12S, 16S and 28S rRNA, wg, H3) as well as 61 morphological characters of adults and immatures. The Brazilian species belong to two new genera. Genus 1 consists of four species associated with Malvaceae. Genus 2 comprises around 60 species of which a majority is associated with Melastomataceae and Annonaceae. Within Melastomataceae, Miconia hosts the largest number of psyllids (19 spp.). The remaining species develop on Asteraceae (4 spp.), Cannabaceae (1 sp.) and Myristicaceae (4 spp.). Neither Melastomataceae nor Annonaceae are restricted to a monophyletic species group, suggesting repeated colonisations by psyllids rather than cospeciation with the psyllids. This is a general pattern known also from other psyllid taxa.

Spatio-temporal dynamics in the microbiomes of pear psyllids reveal complex interactions between host biology and its microbial associates

Authors: Štarhová Serbina Liliya[5], Gajski Domagoj[2], Pafčo Barbora[1], Zurek Ludek[6], Malenovský Igor[2], Nováková Eva[3], Schuler Hannes[4] and Dittmer Jessica[4], [1]Czech Academy of Sciences, Brno, Czech Republic, [2]Faculty of Science, Masaryk University, Brno, Czech Republic, [3]Faculty of Science, University of South Bohemia, Ceske Budejovice,Czech Republic, [4]Free University of Bozen-Bolzano, Bolzano, Italy, [5]Free University of Bozen-Bolzano, Italy, [6]University of Veterinary and Pharmaceutical Sciences, Brno, Czech Republic

Abstract: Psyllids (Hemiptera: Psylloidea) are phloem-feeding insects that can transmit plant pathogens such as phytoplasmas, intracellular bacteria causing numerous plant diseases worldwide. Using 16S rRNA gene metabarcoding, we compared the microbiomes of three sympatric psyllid species associated with pear trees in central Europe, Cacopsylla pyri, C. pyricola and C. pyrisuga, that are vectors of 'Candidatus Phytoplasma pyri', the causative agent of Pear Decline disease. Our results revealed potential relationships between insect biology and microbiome that varied during psyllid ontogeny and between generations in C. pyri and C. pyricola, and among localities in C. pyri. In contrast, no variations related to psyllid life cycle and geography were detected in C. pyrisuga. In addition to the primary endosymbiont Carsonella ruddii, we detected another highly abundant endosymbiont (unclassified Enterobacteriaceae) in C. pyri and C. pyricola which was related to endosymbionts harboured by other Psyllidae. In contrast, C. pyrisuga carried a different taxon of Enterobacteriaceae related to the genus Sodalis. Our study provides new insights into host–symbiont interactions and highlights the importance of host biology and geography in shaping the psyllid microbiome structure.

Wolbachia infection dynamics in a natural population of the pear psyllid Cacopsylla pyri (Hemiptera: Psylloidea) across its seasonal generations

Authors: Štarhová Serbina Liliya[2], Gajski Domagoj[3], Malenovský Igor[3], Corretto Erika[1], Schuler Hannes[1] and Dittmer Jessica[1], [1]Free University of Bozen-Bolzano, [2]Free University of Bozen-Bolzano, Italy, [3]Masaryk University

Abstract: Wolbachia is one of the most abundant intracellular symbionts of arthropods and has profound effects on host biology. Wolbachia transmission and host phenotypes depend on its density within the host, which can be affected by multiple biotic and abiotic factors. However, very few studies measured Wolbachia density in natural host populations. Here, we describe Wolbachia in the pear psyllid Cacopsylla pyri from three populations in the Czech Republic using phylogenetic analyses based on wsp and multilocus sequence typing genes. Our results demonstrate that C. pyri harbours three new Wolbachia strains from supergroup B. To obtain insights into natural Wolbachia infection dynamics, we quantified Wolbachia from C. pyri at one of the sites across an entire year, spanning several seasonal generations of the host. All tested females were infected and Wolbachia density remained stable across the entire period, suggesting highly efficient vertical transmission and no extrinsic influence from the environment and different host generations. In contrast, we observed a tendency towards reduced Wolbachia density in males, with a significant drop in Wolbachia titer in May. This may suggest gender-related differences in Wolbachia-psyllid interactions. Taken together, this study enhances our understanding of Wolbachia infection dynamics in natural host populations.

The Male Aedes Sound Trap: Field results from Central American and Pacific regions

Authors: Staunton Kyran[2], Crawford Jacob[7], Liu Jianyi[6], Grieco John[4], Achee Nicole[4], Snoad Nigel[6], Manrique-Saide Pablo[5], Ritchie Scott[2], Karl Stephan[1], Burkot Thomas[1] and Xiang Wei[3], [1]College of Public Health, Medical and Veterinary Sciences, James Cook University, Cairns, Australia, [2]College of Public Health, Medical and Veterinary Sciences, James Cook University, Smithfield QLD, Australia. Australian Institute of Tropical Health and Medicine, Australia, [3]College of Science & Engineering, James Cook University, Smithfield QLD, Australia, [4]Department of Biological Sciences, Eck Institute for Global Health, University of Notre Dame, Indiana, United States, [5]Unidad Colaborativa para Bioensayos Entomológicos, Universidad Autónoma de Yucatán, México, [6]Verily Life Sciences, South San Francisco, CA, United States, [7]Verily, United States

Abstract: Aedes aegypti and Aedes albopictus are vectors that transmit viruses such as dengue, Zika and chikungunya. Unfortunately, both mosquito species are also expanding their global distributions at alarming rates. Effective surveillance of current and emerging mosquito populations requires sensitive and affordable mosquito traps. We have developed the Male Aedes Sound Trap (MAST), an inexpensive and low maintenance mosquito trap that uses a low power sound lure and a physical design that selectively attracts male Aedes mosquitoes. The Male Aedes Sound Trap was field evaluated in Mexico, Belize, Australia, and Papua New Guinea using a variety of sound lure frequencies in Latin square experiments including BG-Sentinel traps. The Male Aedes Sound Trap captured both male Ae. aegypti and Ae. albopictus in comparable numbers to BG-Sentinel traps, but with dramatic reductions in other insect bycatch including other mosquito species. Male Culex bycatch can be further minimised, when required, by fine-tuning the sound lure frequency emitted from the trap. These results not only present the most comprehensive field studies of male Aedes attraction to various sound lure frequencies, but also support the utility of the Male Aedes Sound Trap as an effective tool for selectively monitoring male Ae. aegypti and Ae. albopictus populations in the Americas and southwest Pacific including Australia.

Environmental drivers of population fluctuations of the painted lady butterfly (Vanessa cardui) in the Western Palaearctic

Authors: Stefanescu Constanti[3], Chapman Jason[1], Reynolds Don[7], Hu Gao[4], van Swaay Chris[2], Roy David[5] and H. Oliver Tom[6], [1]Centre for Ecology and Conservation, and Environment and Sustainability Institute, University of Exeter, China, United Kingdom, [2]Dutch Butterfly Conservation, Wageningen, Netherlands, [3]Museum of Natural Sciences of Granollers, Spain, [4]Nanjing Agricultural University, China, [5]NERC Centre for Ecology & Hydrology, Crowmarsh Gifford, Wallingford, United Kingdom, [6]School of Biological Sciences, University of Reading, United Kingdom, [7]University of Greenwich, United Kingdom

Abstract: One of the main features in the ecology of long-distance migratory insects is the extreme variability of their annual population size. These large fluctuations in numbers are most probably driven by rapid population growth in response to favourable breeding conditions (i.e. a classical ‘r-selected’ strategy) followed by substantial mortality during migration or when new generations are produced in the colonized habitats. However, a rigorous testing of this idea has remained elusive given the lack of precise information on the distribution of wintering populations but also of high quality population data from temperate regions. In this study we focused on the painted lady butterfly (Vanessa cardui), a cosmopolitan multigenerational migrant that, in the Western Palaearctic, undertakes seasonally predictable movements between Europe, North Africa and the Sahelian region. Population data were obtained from 25-yr butterfly counts in three well-established Butterfly Monitoring Schemes in the NW Mediterranean region and NW Europe. Climatic and atmospheric data covering the critical regions and periods where populations originate were extracted with GIS and used as explanatory variables to identify direct and indirect links between the generations monitored in Europe from March to September. Our results confirm that plant productivity (measured as NDVI) in African source regions is the main factor to predict the abundance of populations migrating into Western Europe, but the system is more complex and encompasses a much larger area than previously though. In particular, our results strongly suggest that winter conditions in the Sahel interact with spring conditions in the Maghreb to explain population levels as recorded in Europe in spring and summer. An analysis of migration trajectories demonstrates that it is perfectly feasible for painted ladies to have crossed the Sahara from the West Sahel region to the next potential breeding ground in the Maghreb during periods with suitable high-altitude tailwinds. In addition to conditions in African regions, the climate experienced by populations developing in Europe also explains breeding success and, ultimately, butterfly counts in this continent. Our results shed light not only on the population dynamics of this iconic migrant, but also hold much promise for predicting invasions of a range of other species.

Neither PERIOD, nor TIMELESS 1, nor CRYPTOCHROME 2 are essential components of the molecular clockwork of circadian clock neurons in the Madeira cockroach

Authors: Stengl Monika[1], Werckenthin Achim[2], Koziarek Susanne[2] and Arnold Thordis[2], [1]University of Kassel FB 10 Biology, Animal Physiology/Neuroethology, Germany, [2]University of Kassel, Germany

Abstract: Despite of conserved general schemes, molecular circadian clockworks differ between insect species. With RNA interference (RNAi) the circadian clockwork of the hemimetabolous Madeira cockroach Rhyparobia maderae was examined. With injections of double-stranded RNA (dsRNA) of cockroach period (Rm´per), cryptochrome 2 (Rm´cry2), or timeless 1 (Rm´tim1) we searched for essential components of the clock´s core feedback loop. A single injection of dsRNA of each clock gene into adult cockroaches permanently knocked down respective mRNA levels within ~two weeks, deleting daytime-dependent mRNA rhythms for all three clock genes tested. Rm´perRNAi or Rm´cry2RNAi affected both genes, while Rm´tim1 was independent of both. Unexpectedly, circadian locomotor rhythms always remained. They expressed shorter periods for Rm´cry2RNAi and Rm´tim1RNAi, and normal periods for Rm´perRNAi. We hypothesized that coupled clock cells express different periods based on core feedback loops with either PER, TIM1, or CRY2/PER complexes as negative feedback of the clockwork. [Supported by DFG grants STE531/18-1,2; STE531/26-1 to MS; “clocks” grant by the University of Kassel to MS]

Does it pay off? Fitness consequences of anti-herbivore defence priming by oviposition

Authors: Steppuhn Anke[1], Cramer Rainer[2], [1]Molecular Botany, University of Hohenheim, Stuttgart, Germany, [2]Molecular Ecology, Dahlem Centre of Plant Sciences (DCPS), Freie Universität (FU) Berlin, Germany

Abstract: Insect egg deposition can serve as stimuli which indicate future herbivory for the plant, as it often precedes the attack of herbivorous larvae. Various plant species improve their defence against herbivorous larvae when they previously perceived insect egg deposition as a priming signal. Defence priming is assumed to be an adaptive strategy by which the plant optimizes cost-benefit trade-offs of induced defence. Therefore, we investigated the fitness consequences of oviposition by two herbivorous insect species on the wild tobacco, Nicotiana attenuata. This plant induces more defensive phenylpropanoid-polyamine conjugates in response to feeding by lepidopteran generalist (Spodoptera exigua) and specialist (Manduca sexta) larvae when it had been previously oviposited (1,2). But only larvae of the generalist and not of the specialist are negatively affected in their performance due to this increased defence response. We determined growth parameters and the production of reproductive units such as flowers, capsules and seeds as fitness estimates. Consistent with the effects on larval performance, we found that the fitness loss due to larval feeding by S. exigua was smaller for oviposited plants in terms of seed production, while the fitness loss due to herbivory by M. sexta was not affected by prior oviposition. But, M. sexta herbivory on N. attenuata is also known to induce tolerance responses, such as transient carbon allocation to the roots that can result in a prolonged reproductive phase (3). Therefore, we exposed plants in a full-factorial setup to oviposition and larval feeding by M. sexta, followed by a total aboveground shoot removal. These experiments revealed that a previous oviposition in combination with larval feeding can increase the fitness of regrown plants. Thus, oviposition-mediated defence priming may not just be beneficial if the defence is effective against the herbivore but additionally by increasing tolerance responses to larval feeding.

Improving the use of the IOBC toxicity ratings by using a more realistic test methodology on existing populations and introducing the predator/prey or parasitoid/host ratio

Authors: Sterk Guido, IPM Impact, Belgium

Abstract: Toxicity ratings for side-effects on beneficial organisms, from the IOBC working group ‘Pesticides and beneficial organisms’, are widely used all over the world to identify selective plant protection products, in order to enhance biological control and integrated pest management in crops all over the world. This working group had developed standard methods which are not only used for IPM purposes, but also for registration dossiers. By far the majority of these tests are done under laboratory and semi-field conditions, on fresh residue on glass, plastic or plants, and more rarely in field tests under practical conditions. Although this approach seems to work well for most products, some problems occurred in practice in the early 2000’s where insecticides that were classified as harmless, when tested under IOBC conditions, turned out to be very toxic in practice, eliminating whole populations of pollinators and released predators and parasitoids. Typical examples of this are abamectin, spinosad and indoxacarb. Conversely, some products that were mainly classified as harmful, like tau-fluvalinate, turned out to be rather safe for a number of important biological antagonists. IPM Impact therefore developed its own testing systems on existing populations, rather than on dry residue. More criticism of the IOBC ratings came when it became clear that often no distinction was made between toxicity and the removal of food, in casu the pest, certainly in the case of ‘specialists’ where no alternative food could be given during the trial. Instead, IPM Impact developed a formula to calculate the predator/prey or parasitoid/host ratio, rather than relying only on the toxicity of a product to a beneficial. To achieve this, efficacy trials are conducted for several pests. As a result, products that are moderately harmful (class 3) or even harmful (class 4) could still be used in IPM schemes If effective against the pest, which lead to a more realistic approach in practice.

A heather nectar metabolites inhibits infectivity of a bumblebee parasite through flagellum removal

Authors: Stevenson Phil[1], Koch Hauke[1], Woodward James[1], JF Brown Mark[2] and K Langat Moses[1], [1]Royal Botanic Gardens, Kew, United Kingdom, [2]Royal Holloway University of London, United Kingdom

Abstract: Pollinators may medicate themselves with plant metabolites in nectar or pollen against pathogens. Declining plant diversity through anthropogenic landscape change could, however, reduce the availability of medicinal nectar plants for pollinators, exacerbating their decline. I will here address three important current limits in our understanding of pollinator medication by floral rewards: First, existing studies on the medicinal value of nectar and pollen for bees have either been restricted to few, commercially available phytochemicals, or failed to identify active principles in floral rewards with medicinal qualities. There is therefore a need for new approaches to identify key medicinal plants for pollinators. To overcome this limitation, I here present a bioactivity-guided fractionation in vitro screen of nectar metabolites from 17 important bee foraging plants that newly identifies callunene (4-(3-oxobut-1-enylidene)-3,5,5-trimethylcyclohex-2-en-1-one) from heather (Calluna vulgaris) nectar as a metabolite with strong activity against the common bumblebee gut parasite Crithidia bombi. Second, mechanistic insights into how plant metabolites may affect bee diseases are largely lacking. We therefore studied the interaction between callunene and Crithidia bombi in vivo in the bumblebee host Bombus terrestris. The location of C. bombi infections in the ileum of the host means that the parasite here is protected against the influence of callunene in vivo, as the compound is degraded in the midgut.
In contrast, bumblebees received protection against novel infections through callunene, as short-term exposure to callunene in the anterior gut (crop) of the host induced the loss of the flagellum in C. bombi, a structure that is necessary for attachment and motility in the hindgut. This provides a mechanistic basis for a prophylactic benefit from foraging on heather nectar for bumblebees against C. bombi infections. Third, it remains poorly understood if pollinators can actively chose to visit specific plants with medicinal benefits when infected or threatened with infection, a condition for true “self-medication” behaviour. I will here present novel results analysing the foraging of experimentally infected or uninfected bumblebees in a field experiment, questioning the ability of bumblebees to actively self-medicate. Medicinal benefits may rather be acquired passively through the availability of suitable foraging plants in the environment. The strong decline of a putative medicinal plant like heather (Calluna vulgaris) and plant diversity more generally could therefore affect disease dynamics in the wild.

Harnessing ecosystem services from field margins to support agroecological intensification in common beans (Phaseolus vulgaris).

Authors: Stevenson Phil[6], Gurr Geoff[7], Arnold Sarah[1], Elisante Filemon[9], Darbyshire Iain[5], Ndakidemi Patrick[4], Mkenda Prisila[8], Belmain Steven[3] and Tembo Yolice[2], [1]1. Natural Resources Institute, University of Greenwich 2. The Nelson Mandela African Institution of Science and Technology, United Kingdom, [2]Lilongwe University of Agriculture and Natural Resources, [3]Natural Resources Institute, University of Greenwich, [4]Nelson Mandela African Institution of Science and Technology, [5]Royal Botanic Gardens, Kew, United Kingdom, [6]Royal Botanic Gardens, Kew, United Kingdom, [7]School of Agricultural and Wine Sciences, Charles Sturt University, Orange, NSW, Australia, [8]Sokoine University of Agriculture, [9]The Nelson Mandela African Institution of Science and Technology, Tanzania

Abstract: Agroecological intensification enhances ecosystem services (ES) that have nutritional, environmental and socio-economic benefits for smallholders. Chief among these are natural pest regulation (NPR) and pollination services (PS) which both rely on non-crop habitats for food and refuge. Common beans (Phaseolus vulgaris) are a smallholder staple in East Africa provisioning protein and vitamins alongside income. Smallholders experience major yield shortfalls with beans, but these could be reduced by harnessing ES. Here we report how field margins support beneficial invertebrates in beans. We used exclusion experiments to establish the contribution of PS to yield and economic gain and fluorescent dyes to measure movement between field margins and the crop to identify which insects used field margins. We conducted farmers surveys to assess smallholders’ knowledge about PS and NPR and how farmers value field margins.
Bean yields increased from 681 Kg/Ha in self-pollinated to 1,478kg/Ha in open-pollinated beans with more pods and seeds and greater seed weight per plant. Thus, PS contributes significantly to bean yield. Marking studies demonstrated that flower-visiting insects including natural enemies and pollinators moved from field margins into crops suggesting high levels of spatial flux in the arthropod assemblage. Aphid mortality rates (parasitism levels on sentinel plants) did not differ between the field edges and centre so smallholders with small fields did not experience strong edge effects. Surprisingly few farmers understood the contribution of bees/PS to crop yield while 2% were aware of NPR. Most considered ALL insects as pests. Training programmes explaining the role of field margins supporting ES changed farmers views and behaviours regarding their maintenance. Field margins around smallholder bean fields are useful habitats to natural enemy and pollinating taxa that move to adjacent crops providing NPR sand PS thus safeguarding and augmenting ES through effective land management is vital for optimising bean production sustainably.

Natural Pest Regulation of Orphan Crop Legumes in Africa for smallholders.

Authors: Stevenson Philip [8], Woolley Victoria [1], Belmain Steven [7], Ogendo Joshua[2], Obanyi Janet[2], Ochieng Lawrence[2], Tembo Yolice[3], Ndakidemi Patrick[5], Ndakidemi Baltazar [6] and Arnold Sarah[4], [1]Crop Health and Protection, [2]Egerton University, [3]Lilongwe University of Agriculture and Natural Resources, [4]Natural Resources Institute, University of Greenwich, [5]Nelson Mandela African Institution of Science and Technology, [6]Nelson Mandela African Institution of Science and Technology, Tanzania, [7]University of Greenwich, [8]University of Greenwich and Royal Botanic Gardens, Kew

Abstract: Natural pest regulation (NPR) by wild insects in agriculture is enhanced by flowering plants in field margins that provide shelter, nectar, alternative prey, or pollen. There is little information on how these field margins influence natural enemy abundance or their pest controlling efficacy on orphan crop legumes. Many orphan crops offer climate resilient traits such as drought tolerance, an increasingly important challenge in smallholder farming systems, so support food security among marginalised farmers.

We identified Aphidius colemani as the key natural enemy of black bean aphids (Aphis fabae) a common legume pest in Kenya and Tanzania. The high genetic diversity of the population shown using cytochrome oxidase I barcoding suggested that this species originated in East Africa. In Malawi, Lysiphlebus testaceipes, a neotropical exotic parasitoid, was dominant in legumes and along with A. colemani should be a target for conservation biological control on orphan crops.

Additionally, we report that natural enemy diversity on orphan crop legumes (focusing on beans and lablab) is influenced by crop management strategies and specific field margin species. We also evaluated how NPR integrates with other pest management approaches. For example, we show that commercially available botanical insecticides work more effectively with NPR than synthetic products.

Effects of defoliation on growth and yield in rice

Authors: Stewart Scott[7], Lorenz Gus[6], Crow Whitney[2], Kerns David[3], Thrash Ben[4], Bateman Nick[4], Hardke Jarrod[5] and Gore Jeff[1], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States, [3]Texas A&M University, United States, [4]University of Arkansas Division of Agriculture, United States, [5]University of Arkansas, United States, [6]University of Arkansas, United States, [7]University of Tennessee, United States

Abstract: Rice plants in large field plots were mechanically defoliated at 0, 33, 66, and 100% with a weed eater at two-three leaf, early tiller, late tiller, and green ring growth stages across three planting dates. Large amounts of yield loss were observed when plants were defoliated either 66 or 100% at the green ring growth stage. A delay in heading was also observed when plants were defoliated at 66 or 100% during any growth stage, with delays ranging from 2 days for defoliation occurring at the 2-3 leaf growth stage to 28 days for defoliation occuring at the green ring growth stage. Yield loss and delays in heading were greater for the June planting date compared to the April or May planting date. This data will help form a defoliation based threshold in rice to help keep rice growers profitable.

Evaluation of alternatives to neonicotinoid seed treatments for tobacco thrips management in cotton

Authors: Stewart Scott[6], Lorenz Gus[5], Crow Whitney[3], Kerns David[4], Dodds Darrin[2], Cook Don[2], Gore Jeff[1] and Allen Tom[2], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States, [3]Mississippi State University, United States, [4]Texas A&M University, United States, [5]University of Arkansas, United States, [6]University of Tennessee, United States

Abstract: Tobacco thrips, Frankliniella fusca (Hinds), is a predictable pest of cotton production systems in the United States. Damage from these pests have the potential to delay maturity and reduce crop yields. On average, insecticide seed treatments have resulted in increases of 128 kg ha-1. Thrips management has been highly reliant on insecticide seed treatments, with thiamethoxam and imidacloprid being the two most widely used options. With the decline in efficacy of thiamethoxam, it is vital to identify alternative control measures for effective tobacco thrips control. Therefore, the objective of this study was to evaluate foliar insecticide applications at various timing intervals as an alternative management strategies for thrips control. Studies were conducted during 2015 and 2016, in Arkansas, Mississippi, Louisiana, and Tennessee using a randomized complete block design with four replications. Treatments included foliar applications of acephate at the following intervals: cotyledon, cotyledon plus two weeks post emergence, cotyledon plus two and three weeks post emergence, and only week two and week three post emergence. All treatments were compared to an untreated check and an imidacloprid seed treatment. There were no differences in cotton yield among any treatments, but early management decisions decreased the overall amount of thrips damage sustained.

Evaluation of Bt Resistance in Helicoverpa zea Strains Using Various Bt Cotton Plant Tissues

Authors: Stewart Scott[1], Kerns Dawson[1], Luis Jurat-Fuentes Juan[1] and Ferreira Dos Santos Rafael[1], [1]University of Tennessee, United States

Abstract: Current resistance monitoring methods for Bt resistance in Helicoverpa zea populations consists of populations being assayed for resistance to a single purified Bt protein. Although current monitoring methods adequately indicate if a population has developed resistance to a particular Bt protein, they fail to evaluate how that may impact performance in the field. An assay utilizing Bt cotton plant tissue diet overlays may be utilized to evaluate field performance of a resistant Helicoverpa zea population.

Potential Impact of a New Bt Protein, Cry51Aa2, on Cotton Insect Pest Management in the Southern U.S.

Authors: Stewart Scott[2], Lorenz Gus[3], Gore Jeff[1] and Graham Scott[2], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]The University of Tennessee, United States, [3]University of Arkansas, United States

Abstract: Thrips (Thysanoptera: Thripidae) and tarnished plant bug, Lygus lineolaris (Hemiptera: Miridae), are among the most important economic insect pests of cotton (Gossypium hirsutum) in the mid-southern U.S. including Arkansas, Louisiana, Mississippi, Missouri, and Tennessee. In cotton, these pests are currently managed by insecticides. However, a new Bt cotton technology under development by Bayer CropScience (Cry51Aa2, ThryvOn®) is being evaluated for control of thrips and tarnished plant bug. Field, cage and laboratory studies were conducted to evaluate the effects of this novel Bt-transgenic toxin on insect management in cotton. These data indicated protection from thrips injury to seedling cotton with the Bt trait was as good or better than an insecticide-based approach. The use of this Bt trait also resulted in reduced numbers of immature tarnished plant bugs and protection from plant bug injury. Cotton yields were increased by the use of this Bt trait compared with the non-Bt isoline when insecticides were not used. Although the Bt trait reduced the need for insecticide applications, foliar-applied insecticide applications were needed to provide adequate plant protection against tarnished plant bug. The current recommended treatment thresholds for tarnished plant bug performed similarly well for both Bt and non-Bt cotton isolines.

Interestingly, it appears much of the efficacy of Cry51Aa2 results from insect avoidance, resulting in reduced oviposition on cotton. Adult thrips avoided cotton plants expressing Cry51Aa2c in field choice tests. In a greenhouse choice test, more adult thrips and eggs were found on non-Bt cotton by approximately a 2:1 margin over Bt Cry51Aa2 cotton. In cotton that was not sprayed with insecticides, Bt Cry51Aa2 did not affect the distribution of tarnished plant bugs within the canopy, but in choice tests, adult tarnished plant bugs exhibited a non-preference for Bt-cotton expressing Cry51Aa2 compared with non-Bt cotton. The Bt-transgenic toxin Cry51Aa2 is expected to reduce the need for insecticide applications targeting thrips and tarnished plant bugs and should be a valuable addition to an overall insect management program in cotton. The behavioral response of these pests when exposed to this new Bt toxin will play an important role in the efficacy and potential resistance management strategies once this new technology is introduced commercially.

Use of HaNPV for Corn Earworm Control in Mid-Southern U. S. Soybean & Milo Production

Authors: Stewart Scott[7], Lorenz Gus[6], Crow Whitney[2], Kerns David[3], Thrash Ben[5], Bateman Nick[5], Gore Jeff[1] and Graham Scott[4], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States, [3]Texas A&M University, United States, [4]The University of Tennessee, United States, [5]University of Arkansas Division of Agriculture, United States, [6]University of Arkansas, United States, [7]University of Tennessee, United States

Abstract: Corn earworm (CEW), Helicoverpa zea (Lepidoptera: Noctuidae),is one of the most damaging pests in soybeans. On average, around 50% of southern USA soybeans are infested with corn earworm, costing farmers over $100 million per year. A key part of this cost results from half of the infested acres not being sprayed with chemical insecticides, causing yield loss from “sub-threshold” damage. Among the most used chemical control options are the diamides, which, because of their high cost (>$15 per acre), are applied at high worm thresholds (e.g. 9 per 25 sweeps for $9 per bushel soybeans).

A new approach, based on applying Helicoverpa nucleopolyhedrovirus (NPV) at a much lower threshold, has been evaluated in southern soybeans over the last 6 seasons. NPV is unique, because the virus replicates in the field, providing season-long control at a similar cost to pyrethroids. Using this new approach, farmers can effectively manage low numbers of CEW, thereby greatly reducing the damage that occurs before reaching a diamide action threshold, resulting in significant yield gains. Importantly, NPV will often eliminate the need for a subsequent insecticide application, further improving farmer’s profitability.

There are several other advantages of an NPV-based strategy. This includes resistance management for diamides, which are valuable tools during high pressure situations, and preservation of beneficial species, which provide important “behind-the-scenes” suppression of soybean pests.

The Midsouth Entomologist Group’s NPV recommendation is based on a multi-year evaluation of Heligen, a commercially available Helicoverpa NPV with over 15 years of proven performance in other markets. When applied according to recommendations, a single application of Heligen offers a cost-effective alternative for season long management of corn earworm.

Value of Foliar Insecticide Applications on Bt Cotton Cultivars Against Helicoverpa zea

Authors: Stewart Scott[6], Lorenz Gus[5], Catchot Angus[2], Crow Whitney[2], Kerns David[3], Thrash Ben[4], Bateman Nick[4] and Gore Jeff[1], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States, [3]Texas A&M University, United States, [4]University of Arkansas Division of Agriculture, United States, [5]University of Arkansas, United States, [6]University of Tennessee, United States

Abstract: Cotton is a high input crop for growers. Each year, the cotton bollworm (Helicoverpa zea, Bodie), infests 100% of cotton planted in Arkansas. It remains a major pest of post-bloom cotton in the Mid-South despite widespread use of transgenic Bt cotton varieties and foliar insecticides are often needed to supplement control. Kerns, et. al. conducted studies in 2017 that indicated widespread resistance to Cry1AC, the major gene associated with Bt cotton. Also, a meta-analysis of cotton data since 2007 throughout the Mid-South indicated that there has been increasing amounts of square damage in dual gene technologies. These findings led to research which established a new bollworm threshold based on damaged fruit rather than insect numbers with the new threshold being set at 6% fruit damage; and in some cases where bollworm populations get exceedingly high, such as South-east Arkansas, an egg threshold of 25% is used. This study indicates that dual gene varieties may not provide the protection needed to prevent fruit damage from bollworms and may require foliar applications. In this study, the newer triple gene cotton varieties are currently providing the control needed to maximize yield without requiring foliar applications.

Termites thrive on wood in association with species-specific ectosymbiotic bacterial communities

Authors: Stiblík Petr[1], Bourguignon Thomas[3], Chakraborty Amrita[1], Sillam-Dussès David[5], Odriozola Larrañaga Iñaki[2], Kolarík Mirek[2], Lo Nathan[4], Soukup Patrick[1], Baldrian Petr[2], Vetrovský Tomas[2] and Katerina Votýpková[1], [1]Faculty of Forestry and Wood Sciences, Czech University of Life Sciences, Prague, Czech Republic, [2]Laboratory of Environmental Microbiology, Institute of Microbiology of the CAS, Praha, Czech Republic, [3]Okinawa Institute of Science & Technology Graduate University, Okinawa, Japan, [4]The University of Sydney, Australia, [5]Université Paris 13 – Sorbonne, France

Abstract: Termites have established many associations with gut symbiotic microbes, including many microbes with nutritional functions. In contrast to gut microbes, the associations between termites and ectosymbiotic microbes are known to exist but have rarely been studied. Here, we studied the bacterial communities associated with three wood-feeding termite species using 16S rRNA amplicon sequencing, and we demonstrate the ability of termites to shape the bacterial communities in their direct environment. We show that, on top of their stable association with gut microbes, termites are also associated with numerous ectosymbiotic microbes whose function remains to be determined.

How do termites and humans contribute to the soil fertility in the Congo Basin?

Authors: Stiblík Petr[3], Šobotník Jan[4], Chakraborty Amrita[3], Manourová Anna[4], Lojka Bohdan[4], Sillam-Dussès David[5], Drábek Ondrej[2], Krížová Petra[2], D. Akama Pierre[1], Tejnecký Václav[2] and Penížek Vít[2], [1]Département des Sciences Biologiques Ecole Normale Superieure Université de Yaoundé, Cameroon, [2]Faculty of Argobiology, Food and Natural Resources Czech University of Life Sciences Prague, Czech Republic, [3]Faculty of Forestry and Wood Sciences Czech University of Life Sciences Prague, Czech Republic, [4]Faculty of Tropical AgriSciences Czech University of Life Sciences Prague, Czech Republic, [5]Université Paris 13 – Sorbonne, France

Abstract: Tropical rainforests are treasures of biodiversity, and are increasingly exploited by local communities, to a degree that should alarm us about the biodiversity fate. In order to protect this biodiversity, any modifications can only be initiated by local communities that need to change their land management habits if the new techniques will help them, too. To demonstrate the positive impact of such new practices, we conducted a long-term experiment on the organic matter turnover, weighting the tropical soil incomes and outcomes, and absolute and relative contribution of particular players in this process. We set up eight plots, roughly one hectare each, at the land-use gradient, with identical geological, climatic and geographical conditions, at the North of the Congo Basin (near Mbalmayo, Cameroon). The plots were established in primary and secondary forests, in cocoa agroforestry systems and in a maize field (two plots per habitat). We studied the energy flow through the soil in the plots by using different techniques and we collected about 50 sociological questionnaires focussing at land-use practices, crops and animal stock, means of money-making and spending, in order to suggest a long-term sustainable agricultural strategy which may contribute to protecting the primary forests.

Fungal symbionts of invasive shot hole borers (Euwallacea spp.) in California can support both beetle systems on artificial media

Authors: Stouthamer Richard[2], Dodge Christine[1], Eskalen Akif[3] and Carrillo Joseph[4], [1]Department of Entomology University of California Riverside, CA, United States, [2]Department of Entomology, University of California, Riverside, United States, [3]Department of Plant Pathology University of California Davis, CA, United States, [4]Gulf Coast Research and Education Center Institute of Food and Agricultural Sciences University of Florida Wimauma, FL, United States

Abstract: The specificity of ambrosia beetle-fungus relationships is unknown for the vast majority of ambrosia symbioses, but has important implications for the success of these beetles and fungi in their surrounding environments. The polyphagous shot hole borer and the Kuroshio shot hole borer (Euwallacea spp.) are invasive ambrosia beetles that exist sympatrically in California, USA, and together with their fungi cause Fusarium Dieback in over sixty host tree species. The potential for the two beetle species to exchange symbionts is unknown, but has important ecological consequences. We performed symbiont switching experiments to determine if the polyphagous and Kuroshio shot hole borers can survive and reproduce on each other's symbiotic fungi. Aposymbiotic foundresses were assessed on their ability to reproduce on each of the beetles' primary (Fusarium spp.) and auxiliary (Graphium spp., Paracremonium pembeum) fungal symbionts, grown on sawdust-based artificial media. Offspring were collected to confirm which fungi were present in the different sexes and life stages. The ability of aposymbiotic and non-aposymbiotic foundresses to survive and reproduce on non-ambrosial Fusarium species was also tested. We found that reproduction is maximized on the beetles' primary Fusarium symbionts, regardless of whether a beetle was paired with its own Fusarium symbiont or its congener's, indicating that there is potential for symbiont switching in natural populations of these beetles. The addition of auxiliary fungi to treatments containing Fusarium spp. had no effect on overall offspring production, and females that were fed solely on auxiliary fungi produced significantly fewer offspring. Females that were fed non-ambrosial Fusarium species produced significantly fewer offspring than when reared on symbiotic Fusarium, and this was especially pronounced in aposymbiotic females. From our experiments, the putative roles of the primary versus auxiliary fungal symbionts, as well as the implications of these roles for beetle reproduction and development in their surrounding environment, are discussed.

What phenotype does Wolbachia express in ambrosia beetle hosts of the Euwallacea fornicatus species complex?

Authors: Stouthamer Richard[2], Liu Fang-Ling[1], Tuan Shu-Jen[1], [1]Department of Entomology, National Chung Hsing University, Taiwan, Taiwan, [2]Department of Entomology, University of California, Riverside, United States

Abstract: Wolbachia is an endosymbiotic bacterium, well-known as a reproductive parasite that influences its hosts' reproduction systems. The intracellular bacteria is typically acquired by vertical transmission from mother to offspring, and several reproductive manipulations are caused by Wolbachia which enhance its frequency in the infected population, including cytoplasmic incompatibility, male killing, feminization and parthenogenesis.

Several closely related species of ambrosia beetle, belonging to the Euwallacea fornicatus species complex, have invaded multiple countries over the last few decades. Native to southern and southeast Asia, these beetles carry with them their own food source, symbiotic fungi which are seemingly also pathogenic to many host trees in invaded areas. At least three species of this complex are commonly found in Taiwan, the tea shot hole borer (TSHB) (E. fornicatior), kuroshio shot hole borer (KSHB) (E. kuroshio) and the polyphagous shot hole borer (PSHB) (E. whitfordiodendrus). A fourth (most likely) species, currently referred to as H22, is also common. These four species are variously infected with Wolbachia. No infected populations of KSHB are known, but H22 and TSHB are 100% infected. In contrast, both infected and uninfected individuals exist of PSHB. Interestingly, PSHB is infected with the same strain of Wolbachia as H22 (based on multi locus sequence typing). However, although infection status is known, the actual effect Wolbachia has on these ambrosia beetles is unknown. We will report on our experiments to determine the costs/benefits of Wolbachia infection in these species.

Life span, foraging activity, effect of parasites and the conservation of bees

Authors: Straka Jakub[2], Cerná Katerina[1], Machácková Lenka[1] and Keil Petr[3], [1]Department of Zoology, Faculty of Science, Charles University, Czech Republic, [2]Department of Zoology, Faculty of Science, Charles University, Czech Republic, [3]German Centre for Integrative Biodiversity Research, Germany

Abstract: Recently, global decline of insects and particularly bees is proposed by scientists. Almost 10% of bees are threatened in Europe. Even worse situation with decline of bees is coming from regional red lists and studies. Currently, we know that something is happening on the level of assemblages. However, we know nearly nothing about effects of environmental factors and climatic change to life span, foraging activity, timing of the first emergence of a species in the year and some other important features on the level of individuals from various species. We present research results based on daily observation of two solitary ground nesting bees Andrena vaga (Andrenidae) and Anthophora plumipes (Apidae). We included all available environmental variables to the generalized linear model and interpreted the results. Most of our models explain more than 60% of deviance in the data. In separate analysis we also included observed A. vaga individuals parasitized by Stylops ater (Strepsiptera) endoparasites that castrate host bees and are thought to manipulate host individual behavior. The results in accordance for both species show that the relative activity (activity per life span), emergence date and amount of precipitations are the most important predictors of life span of bees. Relative activity itself is modulated by emergence date, mean foraging activity per day and amount of precipitation during active day. Temperature during active days was far the fourth important factor either for life span, or activity of bees. However, seasonal temperature was together with seasonal precipitation the most important factors for the first emergence date. The most negative effect to length of life have late emergence in season, drought, higher seasonal temperature and possibly low availability of pollen source. Species probably have some optimal temperature for activity and too low or too high temperatures can be negative. We find out that limited and only at most one quarter of bees that are actually alive can be active in a single day. Usually les than 10% from living bees are active. Inactive bees do not leave their nests whole day. We also find out that parasitized bees differ from unparasitized bees only in their emergence date. Other differences, i.e. in length of life and activity, are only effects of earlier emergence and would be the same for healthy bees when emerged early. Described results are important for variable selection in further ecological research and considered effects of climatic change.

Blood feeding initiates hemocyte proliferation through activation of the insulin signaling pathway in mosquitoes

Authors: Strand Michael, Department of Entomology, University of Georgia, United States

Abstract: Anautogenous mosquito species must feed on blood of a vertebrate host to produce eggs. Multiple cycles of blood feeding promote frequent contacts with hosts, which enhance the risk of exposure to infectious agents and disease transmission, as well as proliferation of the gut microbiota, which could put mosquitoes at risk of systemic infection. Blood feeding triggers the release of insulin-like peptides (ILPs) and ovary ecdysteroidogenic hormone (OEH) from the brain of the mosquito Aedes aegypti, which together regulate egg formation through activation of the insulin signaling pathway and ecdysteroid production. In turn, hemocytes have essential immune defense functions. Prior studies indicated that blood feeding stimulates hemocytes to increase in abundance as an anticipatory defense against potential infection. Here, we determined this increase is stimulated by select ILPs but not OEH or ecdysteroids. However, ILP-induced proliferation of hemocytes does not result in up regulation of other immune defense responses. Comparative studies further suggest ILP-induced proliferation of hemocytes after blood feeding is broadly conserved across anautogenous species but has been lost in autogenous mosquito species that no longer blood feed to produce eggs. Taken together, our results further clarify the role of the insulin signaling pathway in regulating an anticipatory immune defense response in mosquitoes that transmit vertebrate pathogens.

Regulation of immune cell proliferation in mosquitoes

Authors: Strand Michael, University of Georgia

Abstract: Most mosquito species are anautogenous, which means they must blood feed on a vertebrate host to produce eggs, while a few are autogenous and produce eggs without blood feeding. Egg formation is best understood in the anautogenous mosquito Aedes aegypti where insulin-like peptides (ILPs), ovary ecdysteroidogenic hormone (OEH) and 20-hydroxyecdysone (20E) interact to regulate gonadotrophic cycles. Circulating hemocytes also approximately double in abundance in conjunction with a gonadotrophic cycle but the factors responsible for stimulating this increase remain unclear. Focusing on Ae. aegypti, we report that hemocyte proliferation is upregulated by insulin-like peptide 3 (ILP3). ILP3 upregulated the insulin signaling pathway in hemocytes but few immune genes with effector functions. ILP3 also stimulated circulating hemocytes to increase in two other anautogenous (Anopheles gambiae and Culex quinquefasciatus) and two facultatively autogenous mosquitoes (Aedes atropalpus and Culex pipiens molestus), but had no stimulatory activity in the obligately autogenous mosquito Toxorhynchites amboinensis. Altogether, results indicate ILPs are the primary regulators of hemocyte proliferation in anautogenous mosquitoes, but also suggest this response has been lost in the evolution of obligate autogeny.

Functional morphology and evolution of an elaborate mechanosensory organ: the subgenual organ complex in the tibia of stick insects

Authors: Strauß Johannes[1], Moritz Leif[2], Rühr Peter T.[3], [1]AG Integrative Sensory Physiology, Institute for Animal Physiology, Justus-Liebig-Universität Gießen, Gießen. Center for Mind, Brain and Behavior (CMBB), University of Marburg and Justus Liebig University Gießen, Germany, [2]Zoological Research Museum Alexander Koenig, Leibniz Institute for Animal Biodiversity, Section Myriapoda, Bonn, Germany, [3]Institute of Evolutionary Biology and Animal Ecology, University of Bonn, Germany

Abstract: Insect mechanosensory organs consisting of scolopidial sensilla are studied in depth for their morphological diversity and sensory physiology. Such scolopidial or chordotonal organs respond to movements of joints and body parts, substrate vibration, airborne sound, or gravity. The neurophysiology of mechanosensory organs is studied in model species of orthopteroid insects like crickets, cockroaches, locusts or stick insects. Orthopteroid insects possess a mechanosensory organ complex in the proximal tibia, the so-called subgenual organ complex. This complex consist of the subgenual organ, the legs main receptor for substrate vibrations, with additional scolopidial organs close-by. Stick insects are important models in neurophysiology and the neuronal control of locomotion. While leg mechanoreceptors are analysed well studied for their functional contributions, the subgenual organ complex in the tibia was not investigated.

The subgenual organ complex of stick insects (Euphasmatodea) shows a unique neuroanatomical organisation, consisting of the subgenual organ and the distal organ, each with 20-40 sensilla. The subgenual organ is arranged perpendicularly to the tibia's main axis, and the sensilla of the distal organ are arranged linearly along the proximo-distal axis of the tibia. These anatomical differences indicate sensory specialisations between the two organs. In Sipyloidea sipylus, the subgenual organ complex is sensitive to sinusoidal vibration stimuli but not to airborne sound. In addition, the sensitivity is influenced by the stimulus direction, with highest sensitivities in response to vertical displacements along the tibias proximo-distal axis. Likely, this is due to the strongest propagation of vibrations if the stimulus direction and leg orientation are aligned. Notably, sensilla in the distal organ are organised linearly and also show a gradient in size, decreasing from proximal to distal. The functional properties of chordotonal organs depend on the attachment structures, which allow different mechanical inputs. Analysis by microcomputed tomography shows that the distal organ is placed in the hemolymph channel like the subgenual organ. It is attached by different tissue strands to the leg cuticle. There are no obvious attachments to a leg tendon, which could indicate a proprioceptive function. The origin of the elaborate, linear organisation of the distal organ raises both functional and evolutionary questions, since the distal organ in other orthopteroid insects, e.g. cockroaches or locusts, form a smaller, dense group of sensilla. From the functional morphology, the stick insect distal organ is likely also a receptor for vibration stimuli, which can be transmitted in the hemolymph or over the leg cuticle. For a better understanding of the adaptations of the distal organ into the linear set of sensory neurons, the specific biomechanical characteristics of the stick insect tibia need to be established.

Olfactory-visual integration and plasticity in mushroom body output neurons

Authors: Strube-Bloss Martin, 1Biocenter University of Würzburg, Department of Behavioral Physiology & Sociobiology, Würzburg, Germany 2Biological Cybernetic, Department of Biology, Universi

Abstract: Brains are fascinating miracles with a multitude of adaptations across the animal kingdom. They receive a tangle of multi-sensory input and hold the capacity to simultaneously select adequate modalities while ignoring others. Hence, the resulting percept reflects a multi-modal construct rather than the neural representation of only a single modality.

Multi-modal integration involves convergence of different sensory pathways at a higher brain level. The bee's mushroom body (MB) represents such an integration center. Its ~170.000 Kenyon Cells are organized in layers each receiving input from a different modality. MB output is conveyed to ~400 MB output neurons (MBON), which we record from on a reliable basis. We characterized olfactory, visual, as well as olfactory-visual (OV) induced activity in the same MBONs. We can show that the layered input of the MB is conserved in a subpopulation of MBONs responding to either odors or light stimulation, whereas a substantial proportion of MBONs was sensitive to both modalities and thus integrated OV information across MB input layers. Another subpopulation of MBONs did not respond to any of the presented stimuli. Previously we showed that such units become recruited after a classical conditioning experiment. We therefore propose that reward association to an OV compound stimulus may recruit initially non sensitive MBONs which will encode the OV-reward association during memory retention after classical conditioning.

LED enhanced yellow traps equipped with cameras for monitoring of whiteflies and fungus gnats

Authors: Stukenberg Niklas[1] and Poehling Hans-Michael[2], [1]Julius Kühn-Institut (JKI), Federal Research Centre for Cultivated Plants, Germany, [2]Leibniz-Universität Hannover, Institute of Horticultural Production Systems, Section Phytomedicine, Hannover, Germany

Abstract: Yellow sticky card traps are used for monitoring and control of alate pests such as whiteflies and fungus gnats in greenhouses. The use of light emitting diodes (LEDs) has turned out as a promising approach to increase the efficiency and reliability of visual traps. The implementation of (semi-)automatic image acquisition and analysis methods is of great interest in order to improve and simplify the identification and counting of insects on traps.

LED enhanced yellow traps were constructed which combine a yellow card with specific edge lighting acrylic glass equipped with green high-power LEDs in a frame. In a next step, traps were equipped with cameras and white high-power LEDs were mounted in the frame and adjacent to the trapping surface to facilitate the acquisition of transmitted and incident light images at dark night-time conditions. The traps were compared with common yellow sticky traps in small-scale tomato crop stands in gauze cages with artificial whitefly infestation (Trialeurodes vaporariorum) and naturally occurring not further determined fungus gnats. A final experiment was conducted in a larger crop stand to evaluate the trap efficiency and the image acquisition method with subsequent pest counting on images.

The results show a significantly increased efficiency of the LED enhanced traps for whiteflies compared to yellow traps in experiments with high population densities and in choice situations with both trap types. A higher attractiveness for fungus gnats was observed throughout. The obtained images allowed reliable counting of both pests comparable with manual counting on traps.

Utility of metagenomic data for Platypezidae

Authors: Ståhls-Mäkelä Gunilla, Finnish Museum of Natural History, Finland

Abstract: Shotgun metagenomic DNA sequencing is a powerful sequencing approach that provides insight into community biodiversity and function. Here it was used to screen genomic DNA of platypezid flies as a first step to decipher the unknown biology of some lineages by characterizing the fungal and microbial biota associated with the flies. About 10GB of genomic information was sequenced per specimen. The mitochondrial genome and nuclear ribosomal gene sequences were extracted for phylogenetic studies.

Insect Community in Beijing Urban Area: Does Functional Type of Green Space Matter?

Authors: Su Zhimin[1] and Ouyang Zhiyun[1], [1]State Key Laboratory of Urban and Regional Ecology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, China

Abstract: Urbanization is the leading cause of biodiversity decrease, while urban green spaces are considered as the important harbor of wildlife in urban area, raising questions about the abilities of different habitats to support the species surviving. The aim of this study was to: (i) understand the composition of insect community, (ii) evaluate how much the theoretical species richness is, (iii) analyze whether the insect diversity have significant differences, (iv) and how about the structure of community in different functional types of urban green space.

We collected insect specimen using suction trapping within 45 green patches across six types of urban green space of Beijing. A total of 11211 specimens, representing 213 species / morphospecies from 11 orders, 98 families, were collected from 1620 samples. Hemiptera, Coleoptera, Hymenoptera, Diptera, Orthoptera and Lepidoptera are the six major orders on the urban lawns, with several highly dominant taxa groups. For the entire study and each green space type, we plotted species-octave histograms to visualize abundance distributions following the method of Preston.

We found that octave-based relative abundance plots for all types of green space produced convincing lognormal distributions. The lognormal equation for species-abundance distribution in the institutional green space had the best goodness-of-fit ($r2 = 0.966$, $P < 0.0001$) than that for other five green types. On the basis of lognormal equation for species-abundance distribution, the theoretical total number of species in the universe being sampled was 320, 2/3 of which (213 species) were represented in the sample. There was not significantly different in insect diversity among different green space types. Vacant land had the highest Fisher's a diversity, followed by protective, institutional and residential green spaces. When using Shannon and Simpson indices as measure of insect diversity, protective green space was most diverse. Street green space had overall the lowest diversity. Insect community composition varied significantly among different green space types (adonis, $F = 2.098$, $P = 0.002$), with the vacant land significantly different from all the other green space types.

Our findings demonstrate that urban green spaces play important but different roles among different functional types in shaping urban insect diversity. Vacant land may be considered as a potential species pool. Its retention, removing, redesign and management needs to consider the environmental concerns, such as supporting biodiversity or improving infiltration of storm water. Therefore, reasonable allocation and management of different greenspace types may help to increase urban insect diversity.

Design and rationale for regional genetic monitoring scheme toward adaptive resistance management

Authors: Sudo Masaaki[2], Yamanaka Takehiko[4], Jouraku Akiya[1], Kitabayashi Satoshi[3] and Kuwazaki Seigo[1], [1]Institute of Agrobiological Sciences, NARO, Japan, [2]Institute of Fruit Tree and Tea Science, NARO Kanaya Tea Research Station, Japan, [3]Nagano Vegetable and Ornamental Crops Experimental Station, Japan, [4]Research Center for Agricultural Information Technology, NARO, Japan

Abstract: Considering the aspect of temporal evolution in the resistance development of an insect pest to insecticides, an ideal management program should be adaptive: guidelines for the normal use of insecticides to delay resistance development (e.g. pesticide pyramiding, rotation, and untreated refuge), combined with the monitoring of field pest populations. Responding the “resistance risk level” based on the resistance allele frequency and/or mortality in bioassays, the insecticide use is halted at regional scale.

Monitoring and risk assessment of a field-evolved resistance comprise of several key techniques. One is the genetic diagnosis, including the development of genetic markers as well as analytical pipeline. Another important factor is the spatio-temporal sampling design to collect insects from field. A simulation suggests the risk of resistance prevalence in near future is correlated to the higher resistance allele frequency in the local mating pool, typically in adult males (Sudo et al. 2018 Evol Appl). Mass capturing methods e.g. sticky trap with attractants is a good way to grasp the tendency, showing high affinity with large-scale diagnosis exploiting next-generation sequence (NGS) analysis.

We preliminarily conducted a two-year, multi-site monitoring of the diamondback moth, Plutella xylostella, to multiple insecticides in Nagano Prefecture, central Japan. The NGS-based diagnosis revealed the spatio-temporal spread of resistance alleles, which can be used to determine the “optimal management unit” for future monitoring and regulation.

Gripping ease in southern green stink bugs Nezara viridula L. (Heteroptera: Pentatomidae) exploring highly variable terrains

Authors: Sudo Masaaki[3], Gorzolka Karin[2], Fujisaki Kenji[5], Varenberg Michael[1] and Perez Goodwyn Pablo[4], [1]George W. Woodruff School of Mechanical Engineering, Georgia Institute ofTechnology, Atlanta, Georgia, United States, [2]Germany, [3]Institute of Fruit Tree and Tea Science, NARO Kanaya Tea Research Station, Japan, [4]Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto University, Kyoto, Japan, [5]Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto University, Kyoto, Japan

Abstract: The highly polyphagous southern green stink bug Nezara viridula L. (Heteroptera, Pentatomidae) prefers apically situated seeds and fruits on more than 150 plant species belonging to over 30 plant families all over the world. This forces them to move over highly variable terrains, including plant stems, leaves, pods and buds, which requires efficient attachment. Stink bugs have long slender legs and feet (tarsi)

equipped with paired curved claws, paired soft adhesive pads (pulvilli), and flattened lanceolate hairs (setae), which arise ventrally on the first and second foot segments (tarsomeres). To characterize their attachment abilities on well-defined test substrates, here we comparatively measured and analyzed the traction forces of bugs walking horizontally and vertically on hydrophilic (water attractive) and hydrophobic (water repellent) glass plates and rods (Voigt et al. 2019). The latter correspond to the geometry of preferred feeding sites of stink bugs in the field. The results show a clear contribution of tarsal flattened lanceolate hairs to the stink bug’s attachment. Higher traction forces are generated on a glass rod than on a glass plate, corresponding to up to individual maximum of 43 times the stink bug’s body weight. Substrate hydrophobicity promotes the attachment, while the measured forces are up to eight times lower when tarsal hairs are disabled. The combination of smooth and hairy tarsal pads results in a remarkable attachment ability, which enables N. viridula to climb unstable apical plant parts. The understanding of the foothold on plants and supports evaluations of stink bugs’ invasive behavior and global dispersion.

Effects of habitat conversion on plant-caterpillar-parasitoid networks in Ecuador

Authors: Sudta Chanchanok, University of Nevada, Reno

Abstract: Are global change parameters, such as increased mean temperatures, extreme weather events, and loss of biodiversity favoring generalist versus specialist organisms? To answer this question, we need to better understand ecological specialization and how it is affected by environmental change or how it varies across gradients. Using 18-years of empirical data from Ecuador on interactions between host plants and caterpillars collected from tropical forests along elevational gradients, we found that specialists are locally more abundant than generalists. The findings also revealed that generalist caterpillars achieve greater prevalence across the landscape. Loss of tropical forests and conversions to grassland can alter biodiversity, species interactions, and ecosystem functions. Concerns about habitat loss have prompted an additional question about associations between diet specialization and caterpillar abundance. Here, we examine variation in plant-arthropod networks across disturbance and elevational gradients in the Eastern Ades of Ecuador. The research will close knowledge gaps about how the complexity of biotic communities is affected by global change. The work will help tropical conservation efforts by identifying how specialist versus generalist organisms respond differently to global change and how that could affect ecosystem services that support local communities.

Biology of Mycetophila ruficollis (Diptera: Mycetophilidae), a fungus gnat pest of the Shiitake mushroom

Authors: Sueyoshi Masahiro, Japan

Abstract: Mycetophila ruficollis Meigen is a fungus gnat recorded from Europe and Japan. It is clearly delimited by some morphological features on the dark marking at the middle of the wing and the absence of any ventral setae on the mid tibia, and the gonotsylus of the male genitalia with narrow tip. This species composes the M. ruficollis species group, together with other 17 morphologically resemble species from Europe, Iran, China, Nepal, Mongolia, USA, and Canada. A molecular work supported the morphological species discrimination but is morphologically unable to identify female specimens to the species level in some species of the group. Mycetophila ruficollis is known as one of pests of the Shiitake mushrooms, Lentinula edodes, cultivated with bed logs of oaks in Japan. The larvae of this fungus gnat mine and injure the fruit bodies of the Shiitake. It also parasites fruit bodies of oyster mushrooms, Pleurotus ostreatus (Pleaurotaceae), and Omphalotus japonicas (Marasmiaceae). Adults of the group visit flowers of some jack-in-the-pulpits, and may pollinate them and contribute to pre-reproductive isolation of closely related Arisaema spp. of the Araceae.

The Shiitake is one of the edible fungi worldwide. They are cultivated with bed logs installed in forests since 17th century, or sawdust-based artificial media in an indoor facility since 1980s, in Japan. More than two 1.7 thousand farms product 65 thousand ton of the Shiitake in 2020. The amount of the Shiitake cultivated with bed logs represented 23% of the overall total in Japan but 60 % of Kyushu, south of Japan. The Shiitake cultivated with bed logs are rich in flavor and chewy taste and are traded at high prices, rather than the Shiitake cultivated with artificial media. Pest controls of M. ruficollis support sustainable use of the Shiitake cultivated with bed logs. I have studied on the biology of M. ruficollis in Kyushu, Japan, in recent years, resolving some aspects of biogeographical distribution, seasonal abundance, and parasitoids of this fungus gnat.

Mycetophila ruficollis has been recorded from Hokkaido to Kyushu in Japan. Based on the male specimens from more than 300 localities (elevation: 1-1292m, altitude: 32-45 degree north) of Japan, adults were found from March to December. Most number of adults emerged on March to June, with a peak on the late April, and some little numbers were also found on October to December in bed log laying yards. These observations support a hypothesis that it has at least two generations per year and overwinters as mature larvae and pupa. The larvae dwelt into soil and litter. Natural enemies of M. ruficollis have not been known well. Zero to 46% of larvae collected from fruit bodies of the Shiitake were infested by proctotrupid, and diapriid, and braconid wasps. The abundance of M. ruficollis in the bed log laying yards are much higher than that in other surrounding forests. It suggest that the population of this fungus gnat repeat generations every year, settling the yards.

Spatiotemporal distance between oilseed rape fields reduces cabbage seed weevil pressure without affecting biocontrol

Authors: Sulg Silva[1], Kaasik Riina[1], Willow Jonathan[1] and Veromann Eve[1], [1]Estonian University of Life Sciences

Abstract: Large monocrops provide sufficient vital resources for agricultural pests, but often do not support the presence of natural enemy populations (e.g. predators, parasitoids). This ecological imbalance can make intensive pesticide use a necessity for farmers. At the farm level, preventive methods in pest control (e.g. landscape complexity, crop-rotation, pathogen-free propagation material, cautious pesticide use) are well-established, whereas spatiotemporal field separation of same crop species remains understudied for most crop–pest systems, yet may be of great importance as a pest management technique. We carried out a three-year study in winter oilseed rape fields, where half of the fields were within 500 m from the previous year's closest oilseed rape field, and half outside this spatial distance. Cabbage seed weevil (Ceutorhynchus obstrictus) abundance was reduced in fields located further than 500 m from the previous year's nearest oilseed rape field, whereas parasitism by its key parasitoids was high in all fields. We demonstrate that spatiotemporal field separation is an effective preventive pest control technique at the landscape scale, and can work together with conservation biocontrol, which helps reduce the next year's pest population. The use of spatiotemporal distancing should be investigated as a key integrated pest management strategy in additional cash crops.

Conservation initiatives on privately owned and leased land can greatly benefit invertebrate fauna: a case study from Australia

Authors: Sullivan Gregory T.[2], Ozman-Sullivan Sebahat[1], [1]Ondokuz Mayis University, Samsun, Turkey, [2]The University of Queensland, Brisbane, Australia

Abstract: The Australian Land Conservation Alliance (ALCA) is the peak group for eleven member organizations that manage privately owned in Australia with the aim of sustainable production and/or biodiversity conservation. The Australian Wildlife Conservancy, with more than 6.5 million hectares, is the largest private owner and manager of land dedicated to conservation in Australia. The land managed by members of the ALCA includes desert, grassland, savanna, heathland, eucalypt forest, rainforest and wetlands. Land management at the landscape level is focused on soil retention, soil health and revegetation or regeneration. Soil, vegetation and vertebrates are the primary foci of conservation actions. Specific initiatives of ALCA members include the restoration of endangered ecosystems, increasing the protected area estate, the control of invasive alien species and using nature-based solutions to tackle climate change. The major indirect beneficiaries of the intensive and extensive land conservation programs being managed by ALCA members across the vast Australian landscape are the invertebrates, mostly arthropods, a high proportion of which are endemic. Tens of thousands of invertebrate species, mostly insects and mites, are very likely inhabiting areas managed under the ALCA umbrella and management practices that increase ecological integrity and resilience can improve their chances of long term survival.

Genome comparisons and genetic diversity of 'Candidatus Liberibacter solanacearum' and its psyllid vectors

Authors: Sumner-Kalkun Jason, SASA; Scottish Government, United Kingdom

Abstract: The phloem-limited bacterium 'Candidatus Liberibacter solanacearum' (Lso) and its psyllid vectors are responsible for significant economic losses in Solanaceous and Apiaceous crops worldwide. Currently little is known about the genetic diversity of Lso and its psyllid vector with only a handful of draft genomes available. The recently described wild haplotypes U, Cras1, and Cras2 will be sequenced and compare to known pathogenic Lso haplotypes to examine genes that play a role in infection/ pathogenicity. We will examine psyllid populations of carrot psyllids (Trioza apicalis and Bactericera trigonica) from 7 European countries to understand their dynamics to infer psyllid movement. Ultimately, this will highlight areas that are at risk of psyllid invasion and help understand psyllid population movements.

Taxonomy at NCBI and GenBank -- An update for entomologists

Authors: Sun Lu[1], [1]National Center for Biotechnology Information (NCBI), United States

Abstract: NCBI Taxonomy database contains names and other taxonomic information for near 2 million organisms of which sequence data are recorded in GenBank and other databases. Additions of new taxa to science (and to NCBI Taxonomy) demonstrate an accelerating rate at present. More than one-fourth of all formal species names in NCBI Taxonomy belong to insects (about 140,000). Still, they account for barely over 10 percent of all published insect species, making Insecta the most "incomplete" group in the database. In addition, about half million insect names with various formats in NCBI Taxonomy are not identified into known species. Meanwhile, their naming and classifications have been undergoing constant, frequent, and often drastic changes.

This presentation provides an update to the curating of NCBI Taxonomy database and general guidelines for validating and registering related information generated among submissions and requests by users. Upgrades of the database software (Tax Editor) are developing and enabling large amount of complex taxonomic information (synonymies, authorities, references, types, etc.) to be registered and linked to other databases. On the other hand, timely data updates basing on newer study results maintain a challenge. Also, new types of research and enhanced, automated submission protocols demand revisions of policies. Resources, limitations and future improvements are discussed."

Identification of maleness factors escaped from doublesex dogma, a novel type of genital development pathway discovered in the silkworm, Bombyx mori.

Authors: Suzuki Masataka[1], Kasahara Ryota[1], Aoki Fugaku[1] and Yamamoto Fumiko[1], [1]Graduate School of Frontier Sciences, The University of Tokyo, Japan

Abstract: Reproduction of most animals is based on precise formation of sexually dimorphic genitalia. In insect species, sexually dimorphic genitalia development is regulated by a Zinc-finger type transcription factor gene, doublesex (dsx). dsx produces sex specific isoform called dsxM, dsxF by alternative splicing and regulate expression of maleness/femaleness factors in each sex. From past studies in many insects, insect sexual development is thought to be regulated by top-down, one-way cascade starts from sex determination gene, end in sex specific sexual development regulated by dsx. Thus, dsx has been believed to be an omnipotent regulator and only nexus in insect sexual development. However, recent studies are beginning to destroy that myth. The dispensable function of dsxF in female genitalia development has been observed in many basal insect species including Hymenoptera, Hemiptera, Dictyoptera. These facts indicate functional diversity of dsx and existence of sexual development factors that escaped from dsx control.

The domesticated silkworm, Bombyx mori is widely used lepidopteran model insect especially for genetics. This species has ZW/WW sex determination system, female sex determination gene Fem on W chromosome and male sex determination gene Masc on Z chromosome decide Bombyx mori dsx (Bmdsx) splicing pattern. Previous studies using forced expression and transient genome editing have demonstrated vital role of Bmdsx on genitalia development. Recently, we newly established stable mutant lines to examine more accurate functions of Bmdsx. During the study, we unexpectedly found unusual sexual development that is inconsistent with canonical model. The Bmdsx stable mutant, especially male, exhibited normal sexual development in some part of genitalia. This is also inconsistent with the case in species whose dsxF only has dispensable functions. From these facts, we are convinced this phenomenon is worth studying.

As first step, we performed transcriptomics (RNA-seq) for dsx mutants and sought responsible genes. Among about 100 candidate genes, we focused on 2 genes that were previously related to sexual development in the silkworm and the fruit fly, Drosophila melanogaster. RNA-seq analysis revealed they were not regulated by BmdsxM, but significantly suppressed by BmdsxF. Their expression was biased in testes during late larval to early pupal stage. Functional analysis of these genes using CRISPR/Cas9 proved their function in male genitalia development where Bmdsx mutation could not affect.

These findings allowed us novel viewpoint on genitalia development. It is said that Lepidopteran males have developed many unique genitalia features such as large testes and two types of sperm. We might be able to say that function of dsx in each species is correlated with sex-specific selection pressure.

Transgenic and knockout analyses of Masculinizer and doublesex illuminated the unique functions of doublesex in germ cell sexual development of the silkworm, Bombyx mori

Authors: Suzuki Masataka[3], Aoki Fugaku[2], Sezutsu Hideki[1], Sumitani Megumi[6], Matsuoka Misato[5] and Yuzawa Tomohisa[4], [1]1) Transgenic Silkworm Research Unit, Institute of Agrobiological Sciences, National Agriculture and Food Research Organization (NARO) 2) Department of Integrat, [2]Graduate School of Frontier Sciences, The University of Tokyo., Japan, [3]Graduate School of Frontier Sciences, The University of Tokyo., Japan, [4]Japan Water Systems Corporation, Japan, [5]SHINYUSHA, Japan, [6]Transgenic Silkworm Research Unit, Genetically Modified Organism Research Center, Institute of Agrobiological Sciences, National Agriculture and Food Research

Abstract: Background: Masculinizer (Masc) plays a pivotal role in male sex determination in the silkworm, Bombyx mori. Masc is required for male-specific splicing of B. mori doublesex (Bmdsx) transcripts. The male isoform of Bmdsx (BmdsxM) induces male differentiation in somatic cells, while females express the female isoform of Bmdsx (BmdsxF), which promotes female differentiation in somatic cells. Our previous findings suggest that Masc could direct the differentiation of genetically female (ZW) germ cells into sperms. However, it remains unclear whether Masc directly induces spermatogenesis or if it promotes male differentiation in germ cells indirectly by inducing the expression of BmdsxM.

Results: In this study, we performed genetic analyses using the transgenic line that expressed Masc, as well as various Bmdsx knockout lines. We found that Masc-expressing females with a homozygous mutation in BmdsxM showed normal development in ovaries. The formation of testis-like tissues was abolished in these females. On the other hand, Masc-expressing females carrying a homozygous mutation in BmdsxF exhibited almost complete male-specific development in gonads and germ cells. These results suggest that BmdsxM has an ability to induce male development in germ cells as well as internal genital organs, while BmdsxF inhibits BmdsxM activity and represses male differentiation. To investigate whether MASC directly controls male-specific splicing of Bmdsx and identify RNAs that form complexes with MASC in testes, we performed RNA immunoprecipitation (RIP) using an anti-MASC antibody. We found that MASC formed a complex with AS1 lncRNA, which is a testis-specific factor involved in the male-specific splicing of Bmdsx pre-mRNA.

Conclusions: Taken together, our findings suggest that Masc induces male differentiation in germ cells by enhancing the production of BmdsxM. Physical interaction between MASC and AS1 lncRNA may be important for the BmdsxM expression in the testis. Unlike in the Drosophila dsx, BmdsxM was able to induce spermatogenesis in genetically female (ZW) germ cells. To the best of our knowledge, this is the first report that the role of dsx in germ cell sexual development is different between insect species.

Environmental RNAi-mediated gene silencing in spider mites and its application to pest control

Authors: Suzuki Takeshi[1], Ghazy Noureldin[1], Arai Yuka[1], Takeda Naoki[1] and Hamdi Faten[1], [1]Tokyo University of Agriculture and Technology, Japan

Abstract: Environmental RNA interference (eRNAi) induced by exogenous double-stranded RNA (dsRNA) has been attracting attention as the mechanism of action of next-generation pesticides. eRNAi acts by suppressing gene expression in a sequence-specific manner, which ultimately enables pest management with species-specific resolution. eRNAi-based pest control is broadly classified into the use of crops expressing dsRNA of the target pest species and the spraying of synthesized dsRNA. The latter is called eRNAi-based biopesticides and is expected to be used in many countries and regions because it does not fall under the category of genetic modification. In this presentation, we discuss the potential application of eRNAi for controlling the two-spotted spider mite, Tetranychus urticae, which has the most serious resistance problem. Here we focus on midgut cells, the most promising target for eRNAi-based biopesticides in spider mites, and introduce the dsRNA uptake mechanism and subsequent dsRNA processing mechanism in the cells. In addition, we introduce a highly efficient method that uses a sheet-like structure mimicking plant leaves for the eRNAi screen in spider mites.

The role of the activin ligand Myoglianin in the developmental timing of metamorphosis in holometabolous insects.

Authors: Suzuki Yuichiro[3], He Lorrie[3], Shin Sara[3], Yuan Isabelle[3], Chiou Allie[3], Koyama Takashi[2] and Nijhout Frederik[1], [1]Duke University, [2]University of Copenhagen, [3]Wellesley College, United States

Abstract: In holometabolous insects, attainment of a threshold size specifies the final larval instar. We investigated the mechanism of threshold size assessment in the tobacco hornworm, Manduca sexta. The threshold size was found to vary with the level of exposure to poor nutrient conditions, whereas it was consistently lower under hypoxic conditions. Under these various conditions, threshold size was correlated with the mass of the muscles plus integuments and myoglianin (myo) expression. RNA interference-mediated knockdown of myo in Tribolium castaneum led to larvae that underwent supernumerary larval molts and stayed in the larval stage permanently even after passing the threshold size. We propose that increasing level of Myo in growing larvae serves a readout of their body size and trigger metamorphosis at the threshold size.

Green is good, grey is bad? - Landscape-level drivers of flying insect biomass

Authors: Svenningsen Cecilie[3], Tøttrup Anders[2] and Bowler Diana[1], [1] German Centre for Integrative Biodiversity Research (iDiv), [2]Natural History Museum of Denmark, [3]Natural History Museum of Denmark, Denmark

Abstract: The proportion of the Earth that is actively managed by humans continues to increase, with at least three-quarters of the global land area currently affected by human activities. Although biodiversity decline is linked to human activities, most evidence is derived from studies on plants and vertebrates with large data gaps on insects.

In this study, we investigated how land cover and land use affects flying insect biomass. To examine landscape level effects, we engaged citizen scientists in Denmark and Germany to sample flying insects using car nets along five km routes during the summer of 2018. We then extracted land use data from various sources, to examine how urban, farmland, grassland, wetland and forest affect flying insect biomass from a local (50 m) to a landscape (1000 m) scale.

By sampling across long transects of both grey and green urban areas, we show clear effects of reduced biomass associated with urban cover that were not evidenced before across a spatial large scale. In addition, we find that semi-natural areas, especially grassland and wetland, have higher insect biomass per relative percentage cover than both urban and farmland areas, signaling their importance for insect conservation.

A Predator as Prey: the evolutionary balancing act of praying mantises

Authors: Svenson Gavin J[3], Bertsch David[1], Martin Joshua[2], Ritzmann Roy[1] and Brannoch Sydney[4], [1]Department of Biology, Case Western Reserve University, United States, [2]Department of Biology, Colby College, United States, [3]Department of Invertebrate Zoology, Cleveland Museum of Natural History, United States, [4]Department of Physiology & Biophysics, University of Washington, United States

Abstract: The evolutionary interplay of predators as prey of vertebrates creates a dynamic organism that functions in its environment in unexpected and complex ways. Past research on the morphological, biogeographical, and ecological evolution of the lineage led to numerous findings that changed the way we think about their deep history and modern relationships. Recent research has focused on the evolution of a highly specialized predatory strategy within flower mantises, which includes shifts in sexual dimorphism, coloration, and crypsis. So extreme were these shifts that the mantis now functions with two signaling channels, one for prey and one for potential predators. New research is focused on the visual tracking, response, and pursuit of prey items and how these can change dramatically based on context. It points to a predator that is both flexible and dynamic, which challenges the traditional notion of these organisms functioning simply as ambush predators. Another project is focused on a highly specialized mantis lineage that has adapted into a very unmantis-like niche, which is even linked to novel ways of perceiving the environment. The final project evaluates the context of visual targets that are attractive as prey, but eventually pass a threshold and change into a threat. This shift in behavior indicates a clear strategy for when to hunt and when to hide. This presentation gives context to praying mantises as organisms that play the game between hunting and being hunted through their cryptic strategies, their level of hunger, and their perception of the environment.

Glial Kir channels as a target for novel mode- and mechanism- insecticides

Authors: Swale Daniel, Louisiana State University AgCenter Baton Rouge, LA, United States

Abstract: Ion channels are ubiquitously expressed across animal tissue systems and they have been conserved throughout evolution to play essential roles in nearly all biological phenomena. Our group has aimed to characterize the physiological role of insect inward rectifier potassium (Kir) channels and have tested the broad hypothesis that inhibition of these channels will have deleterious consequences to insect tissue function and insect survival. Recent work has shown expression of various ion channels in insect glia cells, raising the intriguing possibility that glial cells contribute to neuronal function of insects and may represent a cellular target for insecticide design. Considering this, we tested the hypothesis that insect Kir channels expressed in glia cells contribute to central nerve firing and thus, Kir inhibition will have deleterious consequences to neuronal function and fly survivorship. To test this hypothesis, we used CRISPR/Cas9 in Drosophila to fluorescently tag the endogenous gene loci of Kir1, Kir2 and Kir3. Fluorescent microscopy imaging showed Kir2 channel subunits are localized at the membrane of glial cells, but not neurons. Functional studies support this localization pattern as patch-clamp electrophysiology showed an inward K+ conductance of 104 ± 60 pA/pF in Drosophila glia cells but no significant inward K+ current in central neurons. These data led us to speculate Kir channels constitute a mechanism for rapid clearance of K+ ions from the extracellular space during neuronal activity and thus, inhibition of glial Kir channels would result in membrane depolarization and increased firing. To test this, we performed extracellular recordings of Drosophila descending neurons and found pharmacological inhibition of Kir channels significantly ($P<0.05$) increased the firing rate and lead to nerve death. Importantly, tarsal contact of insect specific Kir channel inhibitors results in fly mortality (LC50: 700 ng/cm2). These data indicate it is possible to alter neural function of insects through inhibition of glia specific ion channels and highlights the potential for developing novel mechanism insecticides targeting glial Kir channels.

Soil-dwelling arthropods as indicators of erosion in a South African grassland habitat

Authors: Swart Vaughn[1], Haddad Charles[1], Bredenhand Emile[1] and Van der Merwe Sylvia[2], [1]University of the Free State, South Africa

Abstract: Soil erosion is a natural process that drives the formation of lowland terrains in mountainous regions. Its role in ecosystem degradation has been strongly debated, due to the significant effect it has on a range of land types. Soil arthropods have been used as indicators of several disturbance types. However, little is known about arthropods in eroded sites in South Africa. The aim of this study was to identify possible indicators of erosion in the Golden Gate Highlands National Park, South Africa, and to determine differences in soil-dwelling arthropod assemblages found in non-rehabilitated and rehabilitated sites over a 24-month period. A total of 5661 soil arthropods were sampled during the study, with the highest species richness recorded in non-rehabilitated eroded sites. A higher number of unique arthropod species were recorded from the non-rehabilitated sites compared to other site types. Overlaps in assemblage structure between site types differed, dependent on site locality. IndVal results indicated a single strong indicator, the mite Speleorchestes meyerae Theron & Ryke, 1969, for the non-rehabilitated eroded sites. Linear model analyses of site richness with mineralogy identified the significance of Phosphorus (in the form of P2O5) in eroded sites. Given these results, soil mineralogy in conjunction with soil arthropod richness of eroded sites could be used to investigate the effect of erosion and form a basis for future study in soil biodiversity and function.

Opportunities for improving early detection of exotic jewel beetles

Authors: Sweeney Jon[5], Miller Dan[7], Gutowski Jerzy M.[3], Plewa Radosław [3], Joe Francese[8], Williams David [2], Hughes Cory[4], Van Rooyen Kate[4], Meng Qingfan[1], Li Yan[1], Roscoe Lucas[4], Mayo Peter[4] and Rassati Davide[6], [1]Beihua University, Jilin, P.R. China, [2]Forest Research, UK, [3]Instytut Badawczy Leśnictwa, Poland, [4]Natural Resources Canada, Canadian Forest Service, [5]Natural Resources Canada, Canadian Forest Service, Canada, [6]University of Padua, Italy, [7]USDA Forest Service, [8]USDA-APHIS

Abstract: Our ability to survey for and detect the presence of potentially invasive, non-native longhorn beetles, bark and ambrosia beetles has improved significantly in recent decades, thanks in large part to the discovery of aggregation/sex pheromones in hundreds of species. On the other hand, the chemical ecology of jewel beetles (Buprestidae) is in its infancy and they are frequently under-represented in traps used in operational surveillance programs by regulatory agencies. The genus Agrilus has more than 3000 species worldwide, and even if only a small fraction of these have the potential to behave like the invasive emerald ash borer if established in a new habitat with naïve hosts and few natural enemies, we must develop improved tools and methods for their early detection. We briefly review some of the factors affecting detection of jewel beetles in surveillance traps such as trap colour, trap position, and semiochemical attractants, and present results from field experiments replicated in Europe, China, and North America.

The fragmented mitochondrial genomes of lice: how a rare and often fatal phenomenon persists in a group of parasitic insects

Authors: Sweet Andrew[1], Stanford-Beale David[2], [1]Arkansas State University, United States, [2]Dept. of Entomology, Purdue University West Lafayette, Indiana, United States

Abstract: The mitochondrial genomes of most animals are contained on single chromosomes. However, in very rare cases mitochondrial (mt) genes are separated on multiple circular chromosomes. The greatest known abundance of these fragmented genomes is in lice (Insecta: Phthiraptera), parasitic insects of mammals and birds. 16 species from a single clade of mammal lice are known to have multiple mitochondrial chromosomes. Yet, some studies have indicated that other groups of lice also have fragmented mt genomes. Here we use whole genome sequence data to test how many times fragmented mt genomes have arisen across parasitic lice and address what factors might be associated with this fragmentation. We applied a bioinformatic approach to assemble and annotate mitochondrial genomes from 32 genera of parasitic lice and found that 19 of these genera have fragmented genomes ranging from 2 to 20 chromosomes. Based on an existing species phylogeny, our results suggest fragmented mt genomes arose at least 12 times within parasitic lice. The majority of these transitions appear to have occurred in avian feather lice. There was very little phylogenetic structure to patterns of genome architecture; however, there was relatively consistent genome structure within specific clades of lice, suggesting that a finer-scale approach is needed to understand how mt genome fragmentation occurs. Comparisons within these clades provided evidence for the order of mt genome fragmentation, and gave some insight into traits that are associated with mt genome architecture. Overall, this study highlights the complexity of mitochondrial genome architecture, particularly in parasitic lice, and provides an essential evolutionary framework for assessing the mechanisms and drivers of this complexity.

Viral-like particles for dsRNA delivery

Authors: Swevers Luc[2], Sun Jingchen[3], Kolliopoulou Anna[1] and Ren Feifei[3], [1]NCSR “Demokritos”, [2]NCSR “Demokritos”, Greece, [3]South China Agricultural University

Abstract: Although RNAi has emerged as a promising strategy for insect pest control, considerable improvements are required to make it suitable for practical applications. One possible strategy would be based on the use of insect RNA viruses that produce dsRNA as part of their infection cycle. However, recombinant viruses would be considered as genetically modified organisms for which strong opposition exists by regulators and the general public. An alternative solution would be to use “viral-like particles” (VLPs) for encapsulation and delivery of non-replicative dsRNA molecules that are capable to induce silencing of essential genes in insect pests.

In this project, attempts are made to employ the baculovirus expression vector system (BEVS) for creating a biotechnological platform for production of VLPs and their encapsulation of dsRNA. VLPs will be derived from the dsRNA virus Cypovirus (Reoviridae) of which the structure has been extensively characterized by cryo-electron microscopy. In addition, the production of dsRNA molecules by the BEVS will be examined and strategies will be explored for their incorporation in VLPs during co-expression in insect cells. Finally, uptake of VLPs by cell lines and insect larvae will be evaluated as well as their capacity to deliver dsRNA and trigger gene silencing.

Influence of laboratory, semi-field and field conditions on Aedes albopictus vector competence

Authors: Sy Victoria[7], Graziozi Ignazio[4], Puggioli Arianna[2], Trusso Alessandro[4], Balestrino Fabrizio[1], Zagrajek Adrian[6], Langlands Zoe[6], Carpenter Simon[5], Bellini Romeo[2], Simoni Alekos[4] and Muller Ruth[3], [1]Centro Agricoltura Ambiente “G. Nicoli”, Bologna, Italy, [2]Centro Agricoltura Ambiente “G. Nicoli”, Bologna, Italy., [3]Institute of Tropical Medicine, Unit Entomology, Antwerp, Belgium, [4]Polo d’Innovazione di Genomica Genetica e Biologia, Terni, Italy., [5]The Pirbright Institute, Woking, United Kingdom, [6]The Pirbright Institute, Woking, UK, [7]The Pirbright Institute, Woking, United Kingdom

Abstract: Experimental infections of mosquitoes with arboviruses are used to infer the potential role of vector populations in the transmission of diseases. The heterogeneity in the design of such studies can affect the results and reproducibility of experiments, making difficult the extrapolation of laboratory results to field conditions and comparisons between studies. Adaptation of mosquito’s colonies to laboratory and rearing conditions is a common step before conducting such studies and can affect the outcome of the research.

In this study we aimed to investigate the impact of Aedes albopictus rearing conditions on vector competence. Mosquito eggs were collected from the field and reared over five generations under different temperature and humidity conditions using cages of different size, to get a gradient of conditions from closer to those in nature to those typically used for colony maintenance in the insectary. Females were infected with Chikungunya virus and saliva and body parts were analyzed by plaque assay.

Results showed that rearing conditions typically used in the laboratory can lead to an overestimation of vector competence, with high values of infection rate and transmission efficiency compared to mosquitoes reared under semi-field conditions.

Molecular signatures for sexual communication in flies

Authors: Syed Zainulabeuddin, Department of Entomology, University of Kentucky, Lexington, KY 40546, United States

Abstract: Insects interpret the rich chemical landscape around them through a combination of physiological and behavioral adaptations. Exploiting vertebrates for a blood meal or, obtaining a sugar meal from plants demand extensive sensory and behavioral adaptations that are apparent across the evolutionary range of vector species. Since animal senses are biological features that have been shaped by natural selection to promote adaptive behavior, a variety of exciting patterns are apparent in what they sense and how. Vectors display robust olfactory driven behaviors. A distinct yet limited range of volatile organic compounds are parsimoniously used as major cues for tracking in various contexts. These chemicals elicit behaviors such as attraction or repulsion/avoidance while vectors seek habitats, hosts, mates, or oviposition sites. Chemoreceptors interact with the chemicals to elicit such essential behaviors: Odorant receptors (ORs), gustatory receptors (GRs) and ionotropic receptors (IRs) together detect and discriminate the chemical landscape. Additionally, they play important roles during adaptation and speciation. I will present data from our recent investigations into the molecular basis of sexual communication. Two critical events, viz., single nucleotide polymorphisms (SNPs) and gene copy number variation (CNVs) in the chemoreceptor repertoire appear to provide a compelling explanation to the chemical ecological findings and provide novel insights into the evolution of the chemosensation in a group of flies, as well as a framework for studies on the molecular basis of chemical communication.

When unhealthy lunch turns into a death trap: Mechanisms of direct and indirect host plant resistance against an invasive aphid

Authors: Szczepaniec Adrianna[1], Eubanks Micky[2], Kiani Mahnaz[3] Helms Anjel[2] and Rooney William[2], [1]Colorado State University, [2]Texas A&M University, United States, [3]USDA ARS Beltsville

Abstract: Indirect plant defenses are plant traits that increase the abundance and/or effectiveness of natural enemies (predators, parasitoids, pathogens) and thereby indirectly reduce herbivory

Most studies of indirect defenses have focused on chewing herbivores (e.g., caterpillars) or spider mites, even though phloem-feeding herbivores like aphids are associated with an abundant and rich natural enemy complex, and indirect defenses against aphids likely play important roles in both wild and crop plants. The goal of this work was to explore the effect of sugarcane aphid herbivory on induction of indirect defenses in sorghum and recruitment of natural enemies. We explored the expression of genes regulating biochemical pathways involved in volatile synthesis, quantified the emission of plant volatiles in response to aphids and measured their attractiveness to natural enemies in laboratory bioassays. We also assessed the preferential attraction of predators to HIPV-emitting plants in the field.

Anchored phylogenomics provides a robust evolutionary history for the Miltogramminae (Sarcophagidae: Miltogramminae)

Authors: Szpila Krzysztof[3], Johnston Nikolas[1], Wallman James[4], Piwczynski Marcin[2], [1]Centre for Sustainable Ecosystem Solutions, School of Earth, Atmospheric and Life Sciences, University of Wollongong, NSW, Australia, [2]Department of Ecology and Biogeography, Faculty of Biological and Veterinary Sciences, Nicolaus Copernicus University, Torun, Poland, [3]Nicolaus Copernicus University, Poland, [4]School of Life Sciences, University of Technology Sydney, NSW, Australia

Abstract: The Miltogramminae (Diptera: Sarcophagidae) are known from ~600 species across 39 genera, and constitute ~20% of global Sarcophagidae (the flesh flies). While not the largest subfamily, this group contains the greatest diversity of life histories (particularly larval feeding strategies) among the sarcophagids, with species known as kleptoparasites, obligate parasites, parasitoids, predators and saprophages. Despite their significant contribution to flesh fly biodiversity, the miltogrammines remain one of the most poorly understood groups, particularly in terms of their evolutionary history.

To date, two phylogenetic studies, Piwczynski et al. (2017) and Buenaventura et al. (2019), have attempted to resolve miltogrammine relationships at the genus-level, with the latter study utilising next generation sequencing methods for the first time in this group. Unfortunately, these studies were heavily biased towards species from the Palearctic region; neither study saw the inclusion of any Australasian miltogrammine taxa and many important miltogrammine genera were excluded completely. As a result, there are several problems with the current phylogeny of this group: several paraphyletic genera, uncertainty surrounding the basal lineage of all miltogrammines, and poor resolution of many nodes.

The present study remedies these issues through the application of Anchored Hybrid Enrichment to the most miltogrammine taxa ever included in a single study. Flies are included from all zoogeographic regions and represent 1/6th of all described species of Miltogramminae. The resultant phylogeny, presented here, provides unprecedented insight into the genus-level relationships of this subfamily globally, allows insights into the evolution of larval feeding strategies and resolves the basal life history of all miltogrammines.

The first molecular phylogeny and species delimitation of the West Palaearctic Pollenia Robineau-Desvoidy (Diptera: Polleniidae)

Authors: Szpila Krzysztof[6], Piwczynski Marcin[2], Johnston Nicolas P., Lutz Lena[5], Grzywacz Andrzej[1], Baz Arturo[7], Akbarzadeh Kamran[3] and Glinkowski Wojciech[4], [1]Department of Ecology and Biogeography, Faculty of Biological and Veterinary Sciences, Nicolaus Copernicus University, Torun, Poland, [2]Department of Ecology and Biogeography, Faculty of Biological and Veterinary Sciences, Nicolaus Copernicus University, Torun, Poland, [3]Department of Medical Entomology and Vector Control, School of Public Health, University of Medical Sciences, Tehran, Iran, [4]Department of Plant Physiology and Biotechnology, Faculty of Biological and Veterinary Sciences, Nicolaus Copernicus University, Torun, Poland, [5]Goethe-University, Germany, [6]Nicolaus Copernicus University, Poland, [7]Universidad de Alcala

Abstract: Cluster flies, representing the genus Pollenia Robineau-Desvoidy, 1830, are known as mass invaders of human dwellings and plant pollinators in the temperate climatic zone. Despite being the most species-rich and widespread genus in the family Polleniidae, no study to date has tested infrageneric relationships using molecular data. Here we use three molecular markers, COI, Ef1α and CAD to reconstruct the phylogenetic relationships between 18 West Palaearctic species of Pollenia, representing 8 predefined morphological species groups, utilising both maximum likelihood and Bayesian approaches. We show several instances where morphological and molecular results are congruent as well as instances where they are discordant. We also develop a COI barcode reference library for 18 species, containing newly generated data (87 sequences) and sequences retrieved from the Barcode of Life Data System. We analyse this dataset using both BPP and ABGD methods to validate morphological species hypotheses and delimit species. The results of these species delimitation analyses were in the most cases identical and aligned with predefined morphological species concepts. Based on the results of our analyses we synonymise P. moravica (Jacentkovskỳ, 1941), stat. rev. with P. amentaria (Scopoli, 1763) and assign 191 unidentified sequences from BOLD to named morpho-species.

Post release evolution of natural enemies: blessing or curse?

Authors: Szucs Marianna[2], Hufbauer Ruth[1] and Bitume Ellyn[3], [1]Colorado State University, United States, [2]Michigan State University, United States, [3]USDA Forest Service, Hawaii, United States

Abstract: The role of rapid evolution, both adaptive and non-adaptive, in biological control has been a core part of the field nearly since its inception and is an area of increasing focus today. Rapid evolution can drive establishment, population growth or decline. Growing experimental evidence shows that the effects on ecological dynamics can be quite large. We will show evidence from our work using Tribolium castaneum as a model species to study rapid eco-evolutionary dynamics, as well as review evidence from the literature on model systems. Further, we will present evidence from biological control systems, and outline a program for studying the role of evolution in biological control. With a focus on evolution following release, evidence suggests that adaptation generally facilitates establishment, population growth and successful control rather than leading to non-target effects. There is insufficient evidence from the field on evolutionary processes that can reduce fitness (for example, genetic drift and inbreeding), but work from model systems suggests such processes might play a role in the failure of natural enemies to control their target pests. Given that evolution of natural enemies following release will occur, we propose managing to favour adaptive over neutral processes.

Next Generation Biocontrol: Using experimental evolution to increase the effectiveness of native parasitoids at attacking invasive pests

Authors: Szucs Marianna[1], Jarrett Benjamin[1] and Linder Shelley[1], Michigan State University, United States

Abstract: We are in an era where the number of invasive species is steadily increasing while simultaneously classical biological control introductions are decreasing due to increasing regulations and costs. These trends are unlikely to change, and thus alternative methods need to be developed to control invasive pests that are safe, sustainable and publicly accepted. Native natural enemies represent a potential alternative as they often try to adopt invasive species but typically have low success rates on them. Laboratory selection, a long-recognized but rarely used method, can be used to speed up evolution and improve the performance of native parasitoids on exotic species within a few generations. We have started assessing the potential of experimental evolution to increase the virulence of native parasitoids on two highly detrimental agricultural pest species, spotted wing drosophila (Drosophila suzukii) and brown marmorated stink bug (Halyomorpha halys). We collected four native parasitoid species in Michigan: Leptopilina heterotoma (a larval parasitoid of drosophilids), Pachycrepoideus vindemmiae (a pupal parasitoid of drosophilids); and Telenomus podisi and Trissolcus euschisti that are egg parasitoids of stink bugs. Initial evaluations indicate that at least two of these four parasitoid species can develop on the target invasive species. We will present preliminary data on the potential of these species to increase their performance on invasive hosts within a few generations during laboratory selection. If this approach is successful, it could provide a safe and effective alternative or complimentary method to classical biological control.

Of Insects and Awareness: The ant colony as a test for scientific theories of consciousness

Authors: Søvik Eirik[2], Friedman Daniel[1], [1]Department of Entomology, University of California, Davis, United States, [2]Department of Science and Mathematics Volda University College, Norway

Abstract: The appearance of consciousness in the universe remains one of the major mysteries unsolved by science or philosophy. Absent an agreed-upon definition of consciousness or even a convenient system to test theories of consciousness, a confusing heterogeneity of theories proliferate. In pursuit of clarifying this complicated discourse, we here interpret various frameworks for the scientific and philosophical study of consciousness through the lens of social insect evolutionary biology. To do so, we first discuss the notion of a forward test versus a reverse test, analogous to the normal and revolutionary phases of the scientific process. Contemporary theories of consciousness are forward tests for consciousness, in that they strive to become a means to classify the level of consciousness of arbitrary states and systems. Yet no such theory of consciousness has earned sufficient confidence such that it might be actually used as a forward test in ambiguous settings. What is needed now is thus a legitimate reverse test for theories of consciousness, to provide internal and external calibration of different frameworks. A reverse test for consciousness would ideally look like a method for referencing theories of consciousness to a tractable (and non-human) model system. We introduce the Ant Colony Test (ACT) as a rigorous reverse test for consciousness. We show that social insect colonies, though disaggregated collectives, fulfill many of the prerequisites for conscious awareness met by humans and honey bee workers. A long lineage of philosophically-neutral neurobehavioral, evolutionary, and ecological studies on social insect colonies can thus be redeployed for the study of consciousness in general. We suggest that the ACT can provide insight into the nature of consciousness, and highlight the ant colony as a model system for ethically performing clarifying experiments about consciousness.

Global Perspectives on Field-Evolved Resistance to Bt Crops

Authors: Tabashnik Bruce[2], Fabrick Jeffrey[3] and Carrière Yves[1], [1]University of Arizona, [2]University of Arizona, United States, [3]USDA ARS, U.S. Arid Land Agricultural Research Center

Abstract: Crops genetically engineered to produce insecticidal proteins from Bacillus thuringiensis (Bt) have revolutionized control of some key pests, but their benefits are reduced by evolution of resistance to Bt toxins in pests. The global monitoring data reviewed here reveal at least 22 cases of practical resistance to Bt crops, which is field-evolved resistance that reduces Bt crop efficacy and has practical consequences for pest control. Each case represents the responses of one pest species in one country to one Bt toxin. The 22 cases of practical resistance involve resistance of some populations of nine major pests (seven lepidopterans and two coleopterans), six countries, and nine crystalline (Cry) toxins. Field outcomes confirm predictions from theory that abundant refuges of non-Bt host plants can delay evolution of resistance to Bt crops. Also, multi-toxin Bt crops can most effectively delay resistance to Bt crops when each of the toxins is highly effective against the target pest.

Global Patterns of Field-Evolved Resistance to Transgenic Bt Crops

Authors: Tabashnik Bruce[2], Fabrick Jeffrey[3] and Carriere Yves[1], [1]Department of Entomology, University of Arizona, United States, [2]University of Arizona, United States, [3]USDA ARS, U.S. Arid Land Agricultural Research Center, Maricopa, AZ, United States

Abstract: In each of the past two years, farmers worldwide planted over 100 million hectares of crops genetically engineered to produce insecticidal proteins from the bacterium Bacillus thuringiensis (Bt) These Bt crops have revolutionized control of some major pests, but evolution of resistance by pests has reduced their efficacy. Practical resistance to Bt crops, which is field-evolved resistance that has practical consequences for pest control, increased from 3 cases in 2005 to 21 cases in 2018 (Calles-Torrez et al. 2019, Smith et al. 2019, Tabashnik and Carrière 2019). Each case represents the response of one pest species in one country to one Bt toxin. The 21 cases of practical resistance represent resistance of some populations of nine major pests to nine crystalline (Cry) toxins, with each toxin produced by widely grown Bt crops affected by resistance in at least one case. The switch to multi-toxin Bt crops has not stemmed the tide of resistance. Indeed, the time from commercial introduction of Bt crops to practical resistance has decreased significantly over the past two decades.

The results with pink bollworm (Pectinophora gossypiella) and Bt cotton differ strikingly among the world's three leading cotton-producing nations. In the southwestern United States, farmers delayed resistance by planting non-Bt cotton refuges from 1996-2005, then cooperated in a program that used Bt cotton, mass releases of sterile moths, and other tactics to eradicate this pest from the region. In China, farmers reversed low levels of pink bollworm resistance to Bt cotton by planting second-generation hybrid seeds from crosses between Bt and non-Bt cotton. This approach yields a refuge of 25% non-Bt cotton plants randomly interspersed within fields of Bt cotton. Farmers adopted this tactic voluntarily and unknowingly; not to manage resistance, but apparently because of its perceived short-term agronomic and economic benefits. In India, where non-Bt cotton refuges have been scarce and pink bollworm resistance to pyramided Bt cotton producing Cry1Ac and Cry2Ab toxins is widespread, integrated pest management (IPM) emphasizing shortening of the cotton season, destruction of crop residues, and other tactics is now essential.

Calles-Torrez, V. et al. 2019. Field-evolved resistance of northern and western corn rootworm (Coleoptera: Chrysomelidae) populations to corn hybrids expressing single and pyramided Cry3Bb1 and Cry34/35Ab1 Bt proteins in North Dakota. J. Econ. Entomol.: doi: 10.1093/jee/toz111.

Developing a camera trap for monitoring Sympetrum dragonflies and its application to resuming rice paddy fields in the Fukushima nuclear plant disaster area

Authors: Tabuchi Ken[8], Mitamura Toshimasa[3], Yoshioka Akira[6], Matsuki Nobuhiro[4], Shimizu Akira[1], Ouchi Hirofumi[5], Oguma Hiroyuki[5], Jo Jaeick[7], Fukasawa Keita[5], Kumada Nao[5], Jingu Shoma[9] and Endo Wakana[2], [1]Freelance, Japan, [2]Fukushima Agricultural Technology Center, Japan, [3]Fukushima Agricultural Technology Center, Japan, [4]Fukushima Agricultural Technology Centre, Japan, [5]National Institute for Environmental Studies, Japan, [6]National Institute for Environmental Studies, Japan, [7]National Institute for Environmental Studies, South Korea, [8]Tohoku Agricultural Research Center, NARO, Japan, [9]University of Tsukuba, Japan

Abstract: The Fukushima Daiichi nuclear power plant accident in 2011 led to the establishment of evacuation zones across a large area. In the area, irrigation to rice paddy fields, which had provided various aquatic insects with habitats, was stopped. Although the evacuation order was cancelled at a large part of the area by the spring of 2017 owing to decrease in the radiation level and the rice paddy fields has been resuming, status of the aquatic insects has not been monitored adequately. To support monitoring of aquatic insects, we designed a novel camera trapping system, which can automatically detect and record perching dragonflies such as Sympetrum spp., known as an indicator species for environment of rice paddy fields. The camera trap system is based on a simple idea that perching dragonflies can be detected using inexpensive and energy-saving photosensors built in a perch-like structure. In the autumn of 2018, fifteen trial camera traps were set in the five plots of rice paddy fields of Fukushima for about two months, and successfully took photos of Sympetrum dragonflies. Furthermore, the frequency of detection was positively related to the result of dragonfly surveys based on observation by an investigator. Though there is room for improvement on the camera trap system, it can be a powerful tool for automatically monitoring dragonflies not only in the resuming rice paddy fields, but also in the areas where access by investigators is restricted.

The fauna of aquatic insects in the rice paddy fields on farming interruption and decontamination after an accident at the TEPCO Fukushima Daiichi Nuclear Power Plant

Authors: Tabuchi Ken[5], Mitamura Toshimasa[2], Yoshioka Akira[4], Matsuki Nobuhiro[3] and Endo Wakana[1], [1]Fukushima Agricultural Technology Center, Japan, [2]Fukushima Agricultural Technology Center, Japan, [3]Fukushima Agricultural Technology Centre, Japan, [4]National Institute for Environmental Studies, Japan, [5]Tohoku Agricultural Research Center, NARO, Japan

Abstract: The Great North Eastern Japan Earthquake & Tsunami on March 11 2011 inundated the coastlines of Fukushima prefecture. This force damaged many human lives and biodiversity. In addition, many residents were evacuated due to the accident at the Fukushima Daiichi Nuclear Power Plant. In these regions farming was interrupted. After that, the farmland was decontaminated and farming was gradually resumed. But changes in biodiversity are not monitored in farmland where has resumed. Therefore, in rice paddy fields where resumed, we investigated Sympetrum and damselfly (Coenagrionidae, Lestidae), aquatic Coleoptera and Hemiptera according to the Functional Agro-biodiversity Indicators and Assessment Manual (2012).

As a result, three species of Sympetrum, S. frequens, S. infuscatum, S. kunckeli were confirmed in the paddy fields where farming resumed. Of these, S. frequens was the most common and the nymphal exuviae were confirmed even in the reopening year. In the damselfly, seven species were confirmed and the most common species was Ischnura asiatica. On the other hand, 23 species of aquatic Coleoptera and Hemiptera were confirmed in a 2019 survey. Among them, a large number of individuals were identified in Enochrus simulans, Gerris latiabdominis and the genus Sigara. In addition, we will report the results of analysis examining effects of cultivation method, decontamination, and farming interruption on these aquatic insects, and discuss on aquatic insect biodiversity in the resuming rice paddy fields.

The fauna of frogs and spiders in resuming rice paddy fields after an accident at the TEPCO Fukushima Daiichi Nuclear Power Plant

Authors: Tabuchi Ken[5], Mitamura Toshimasa[2], Yoshioka Akira[4], Matsuki Nobuhiro[3] and Endo Wakana[1], [1]Fukushima Agricultural Technology Center, Japan, [2]Fukushima Agricultural Technology Center, Japan, [3]Fukushima Agricultural Technology Centre, Japan, [4]National Institute for Environmental Studies, Japan, [5]Tohoku Agricultural Research Center, NARO, Japan

Abstract: TEPCO Fukushima Daiichi nuclear power plant accident was occurred due to the Great North Eastern Japan Earthquake in 2011. Many residents of 12 municipalities Fukushima prefecture were force to evacuation due to diffusion of radioactive substances follow the accident. Decontamination, including soil stripping and soil dressing, has been conducted in these regions, and farming was gradually resumed. These changes of agricultural environment were anthropogenic disturbance of ecosystem, which was unprecedented in the history.

As a preliminary study, we surveyed the fauna in 5 paddy fields where resumed in Iitate village after decontamination in 2016. Although Tokyo Daruma pond frog (Rana porosa porosa) was common species before the accident, no individuals were found in 2016. It was assumed that interrupted rice cultivation at a large part of the area affected populations of this species, which mainly inhabits rice paddy fields. To assess effects of these changes of agricultural environment on agro-biodiversity, we investigated frogs (Ranidae, Hylidae), spiders (Tetragnatidae), Sympetrum dragonfly and damselfly (Coenagrionidae, Lestidae), aquatic Coleoptera and Hemiptera at 16 distincts in 7 municipalities including Iitate village, according to the Functional Agro-biodiversity Indicators and Assessment Manual compiled by the government of Japan. At this presentation, we report about frogs and spiders as potential predatory natural enemies of various insect pests in rice paddy fields.

From the field research at more than forty rice paddy fields in 2018 and 2019, R. porosa porosa were found in Iitate village. Moreover, Rana japonica, Rana rugose, Hyla japonica were observed. In the spiders, 5 species of Tetragnatidae were observed, with the most common being Tetragnatha caudicula. In addition, we will discuss effects of interrupted cultivation, decontamination and region on these frogs and spiders.

Apoptosis-mediated vasa down-regulation controls developmental transformation in Japanese Copidosoma floridanum female soldiers

Authors: Tabunoki Hiroko[1], Ohno Hitomi[2] and Iwabuchi Kikuo[2], [1]Department of Science of Biological Production, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Japan, [2]Tokyo University of Agriculture and Technology, Japan

Abstract: Copidosoma floridanum is a polyembryonic, caste-forming, wasp species. The ratio of investment in different castes changes with environmental stressors (e.g. multi-parasitism with competitors). The vasa gene was first identified in Drosophila melanogaster as a germ-cell-determining factor, and C. floridanum vasa (Cf-vas) gene positive cells have been known to develop into reproductive larvae. Cf-vas seems to control the ratio of investment in C. floridanum larval castes. In this study, we identified environmental factors that control Cf-vas mRNA expression in Japanese C. floridanum by examining Cf-vas mRNA expression under competitor (Meteorus pulchricornis) venom stress; we treated the male and female morulae with M. pulchricornis venom. We also assessed the effects of multi-parasitism of Japanese C. floridanum with M. pulchricornis and found an increasing number of female soldier larvae. The results showed that several amino acid sequences differ between the Japanese and US Cf-vas. Quantitative reverse transcription polymerase chain reaction (qRT-PCR) showed that Japanese Cf-vas mRNA is expressed in both male and female larvae and pupae, but mRNA expression decreases in adults. Cf-vas mRNA expression significantly decreased, while C. floridanum dronc (Cf-dronc) mRNA expression increased, in female morulae after M. pulchricornis venom treatment at 20 h and 0 h of the culture period, respectively. Females and males showed different Cf-vas or Cf-dronc mRNA expression after M. pulchricornis venom treatment. Therefore, M. pulchricornis venom could affect the ratio of investment in different female castes of Japanese C. floridanum by decreasing Cf-vas mRNA expression via apoptosis.

Exploration of the ingredients which effect to human cancer cell line in the larval frass of Euploea mulciber

Authors: Tabunoki Hiroko[1], Nakano Miho[1], Kihara Rinka[3] and Ito Natsumi[2], [1]Department of Science of Biological Production, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Japan, [2]Global Innovation program for Young Scientists and Engineers, Organization for the Advancement of Education and Global Learning, Tokyo University of Agriculture, [3]Global Innovation program for Young Scientists and Engineers, Organization for the Advancement of Education and Global Learning, Tokyo University of Agriculture, Japan

Abstract: To date, many medicines have been discovered from natural products. However, exploration for the plant-derived natural products are almost completed, and other resources, which include ingredients for utilizing pharmaceutical agents, are required. Thus, there is an urgent need to find new pharmaceutical resources. Lepidoptera comprises 200,000 species of butterflies and moths, the majority of lepidopteran insects eat plants at the larval stage and take up secondary metabolites in the process of ingesting nutrients. Besides, insects have evolved a unique system that metabolizes secondary metabolites, including host plants, for escaping food competition. Furthermore, they keep the secondary metabolites that uptake from the plant in their body, and these secondary metabolites are utilized for escaping from predators. In this way, insects and plants have a strong relationship with the planets.
E.mulciber eats Ficus microcarpa and several kinds of Apocynaceae plants containing toxic ingredients such as alkaloids. E.mulciber might convert plant-derived ingredients into other substances through their metabolic system. We are interested in the ingredients produced through this species-specific metabolic system in E.mulciber. In this study, we investigated cell viability to several human cancer cell lines in the ingredients extracted from the frass of E.mulciber larva, which ate Ficus microcarpa. First, we extracted ingredients from the host plant or the larval frass using three types of organic solvents. Then, we examined morphological observation, cell viability to the several types of human cancer cell lines in these extracts.
Consequently, cell viability was significantly inhibited by the chloroform extract of larval frass. To seek the compounds which have inhibition of cell viability to the human cancer cell lines, we compared these ingredients from the host plants and larval frass using Thin-layer chromatography (TLC). Specific spots were presented only in the ingredients from the larval frass of E.mulciber. These findings suggested that E.mulciber larval frass might contain the compounds that changes the chemical structure and biological activity. In this presentation, we would like to discuss the metabolic factor that alters chemical structure and biological activity in E.mulciber.

Isolation of the ingredients which have biological activity for the human cancer cell lines in the frass of Papilio machaon and Papilio memnon

Authors: Tabunoki Hiroko[2], Nakano Miho[2] and Kitano Yoshikazu[1], [1]Department of Applied Biological Science, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Japan, [2]Department of Science of Biological Production, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Japan

Abstract: Lepidoptera comprises 200,000 species of butterflies and moths. The majority of lepidopteran insects eat plants at the larval stage and take up secondary metabolites in the process of ingesting nutrients. Byasa alcinous utilize secondary metabolites that are toxic to other organisms, including their host plants, to protect against predation. Pieris rapae eat poisonous plants, and they absorb poisonous secondary metabolites to their body. However, they can detoxify them by their unique metabolic system. Thus, some lepidopteran insects have a species-specific metabolic system. We are interested in ingredients produced through these unique metabolism systems in lepidopteran insects.

In this study, we investigated ingredients which have anti-cancer action to a human cancer cell lines from larval frass of Papilio machaon and Papilio memnon.

First, we extracted ingredients from the host plant and the larval frass using three types of organic solvents, and we examined morphological observation, cell viability, and SOD (anti-oxidative) activity to human cancer cell line in these extracts.

As a result, cell viability was inhibited by the chloroform extracts of larval frass from P. memnon fed Citrus paradisi. Cell viability was also inhibited by the chloroform extracts of larval frass from P. machaon fed Angelica keiskei.

Next, the frass extracts and plant extracts were compared by thin layer chromatography or nuclear magnetic resonance spectrometry, and we found specific spots or peaks only in the frass extracts from P. machaon fed A. keiskei.

To isolate ingredients which accelerates decreasing of cell viability, the chloroform extract from larval frass of P. machaon fed A. keiskei was separated using open column chromatography. One fraction significantly accelerated the decreasing of cell viability only in the human colon cancer cell line, HCT116. However, SOD activity did not change in HCT116.

Our findings strongly suggested that larval frass of P. machaon fed A. keiskei could contain the compounds that chemical structure and biological activity were changed by their unique metabolic system. In this presentation, we would like to discuss the metabolic factor that change the chemical structure and biological activity in P. machaon .

The new type of SOD knockdown leads to the abnormal leg movement and embryogenesis in T.castaneum

Authors: Tabunoki Hiroko[2], Nishiko Maaya[3], Noh Mi[1], Mun Seulgi[1] and Arakane Yasuyuki[1], [1]Chonnam National University, South Korea, [2]Department of Science of Biological Production, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Japan, [3]Tokyo University of Agriculture and Technology, Japan

Abstract: Superoxide dismutase (SOD) has been identified in the model insects. SOD is an essential key enzyme with the primary role of eliminating the superoxide anion which one of the reactive oxygen species (ROS). The red flour beetle (Tribolium castaneum) is a holometabolous insect belonging to the Order Coleoptera. The genome information of this species is well characterized, and systematic RNA interference (RNAi) is available. Previously, we found a new type of SOD gene which has three copper/zinc SOD domain in the T. castaneum genomic database, and we named this gene as T. castaneum SOD6 (TcSOD6) and then analyzed the function of TcSOD6 gene using RNAi. Quantitative RT-PCR experiments revealed that the transcript level of TcSOD6 mRNA was increased in the pupal developmental stages. To evaluate the TcSOD6 function in T. castaneum, we performed RNAi in the each developmental stage and observed these phenotypes. When TcSOD6 dsRNA was injected into larva, prepupa, or pupa, the phenotype appeared as short longevity and abnormal leg movements in the adult stage. Also, the amount of fat body was significantly decreased in the adult abdomen. Thus, it was suggested a short life span might be induced by fat body loss.

While we observed the tendons structure in their legs by pathological analysis to investigate their abnormal leg movements. However, tendons structure had a healthy structure.

Next, to carry out parental RNAi, TcSOD6 dsRNA was injected into a mature female adult and then performed the mating with a normal male adult. Almost eggs from the female adult which treated with TcSOD6 dsRNA did not progress embryogenesis. The phenotypes of the TcSOD6 knockdown were different depending on the developmental stage that injected dsRNA. Therefore, TcSOD6 might have a specific functions in each developmental stage. In this presentation, we would like to discuss how the TcSOD6 gene relates to adult leg movements, and egg embryogenesis.

Belowground microbiomes drive aboveground plant–pathogen–insect interactions

Authors: Tack Ayco[3], van Dijk Laura[1] and Ehrlén Johan[2], [1]Department of Ecology, Environment and Plant sciences, Stockholm University, Sweden, [2]Department of Ecology, Environment and Plant sciences, Stockholm University., Sweden, [3]Stockholm University, Sweden

Abstract: Plants interact with a large diversity of microbes and insects, both below and above ground. While studies have shown that belowground microbes affect the performance of plants and aboveground organisms, we lack insights into how belowground microbial communities may shape interactions between aboveground pathogens and insects. In this study, we investigated the effects of soil microbiomes and aboveground organisms on plant growth and development. We further examined whether differences in soil microbiomes influenced interactions between aboveground organisms. We conducted a growth-chamber experiment with oak seedlings (Quercus robur) growing in three soils with similar abiotic soil properties but with distinct natural soil microbiomes. Seedlings were subjected to single or dual attack by powdery mildew (Erysiphe alphitoides) and aphids (Tuberculatus annulatus), either in the presence or absence of prior attack by a free-feeding caterpillar (Phalera bucephala). Soil microbiomes were associated with differences in seedling height, and seedlings with multiple aboveground organisms had more but smaller leaves than healthy seedlings. The soil microbiome affected the severity of powdery mildew infection, and mediated the impact of co-occurring aboveground organisms on aphid population size. Our study highlights that plant performance is affected by natural soil microbiomes as well as aboveground organisms, and that natural soil microbiomes can shape interactions between pathogens and insects. These findings are important to understand species interactions in natural systems, as well as for practical applications, such as manipulation of soil microbiomes to manage agricultural pests and diseases.

The impact of latitude on patterns of voltinism and the host selection and performance of multivoltine herbivores within the oak-associated community

Authors: Tack Ayco[2], Gotthard Karl[1], Gaytán Álvaro[3], [1]Dept. of Zoology and Bolin Centre for Climate Research, Stockholm University, Sweden, [2]Stockholm University, Sweden, [3]Stockholm University. Department of Ecology, Environment and Plant Sciences., Sweden

Abstract: The phenology of insects consists of the timing of life events, as well as the number of generations (voltinism). While several studies have focused on the impact of climate change on the timing of seasonal events, or the voltinism of single species, we still have few insights in the factors that shape patterns of voltinism within ecological communities. Importantly, voltinism can have a major impact on population growth, trophic interactions, and the rate of evolution. We investigated the relative importance of latitudinal variation as a proxy of temperature in shaping patterns of voltinism within an herbivore community feeding on deciduous oak, and how these changes in voltinism, as well as plant phenology, can affect host selection and herbivore performance in the presence and absence of a third species (a plant pathogen). First, we used citizen science data on the seasonal flight periods of lepidopterans feeding on deciduous oaks (Quercus spp.) within Sweden and across Europe. Second, we conducted a multifactorial experiment to assess the influence of spring phenology and pathogen infection on the preference and performance of multivoltine herbivores during the different herbivore generations (spring, summer, autumn). The proportion of multivoltine species within Sweden decreased with latitude, caused by a lower number of partially multivoltine species in northern Sweden, while no clear latitudinal pattern in voltinism was found in Europe. We did not find consistent differences in the relative abundance of the first and subsequent generations along a latitudinal gradient in Sweden or Europe. Regarding the preference of herbivores, leaf-miners preferred to oviposit on late phenology and healthy plants during the entire growing season, while pathogen infection reduced aphid preference in spring and summer, but not in autumn. We found a weak influence of plant phenology on the performance of leaf-miners, and a high variability on aphid performance. Our findings highlight that latitude (as a proxy for temperature) explains part of the variation in the voltinism of herbivores, and that changes in voltinism will affect the distribution and performance of herbivores within plant populations, with important consequences for the ecology and evolution of species interactions and food web structure.

Biological activity of Ajuga iva extracts (phytoecdysteroids and clerodanes) against the African cotton leafworm Spodoptera littoralis

Authors: Taha-Salaime Leena[3], Inbar Moshe[3], Ghanim Murad[1] and Aly Radi[2], [1]Department of Entomology The Volcani Center Rishon LeZion, Israel, [2]Newe Ya'ar Research Center, Agricultural Research Organization, Israel, [3]University of Haifa, Israel

Abstract: The African Cotton Leafworm Spodoptera littoralis, a major crop pest worldwide, is usually controlled by chemical insecticides that led to serious environmental problems. Ajuga plants produce phytoecdysteroids which are analogues of steroid hormones that regulate metamorphoses in arthropods) and clerodanes,diterpenoids exhibiting anti-feedant activities. Our objective was to evaluate their potential to control S. littoralis.

Using Liquid Chromatography-Time Of Flight-Mass Spectrometry (LC-Tof-MS) and Thin-Layered Chromatography (TLC), we analyzed the profilesof phytoecdysteroids and clerodanes in Israeli Ajuga iva leaf extracts and evaluated their efficiency in controlling S. littoralis using bioassays. To test the biological activity of A. iva crude extracts, leaves of Castor bean were treated with water suspended-dried methanolic crude extracts of phytoecdysteroid and clerodanes from A. iva leaves at the concentrations of 50, 100 and 500µg/µl. For each repeat, 10 1st and 3rd larvae of S. littoralis were feed with one treated leaf for 3 and 4 days, respectively. Mortality, Larval weight gain (LWG), relative growth rate (RGR) and survival rate were compared to control leaves. DAPI and phalloidin staining of actin filaments were used to test the effectof the A. iva crude extracts on the insect gut morphology and intactness.

The tested crude extracts at the aforementioned concentrations significantly increased mortality of S. littoralis 1st stage larvae and caused36%, 70% and 87%, respectively, compared to 6% in the the control. LWG and RGR of 3rd stage larvae were significantly decreased (52%, 44% and 30% respectively) as compared with the relevant controls. Larvae that survived the different treatments with A. iva extracts were used forstaining the cellular nuclei and actin filaments with DAPI and phalloidin, respectively. The major phenotypes that were observed following treatment with 250µg/µl of crude leaf extract were reduced gut size, dislocation of the nuclei, abnormal and malformed actin filaments organization. Those results strongly demonstrate the potential in developing extracts from A. iva as alternative environmentally-safe insect pest control materials.

Establishment of breeding condition and efficacy test methods for textile-attacking insect pests, the oriental silverfish, Ctenolepisma sp. and the booklice, Liposcelis bostrychophila.

Authors: Tak Jun-Hyung[1], An Huijun[1]and Jung Hun[1], [1]Seoul National University, South Korea

Abstract: Silverfishes and booklice give damages on fabrics or furnitures, and are usually found in warm, humid environments worldwide. Although they are not known to transmit any disease nor to physically damage mammals including human, the control methods involve chemical insecticides, mostly naphthalene or empenthrin. As of 2012, the European Union legislated Biocidal Product Regulation (BPR), and started to legally control the registration and the use of pesticidal products for textile-attacking insect pests. In South Korea, a similar regulation has started in effect on January 1st, 2019, under the Chemical Products Safety Act, all household insecticides including the ones intended for textile-attacking insect pests have to be registered to the Ministry of Environment for commercial use. While the new regulation is already in effect, the establishment of test guidelines for newly regulated insecticides, including for stored-product pests and textile-attacking ones is urgently necessary. The present study aims to provide collection and breeding methods for lab colonies setup and to suggest the evaluation procedure for active ingredients. In the collection study, three types of lure traps were designed and evaluated. For the growth condition study, two different food compositions (high protein : low carbohydrate or low protein : high carbohydrate) with three different temperature setup were tested. For the toxicity test, the bioactivity of chemicals and plant essential oils were examined via the contact and residual bioassay, fumigation bioassay, and repellent assay.

Synergistic effects of uninfested plants and honey on the attractiveness of the synthetic host-infested plant volatiles to parasitoid wasps

Authors: Takabayashi Junji[1], Uefune Masayoshi[4], Ozawa Rika[2], Shiojiri Kaori[3], Kakibuchi Kazumas[5], Sano Kota[7], Uchida Toru[5] and Ohara Yoshitsugu[6], [1]Center for Ecological Research, Kyoto University, Japan, [2]Center for Ecological Research, Kyoto University, Otsu, Shiga, Japan, [3]Department of Agriculture, Ryukoku University, Otsu, Shiga, Japan, [4]Faculty of Agriculture, Meijo University, Nagoya, Aichi, Japan, [5]Shikoku Research Institute Inc., Takamatsu, Kagawa, Japan, [6]Shikoku Research Institute Inc., Takamatsu, Kagawa, Japan, [7]Soda Aromatic Co. Ltd., Tokyo, Japan

Abstract: When infested by herbivores, plants start emitting specific blend of volatiles, so-called herbivory-induced plant volatiles (HIPVs) that attract carnivorous natural enemies of the herbivores. We already reported that a blend of four volatile compounds of HIPVs emitted from cabbage plants infested by diamond back moth (DBM; Plutella xylostella Lepidoptera: Plutellidae) larvae, attracted larval parasitoid wasps, Cotesia vestalis (Hymenoptera: Braconidae) under both laboratory and field conditions. The blend of synthetic four compounds is hereafter called the attractant.

DBM larva is one of the important pests of cruciferous crops worldwide. C. vestalis is considered to be an effective biological control agent for DBM larvae. To develop the biological control method of DBM larvae with C. vestalis, we have been studying the possible use of the attractant using komatsuna plants (Japanese mustard spinach; Brassica rapa var. perviridis) as a model. In this presentation, we will show that (1) C. vestalis females prefer DBM-infested komatsuna plants to uninfested komatsuna plants in an experimental greenhouse, and (2) the presence of the attractants next to infested komatsuna plants results in the increased attractiveness to C. vestalis when compared with infested komatsuna plants alone.

In general, infested plants were surrounded by conspecific and/or heterospecific uninfested plants under field conditions. Thus, we further tested the effects of the presence of uninfested komatsuna plants on the attractiveness of the attractant. In addition, the effect of the presence of honey (food for C. vestalis females) was also tested. In choice chamber experiments in the laboratory, the presence of the attractant together with either the uninfested plants or honey synergistically increased the attractiveness of the attractant. In the greenhouse, when infested plants were coupled with the attractant, uninfested plants and honey, the attractiveness was increased significantly when compared to infested plants coupled only with the attractant. These data indicated the importance of volatiles from uninfested plants and honey on the attractiveness of the attractants to C. vestalis. We will discuss the synergistic effects of uninfested plants and honey on the attractiveness of the synthetic host-infested plant volatiles to parasitoid wasps in the viewpoint of DBM control.

The induction of defense in eggplants exposed to conspecific volatiles induced by omnivorous predator, Nesidiocoris tenuis

Authors: Takabayashi Junj[1], Rim Hojun[1], [1]Center for Ecological Research, Kyoto University, Japan

Abstract: In response to damage made by herbivorous arthropods, plants start emitting so-called HIPVs (Herbivory-Induced Plant Volatiles) that attract carnivorous naturel enemies of the currently infesting herbivores. Further, HIPVs mediate communication between plants. Plant-plant communication via HIPVs is now wildly recognised as one of the induced defence strategies of plants against herbivores.

HIPVs are also induced by omnivorous insects, and such HIPVs would also mediate plant-plant communication. In this study, we tried to clarify whether volatiles emitted from eggplants infested by omnivorous insects, Nesidiocoris tenuis Reuter (Heteroptera: Miridae) induce direct and/or indirect defence in neighbouring uninfested conspecific plants. Eggplants infested by N. tenuis adults emitted specific HIPVs that are qualitatively and quantitatively different from HIPVs emitted from eggplants infested by tobacco cutworm (Spodoptera litura Fabricius, Lepidoptera: Noctuidae), and two spotted spider mites (Tetranychus urticae Koch, Trombidiformes: Tetranychidae). In this study, intact eggplants were exposed to N. tenuis-HIPVs for 3 days, and then their defence traits were measured. Volatiles from the exposed eggplants were not significantly different from those from control eggplants (plants exposed to volatile from uninfested conspecifics). The exposure of N. tenuis-HIPVs to uninfested eggplants affected their production of HIPVs neither qualitatively nor quantitatively when they were infested by herbivore (S. litura) or N. tenuis. These data suggested that the exposure of N. tenuis-HIPVs did not affect the induced indirect defense in uninfested eggplants. By contrast, the direct defences were induced by exposure of N. tenuis-HIPVs. The exposed eggplants were more defensive against S. litura larvae when compared with the control eggplants: the reduction of the growth rate was recorded when the larvae were on the exposed eggplants. We will also report the performance of other herbivore species (T. urticae) and N. tenuis itself on the exposed eggplants. The possible effects of N. tenuis-HIPVs in plant-plant communication and in tritrophic interactions will be discussed.

A parental volatile pheromone triggers offspring begging in a burying beetle

Authors: Takata Mamoru[2], Mitaka Yuki[4], Mori Naoki[3] and Steiger Sandra[1], [1]Department of Evolutionary Animal Ecology, University of Bayreuth, Germany, [2]Kyoto University, Graduate School of Agriculture, Japan, [3]Laboratory of Chemical Ecology, Graduate School of Agriculture, Kyoto University, Japan, [4]Laboratory of Insect Ecology, Kyoto University, Japan

Abstract: Parental care is a notable aspect of reproductive effort in many animals. The interaction between offspring begging and the parental feeding response is regarded as an important communication mechanism that regulates offspring food supply. The costs of begging are hypothesized as necessary for evolutionally stable parent–offspring communication. Reducing the cost of superfluous begging is beneficial to both parents and offspring; thus, selection impels parents to emit signals informing that they are ready to provision, and offspring to respond to these parental signals. However, no study has demonstrated that parents send signals to elicit offspring begging. In this study, we concluded that parents of the burying beetle species Nicrophorus quadripunctatus inform their offspring of their preparation for provisioning by emitting a volatile signal, and we term this newly identified pheromone type the “provisioning pheromone”. Gas chromatography–mass spectrometry analysis and behavioral assay revealed that female parents emitted an antimicrobial aromatic compound, 2-phenoxyethanol, in their regurgitation before provisioning, and that this compound elicits begging behavior from their offspring. These results suggest that the provisioning pheromone originates from a germicidal agent that the female parent invests in the regurgitated food. Furthermore, begging incurs growth and survival costs, and parents spent more than 85% of their time in close proximity to their offspring without provisioning. Therefore, it is suggested that limiting offspring begging during provisioning is beneficial to both parents and offspring. We report here a novel aspect of parent–offspring communication in family life.

Key role of systematics in biological control of invasive stink bugs

Authors: Talamas Elijah[2], Hoelmer Kim A.[3], Pickett Charlie[1], [1]California Department of Food and Agriculture, United States, [2]Florida State Collection of Arthropods, [3]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States

Abstract: Two species of pentatomid stink bugs have recently become worldwide pests of agriculture, the brown marmorated stink bug (Halyomorpha halys) and bagrada bug (Bagrada hilaris). Programs to manage these pests rely on accurate identification of natural enemies, especially egg-parasitoid wasps in the genera Gryon and Trissolcus (Scelionidae). The taxonomy of these wasps is thus essential for efficacious biological control programs in North America, Europe, Australia and New Zealand. Ecological studies, including surveys with sentinel eggs, have resulted in a greater understanding of parasitoid biology and the discovery of multiple adventive populations of Trissolcus in areas invaded by H. halys and B. hilaris. These include Trissolcus japonicus in Europe and North America, T. mitsukurii in Europe, and T. hyalinipennis in California. Classical biological efforts conducted in concert with research on parasitoids systematics have yielded a wealth of new information on parasitoid diversity, host-associations, and phylogenetic relationships. The role of systematics in multi-institutional, multi-continental projects will be discussed, highlighing recent advances in alpha taxonomy, emerging diagnostic technologies, and the challenges of identifying parasitoids on a world scale.

Disrupting the transmission of Liberibacter by psyllids

Authors: Tamborindeguy Cecilia, Dept. of Entomology Texas A&M University College Station, United States

Abstract: Psyllids are phloem feeding hemipterans that transmit plant bacterial pathogens Liberbacter. Control of diseases caused by Liberibacter relies on chemical control of the vector populations, with great economic and environmental consequences. ‘Candidatus Liberibacter solanacearum’ (Lso) has emerged as a serious bacterial pathogen of crops worldwide. In North America, two bacterial haplotypes, Lso A and Lso B, are transmitted by the potato psyllid Bactericera cockerelli, to solanaceous plants and cause zebra chip disease in potato. We are investigating this pathosystem to understand the key molecular mechanisms involved in the transmission of these pathogens in order to identify targets that could be used to disrupt their transmission. In this presentation we describe the differences in the transmission of these haplotypes and potential genes that could be targeted to disrupt Liberibacter transmission or its ability to infect its hosts.

Larval colour polyphenism in Lepidoptera: birds rule the game

Authors: Tammaru Toomas[1] and Sandre Siiri-Lii[1], [1]Department of Zoology, University of Tartu, Estonia

Abstract: We will advocate the view that bird predation forms by far the most important selective force on insect appearance: alternative factors appear to have limited contribution at best. In a series of experiments with colour-polyphenic, hairy larvae of Orgyia antiqua (Lepidoptera: Erebidae) we showed that empirical evidence is well consistent with this ‘bird hypothesis’. In particular, we did not find evidence of the effect of cuticular darkness on thermoregulation of these insects. Instead, the dependence between the colouration and body size of the larvae could well be explained by size-specific optima for cryptic appearance. Despite the yellow-red-black colour pattern of the larvae, there was little support for the alternative hypothesis based on size-dependent warning effect. Vertebrate ecologists have developed the idea that the colouration of an animal can reflect its ’quality’, with darker and brighter colouration being positively correlated with individual fitness. In contrast, in O. antiqua, we were not able to detect any phenotypic correlations between performance of the larvae and their colouration parameters. This question was further addressed in a quantitative genetic study on Ematurga atomaria (Lepidoptera: Geometridae), a species showing a complex pattern of larval colour polyphenism, encompassing both genetic and environmental effects (Journal of Evolutionary Biology, 31: 1959-1968). There was very weak to no evidence of either genetic or environmental correlations between a composite trait describing variation in larval colouration, and fitness-related parameters of growth performance of the insects. In other words, there was no support for trade-offs between colouration and performance, neither could we find any evidence for physiological cost of certain colour patterns. In contrast, we showed that the variation in appearance of E. atomaria is partly based on plastic responses to host plant species, which contributes to the situation-specific camouflage of the larvae. There is however considerable residual variance in colour-related traits which can be interpreted as a result of negatively frequency-dependent selection imposed by bird predators, which can both maintain genetic variance and select for coin-flipping plasticity in colour patterns.

A determining factor for insect feeding preference in Bombyx mori

Authors: Tan Anjiang[2], Ye Chongjun[1], Li Ruixue[1] and Wang Taichu[1], [1]Sericulture Research Institute of Anhui Academy of Agricultural Sciences, Hefei, China, [2]Shanghai Institutes for Biological Sciences, China

Abstract: Feeding preference is critical for insect adaptation and survival. However, little is known regarding the determination of insect feeding preference, and the genetic basis is poorly understood. As a model lepidopteran insect with economic importance, the domesticated silkworm, Bombyx mori, is a well-known monophagous insect that predominantly feeds on fresh mulberry leaves. This species-specific feeding preference provides an excellent model for investigation of host-plant selection of insects, although the molecular mechanism underlying this phenomenon remains unknown. Here, we describe the gene GR66, which encodes a putative bitter gustatory receptor (GR) that is responsible for the mulberry-specific feeding preference of B. mori. With the aid of a transposon-based, clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein-9 nuclease (Cas9) system, the GR66 locus was genetically mutated, and homozygous mutant silkworm strains with truncated gustatory receptor 66 (GR66) proteins were established. GR66 mutant larvae acquired new feeding activity, exhibiting the ability to feed on a number of plant species in addition to mulberry leaves, including fresh fruits and grain seeds that are not normally consumed by wild-type (WT) silkworms. Furthermore, a feeding choice assay revealed that the mutant larvae lost their specificity for mulberry. Overall, our genetic and phenotypic evidence demonstrates that GR66 is a major factor affecting the feeding preference of the silkworm.

A comparison of hyperuricemia model mice loaded with oxonic acid and the silkworm “o06” strain as an alternative for evaluating voluntary oral administration (II)

Authors: Tanaka Ryuichiro[3], Masuda Hiroto[3], Kawakami Hikaru[2], Hosoki Miku[2], Yamaguchi Shoji[2] and Banno Yutaka[1], [1]Faculty of Agriculture, Kyusyu University, Japan, [2]Faculty of Pharmaceutical Sciences, Setsunan University, Japan, [3]Faculty of Pharmaceutical Sciences, Setsunan University, Japan

Abstract: We proposed the silkworm “o06” strain as a hyperuricemia model. When silkworms were given either a single subcutaneous or single intestinal dose of medication for hyperuricemia (Feburic®, allopurinol, etc.), the medication effectively reduced the uric acid (UA) levels . Here, we examined the optimal conditions for evaluating long-term voluntary oral dosage, and dose response effects were considered.

Methods: The UA content was measured in the silkworm “o06” strain (from the 3rd to the 6th day of the fifth instar) from NBRP (National BioResource Project ; Kyushu University). The silkworm groups given the leaves soaked in CPPG solution, Feburic® suspension, Allopurinol solution, and Milli-Q water formed the evaluation, treatment, and control groups, respectively. All silkworms were treated and kept in a room maintained at 23°C ± 3°C with 40–70% humidity. We performed deproteinization using the chloroform-methanol method. Ten microliters of fresh silkworm hemolymph was placed in the sample reservoir of a Cosmospin Filter G spin filter with 100 µL of methanol, 100 µL of chloroform, and 90 µL of H2O; the solution was then sonicated. The filters were centrifuged at 10,000 rpm for 20 min to collect the aggregated protein. The filtrate was lyophilized for 90 min. Dried residue was dissolved in 15 µL H2O. The solution (3 µL) was injected into the HPLC instrument and was immediately analyzed in triplicate. Standard UA (0, 1.25, 2.5, and 5.0 mg/dL) solutions were prepared using reagent-grade chemicals at the time of use. Each (3 µL) solution was subjected to HPLC under the aforementioned conditions. The automatic peak area counts for each peak of interest were plotted against concentration (mg/dL) to generate a calibration curve. The areas of the peaks in the chromatogram were compared with the amount of UA injected. Each dose was determined using four or five independent samples, and each result is shown as a scatter plot. The determination coefficient for UA was 0.999. The HPLC assays were performed in triplicate, and the averages were calculated. All animal experiments used 12–17 silkworms, and the data are presented as means ± standard deviations. Differences between the means of the control silkworms and the sample-treated silkworms were analyzed using one-way analysis of variance and Student’s t-test with Bonferroni’s correction. A P-value of < 0.05 was deemed to indicate statistical significance. We hold significant difference authorization with OriginPro 9.1J and IBM SPSS Statistics 20.

Results:A significant difference in the UA level 20 hours after starting was observed between the treatment and control groups. Evaluation of the UA levels was possible. And each CPPG and allopurinol showed in terms of efficacy, but the effect of Feburic® was barely measurable. We plan to make comparisons with the sample dose (mg/g) in mice and evaluate whether the silkworm is a useful model of hyperuricemia.

Excretion of uric acid (and allantoin) in the silkworm “o06” strain as an animal model of hyperuricemia

Authors: Tanaka Ryuichiro[3], Sakazaki Fumitoshi[4], Nishikubo Nanae[2], Manato Sakamoto[2] and Banno Yutaka[1], [1]Faculty of Agriculture, Kyusyu University, Japan, [2]Faculty of Pharmaceutical Sciences, Setsunan University, Japan, [3]Faculty of Pharmaceutical Sciences, Setsunan University, Japan, [4]Faculty of Pharmacy, Osaka Ohtani University, Japan

Abstract: A large number of patients suffer from gout or hyperuricemia, a condition that significantly degrades the quality of life of patients with hypertension. The use of a sensitive method for uric acid (UA) analysis is necessary to diagnose and to facilitate the development of treatments for hyperuricemia. Hyperuricemia mice models involving the administration of potassium oxonate (a uricase inhibitor) have been developed to evaluate and screen medications used for the treatment of hyperuricemia. We have been developing methods for measuring compounds in small quantities of plasma that can be collected from a mouse-tail vein without anesthesia. This is now possible due to the development of a UA quantitative analysis that allows the use of microliter volumes of plasma. However, the use of hyperuricemia mice models involving the administration of potassium oxonate creates a number of problems, potentially. One is the difference between humans and mice in the end product of purine metabolism; mice excrete allantoin by urinary excreation because they have an uricase. The second problem is cost for the maintenance of experimental mice, are expensive. Third, ethical issues exist surrounding the use of mice and rats, which is regulated by law in European Union (enforce in March 2013). From this kind of circumstance, we need to renew the hyperuricemia model in medical studies.

Silkworms normally produce UA as a result of nucleic acid metabolism and reserve it in epidermal cells for use after the pupal stage. Mutant silkworms, called ”Aburako”, have decreased ability to store UA in the epidermis, which then builds up in the hemolymph and causes the skin of the mutants to become translucent.

Herein, we discuss the o06 strain as a possible substitute for the mouse hyperuricemia model in medical studies, and examine its UA (and allantoin; AL) excretion of feces, larval urine, and meconium.

Materials and Methods: AL and UA were measured in the o06 strain (3 to 6 days of the 5th instar) from the National BioResource Project silkworm collection. The UA content was analyzed using improved high-performance liquid chromatography with ultraviolet detection, and the quantity of AL was determined of hydrophilic interaction liquid chromatography. The silkworm mutants were then treated with allopurinol or Febuxostat (a xanthine oxidase inhibitor) for hyperuricemia.

Results: There was no difference in the total amount of UA excreted (mg/individual) between normal and diet groups. The UA level in the hemolymph of the diet group was lower than that of the normal group. Because 5th instar larva of strain o06 contain less AL, they do not express uricase, an enzyme that degrades UA to AL, as Hayashi showed in vitro. Purine metabolism is similar in silkworms and humans and the end product of both is UA. Our results indicate that strain o06 is a potential substitute for the mouse hyperuricemia model.

Pollinators and Their Conservation Helps a Hungry Planet

Authors: Tanda Amarjit, Australia

Abstract: Major crops are mainly dependent upon managed honey bees and wild bee pollinators which are of great significance. Bee pollinated crops being a great part of the bio-diverse system, 4,000 native bees, and offer over US$1.5 billion each year in North America. In the US, the value of wild bees in food production was determined to be over $1.5 billion annually. However, the worth of wild bee pollination in insect cross-pollinated crops may be much more. These great wild players are now in a fast-declining phase or possibly extinct due to human-disturbed habitats. More studies are needed in population biodiversity, bee abundance and protection measures, suitable habitat, nesting sites especially their immediate conservation strategies. As progress is demanded in entomology, honeybees and the wild bee pollinators should be protected from the overuse of pesticides by conserving bee populations for better agricultural production to feed the hungry planet by sustaining global biodiversity. We highlight in this presentation, the various measures, and actions to conserve the wild bees so that they can serve the growers as co-players to managed honey bees in boosting agricultural food production worldwide.

Natural enemies of black soldier fly (Hermetia illucens L.) threaten the growth of emerging insect-based enterprise in Africa

Authors: Tanga Chrysantus M.[2], Khamis Fathiya[1], Ekesi Sunday[2] and Subramanian Sevgan[3], [1]International Centre of Insect Physiology and Ecology (ICIPE), [2]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya, [3]International Centre of Insect Physiology and Ecology, Nairobi, Kenya

Abstract: Sustainable utilization of black soldier fly (BSF, Hermetia illucens) larvae as a novel protein source to substitute the major source of protein (fish and soya bean) in animal feeds has gained momentum globally. However, information on their natural enemies an implication for mass production has received limited research attention. We evaluate for the first time the threats posed by two important natural enemies (phoretic mite, Macrocheles muscaedomesticae Scopoli and newly described parasitoids, Eniacomorpha hermetiae Delvare) on potential colony collapse under on-farm conditions. Significantly higher infestation of the mites was observed on the fly's abdominal space with mortality occurring within 2 – 5 days. There was a significant negative effect of mite load on the survivorship and fecundity. For the parasitoid, pupation substrate type and depth of the pupae significantly influenced the parasitism rates with over 75% of fly pupae buried up to <10 cm deep in dry grasses and sawdust compared to sandy soil. We conclude that the mite and parasitoid described represent a serious threat to BSF colony viability and shed light of their possible contribution to a cascade of negative implications in the animal feed industry that might rely on BSF larvae meal as alternative source of protein.

Mosquito midgut epithelial profiles show shared trends amongst Aedes, Anopheles and Culex and uncover differences in cellular dynamics in response to infection and blood feeding

Authors: Taracena Mabel[2], Hixson Bretta[1], Nandakumar Shyama[1], Chen Robin[1] and Buchon Nicolas[1], [2]Cornell University, United States, [1]Cornell University

Abstract: The cellular dynamics of the insect gut are key for the maintenance of epithelial integrity and, in hematophagous vector species, could have important implications for disease transmission. We studied mosquito midgut epithelial dynamics by measuring DNA synthesis and mitotic proliferation in the posterior midguts of Aedes, Culex, and Anopheles mosquitoes during post-emergence maturation, and in sugar-fed, pathogen-challenged, and blood-fed adults. We found that in the first 24 hours post-emergence ~15 cells/posterior midgut can be seen undergoing mitosis and by the end of the maturation period (72 h) ~20% of the midgut cells have synthesized DNA,. Mature mosquitoes (five to eight-days-old) maintained on sugar water had an average of ~3.5% of cells undergoing DNA synthesis over three days, and displayed ~5 mitotic cells/posterior midgut, indicating a modest but constant cell turnover. Pathological challenge by oral bacterial infection triggered a substantial increase in these parameters, suggesting an active modulation of cell dynamics to deal with stress. Interestingly, we found that the Aedes aegypti response to bacterial infection started a day earlier than Anopheles gambiae's, but both species responded strongly to infection, with final counts of 209 ± 102 and 207 ± 80.54 mitotic cells/posterior midgut respectively. Finally, responses to blood-feeding were significantly different across species and between blood sources (human, bovine, avian, and artificial). All mosquito species tested showed increased cumulative DNA synthesis in the period of blood digestion (72 hours post-blood-meal). Our results suggest that cell proliferation, differentiation, and endocycling can occur as a response to the blood meal in these mosquitoes, but how these events occur and their progression, are significantly different between Ae. aegypti and An. gambiae. Our results highlight the diversity and relevance of cell cycle regulation in hematophagy, and the implications of these observations for examining vector competence and designing transgenic strains.

The Biodioversity of Entomopathogenic nematodes and their use in IPM strategies

Authors: Tarasco Eustachio[1] and Puza Vladimir[2], [1]Department of Soil, Plant and Food Sciences University of Bari "Aldo Moro"; Bari, Italy, [2]Institute of Entomology Branišovská Ceské Budejovice, Czech Republic

Abstract: Important updates on different aspects of entomoparthogenic nematodes biodiversity and their role in microbial control strategies

Boosting phenomics: PhenoScript the new computer language for describing and comparing species

Authors: Tarasov Sergei, Finnish Museum of Natural History, Finland

Abstract: Analyzing phenotypes is central to much of the research in biology. In biosystematics, phenotypes are used for describing species and characterizing their evolutionary history. Although accumulating rapidly through species descriptions, phenotypic data, unlike molecular ones, are challenging to compare and analyze, which impedes phenomic-scale research in biology. This happens because organismal anatomies (= phenomes) have complex hierarchical structure (e.g., digits are parts of limbs which, in turn, are parts of body), while anatomical entities have diverse semantic qualities (e.g., shape and coloration of digits and limbs), which are largely neglected by available approaches. Both complex anatomical systems and their semantics can be modeled using ontologies – computer-understandable representation of knowledge, with well-defined terms, relationships, and logic. The application of ontologies to biosystematics is recent but extremely promising. In this talk, I will explore PhenoScript the computer language designed to stimulate the phenomic-scale research in biology and further reuse of phenotypic data. PhenoScript aims at providing a user-friendly environment for writing computer-parsable semantic species descriptions and running automatic species comparison. I will also discuss how future developments in ontology-driven approaches can change the way we analyze and represent phenotypes.

The potential role of queen reproductive potential in colony losses of honey bees

Authors: Tarpy David, Department of Entomology, North Carolina State University, Raleigh, NC, United States

Abstract: Both empirical and anecdotal evidence suggests that one of the primary problems for beekeepers is ‘poor queens,’ including premature supersedure (queen replacement), inconsistent brood patterns, early drone laying (indicative of sperm depletion), and failed requeening. There are many factors that affect queen reproductive potential (=quality), and it is therefore fundamentally important to promote high queen quality to maximize colony productivity and fitness. Our research has explored the connections among queen rearing, insemination success, management practices, and various measures of colony phenotype and health that has helped to elucidate the central role that queens play in modern bee management.

Cold hardiness of Tuta absoluta (Lepidoptera: Gelechiidae): implications and overwintering strategy

Authors: Tarusikirwa Vimbai[1], Nyamukondiwa Casper[1], Chidawanyika Frank[2], Mutamiswa Reyard[3], [1]Botswana International University of Science and Technology, Botswana, [2]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa, [3]University of the Free State, South Africa

Abstract: For many ectotherms, overwintering survival is achieved through entering diapause. However, this phenomenon has not been observed in the highly invasive tomato pinworm, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae). Reports suggest the ability to survive during cold seasons in both protected and open-field crops in the Mediterranean region. However, it is unknown how the pest responds to sub-zero temperatures and whether it uses cold hardiness as an overwintering adaptation strategy. To assess T. absoluta winter survival strategy, we measured cold hardiness in T. absoluta larvae and adults. We measured the larval supercooling point (SCP) and investigated various factors that affect SCP vis cooling rates, feeding status, hydration status and inoculative freezing as well as the pest’s lower limits of activity (critical thermal minima [CTmin]). Furthermore, we investigated the freeze strategy, using lower lethal temperatures (LLTs) and supercooling point mortality assays. The effects of low temperature exposure and duration of exposure (i.e., LLT) on larval survival showed that the temperature at which 50% of the larval population survives was -10°C after 2 h exposure. Following supercooling, both the larvae and adults failed to survive a 24h post recovery period. Feeding status had no effect on adult SCP, however a significant SCP depression was noted in fasted larvae. Adults showed a superior CTmin (mean -1.9°C) as compared to the larvae (mean 3°C), however, no significant difference was noted between fed and fasted for both adults and larva. Low relative humidity treatments significantly decreased SCP from -19.1°C (control) to -20.3°C for larvae and no differences were noted in control vs desiccated adults. Inoculative freezing (by water contact) raised SCP to -7.5 °C (larvae) and –8.7 (adults) respectively. The slowest cooling rate (0.12°C) significantly improved larval SCP while significantly impairing adult SCPs. These results suggest both T. absoluta larvae and adults are chill-susceptible and that different ecological factors e.g. cooling rates, feeding status, hydration status and inoculative freezing may affect their cold hardiness and survival at extreme low temperatures. These results are important in determining this species range limits, its response to seasonal temperature variation, overwintering pest management and modelling pest risk status.

How do combinations of agricultural chemicals affect bee-microbe-plant interactions?

Authors: Tatarko Anna[2], Richman Sarah[1], Leonard Anne[2], [1]Institute of Integrative Biology, Zurich, Switzerland, [2]University of Nevada, Reno, United States

Abstract: Population declines of wild bees are linked to the widespread use of pesticides and fungicides they encounter when foraging, yet whether combinations of chemicals alter pollinator visitation or floral microbial third parties remains unknown. Here I ask if the presence of a pesticide and fungicide alter bee visitation, fruit production, and the abundance of floral microbes. I treated Penstemon palmeri, (n = 126) with the neonicotinoid pesticide imidacloprid, the fungicide tebuconazole, their combination, or a water control (31 plants per treatment). Plants were placed in a randomized block array, and I observed the frequency and identify of floral visitors. I also collected flowers, rinsed them in 1x-0.15% PBS-Tween solution, and plated these rinses to culture floral microbes. Finally, I collected seed pods from each plant as a measure of reproductive success. Since plants face a tradeoff between growth and defense, chemical treatment may allow plants may allocate more resources to growth and reproduction, having more inflorescences and receiving higher pollinator visitation. Alternately, if treatment disrupts microbial communities, this could alter their attractiveness to pollinators by changing scent or nectar chemistry. Given the ubiquity of these chemicals, any findings will inform our knowledge of how wild pollinators cope with chemical stressors.

Reciprocal interactions between nutrition and immunity influence coinfection dynamics in flour beetles

Authors: Tate Ann[1], Jent Derrick[2] and Deng Yongjia[2], [1]Department of Biological Sciences, and Center for Evolutionary Studies, Vanderbilt University, United States, [2]Vanderbilt University, United States

Abstract: Insect hosts are exposed to a suite of microbes over the course of their lives. Each microbe leaves an imprint on the within-host environment through their influence on immunity and stored energetic resources that modulates the fitness of other within-host community members. An open question, however, is whether direct competition for nutritional resources among parasite community members modifies the role of immunity in mediating apparent competition among parasites. On the one hand, by modifying the relative and absolute densities of each parasite population, resource competition could indirectly influence the magnitude and timing of immune defenses that respond dynamically to parasite density. Parasite-mediated depletion of host resources could also directly affect immunological investment, however, if immunity is competing for the same resources as the microbes. In this study, we manipulated the within-host parasite community of flour beetles (Tribolium castaneum) by infecting them with a relatively benign protozoan parasite (Gregarina spp) or mildly virulent bacterial strain (Bacillus thuringiensis Bt1). These parasites, as measured by metabolite assays and RT-qPCR on immune gene expression, modify different aspects of the immunological and nutritional within-host environments subsequently experienced by a more virulent Bt strain (Bt2). We used a nutritional geometry approach to manipulate macronutrient acquisition by beetles infected with the benign parasites, and then performed RNA-seq on beetles collected at multiple time points after Bt2 infection to determine the role of resource competition on immune system dynamics in singly- and co-infected beetles. Most notably, our results suggest that gregarines reduce within-host carbohydrates available to the bacteria but also suppress the expression of key antimicrobial peptides, with net outcomes for bacterial growth and survival that depend on both the developmental stage and protein to carbohydrate diet ratio of the host. Our study therefore sheds new light on the nutritional regulation of within-host parasite communities and the impact of multiple infections on the evolution of host life history and immune systems.

The stable fly conundrum

Authors: Taylor David, USDA-ARS, Agroecosystem Management Research Unit, Lincoln, Nebraska, United States

Abstract: Stable flies, Stomoxys calcitrans, are pests of livestock, wildlife, and humans throughout much of the world. Adults, both males and females, require bloodmeals for reproductive success. Their painful bites reduce productivity of livestock, molest wildlife, and disrupt recreational activities of humans. Although traditionally considered pests of confined livestock developing in bedding contaminated with manure and urine, extreme outbreaks associated with post-harvest plant residues are becoming serious issues in several locations around the globe. The social, economic, and management issues associated with these outbreaks will be discussed.

Strategic nomination of insects and allied invertebrates for conservation management in Australia

Authors: Taylor Gary, The University of Adelaide, Australia

Abstract: Insects and allied invertebrates are the most numerous and diverse organisms in terrestrial and freshwater environments. They play critical roles in ecosystem function including pollination, herbivory, nutrient cycling, parasitism and predation, and providing food for most invertebrates and vertebrates. The Australian fauna is highly endemic, with numerous ancient lineages, relicts and evolutionary radiations. Yet, under increasing environmental stress, they may be disappearing rapidly, undocumented, in the face of key threatening processes such as habitat loss and fragmentation, exotic and invasive species, pollution and climate change. As impediments to conservation, terrestrial invertebrates are impacted by the Public dilemma (too small, too hidden and too little known), the Political dilemma (too little attention from decision-makers), the Scientific dilemma (too few scientists and scarce funding), the Linnean shortfall (many undescribed species), the Wallacean shortfall (too little known about distribution), and the Prestonian shortfall (too little known about abundance). Of the 285 species of insects and allied invertebrates listed under the Australian State/Territory Acts, the national EPBC Act and the international IUCN Red List shows a highly biased (mis)representation across the Australian landscape. Of the 89 Australian IBRA regions, six had more than 18 species, 23 had less than five species and thirty-six (40%) had no species at all. For a more uniform representation, the AESCC proposes a novel regional approach by selecting a relatively small number (3-5) ‘flagship taxa’ from each IBRA region to engage scientists, government agencies, local community groups and the general public in conservation management. The nomination of iconic flagship species that may include threatened species at risk of extinction, or species of important scientific, social or cultural value from under-represented IBRA regions is currently being advanced to better represent insects and allied invertebrates across the Australian landscape. Nominations will be progressively posted on the AES website at www.austentsoc.org.au.

Traditional medicinal uses of arthropods in francophone West Africa

Authors: Tchibozo Severin[2], Lupoli Roland[3] and Meyer-Rochow Victor Benno[1], [1]1. Department of Genetics and Physiology, Oulu University, Finland; and 2. Department of Plant Medicals, Andong National University, South Korea, [3]Institut de Recherche pour le Développement (IRD), 32, France, [2]Centre de Recherche pour la Gestion de la Biodiversité (CRGB), Benin

Abstract: From ancient times to the present day, insects, arachnids and other arthropods have been used worldwide for treatment. They play an important role in the traditional therapy of local populations because of their availability in the field, their cost and their effectiveness.

Arthropods were also present, until the end of the 19th century, in the pharmacopoeias of Western countries. But they have been gradually abandoned since, because they were considered harmful, vectors of diseases, or dirty.

In French-speaking West Africa, this knowledge has been little or not listed and disappears when traditional healers die, because it has been transmitted orally for generations.

During our investigations in the rural areas of Benin, Niger, Mali and Guinea-Conakry, we identified new data on arthropods used in traditional medicine.

Here we present these species and their therapeutic properties.

Cytochrome P450 metabolic resistance (CYP6P9a) to pyrethroids imposes a fitness cost in the major African malaria vector Anopheles funestus

Authors: TCHOUAKUI Magellan[1], WONDJI Charles[2], [1]CRID, Cameroon, [2]LSTM/CRID, United Kingdom

Abstract: Metabolic resistance threatens the sustainability of pyrethroid-based malaria control interventions. Elucidating the fitness cost and potential reversal of metabolic resistance is crucial to design suitable resistance management strategies. Here, we deciphered the fitness cost associated with the CYP6P9a (P450-mediated metabolic resistance) in the major African malaria vector Anopheles funestus. Reciprocal crosses were successfully performed between a pyrethroid susceptible (FANG) and resistant (FUMOZ) laboratory strains and the hybrid strains showed intermediate resistance level. Genotyping the CYP6P9a–R resistance allele in oviposited females revealed that CYP6P9a negatively impacts the fecundity as homozygote susceptible mosquitoes (CYP6P9a-SS) significantly lay more eggs than heterozygote (OR = 2.04: P =0.01) and homozygote resistant. CYP6P9a also imposes a significant fitness cost on the larval development as homozygote resistant larvae (CYP6P9a-RR) developed significantly slower than heterozygote and homozygote susceptible mosquitoes (?2=11.2; P = 0.0008). This fitness cost was further supported by the late pupation of homozygote resistant than susceptible mosquitoes (OR = 2.50; $P < 0.01$). However, CYP6P9a does not impact the longevity as no difference was observed in the life span of mosquitoes with different genotypes (?2 = 1.6; P = 0.9). A significant decrease of the resistant CYP6P9a-RR genotype was observed after 10 generations (?2 = 6.6; P = 0.01) suggesting a reversal of P450-based resistance in the absence of selection. This study shows that the P450-mediated metabolic resistance imposes a high fitness cost in malaria vectors supporting that a resistance management strategy based on rotation could help mitigate the impact of such resistance.

Simultaneous Identification of Mosquitoes, Their Microbiota and Blood Meal Sources Using Next-Generation Sequencing

Authors: Tchouassi David P[1], Muturi Ephantus[2] and Ramirez Jose[2], [1]International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya, [2]USDA-ARS, United States

Abstract: Mosquitoes transmit many devastating and life threating diseases to humans, domestic animals and wildlife. Many mosquito species occur as complexes that are typically difficult to identify based on morphological characteristics. Yet, effective control of mosquito-borne diseases relies on proper identification of the major vectors and their ecological traits. One such ecological trait that is critical for mosquito-borne transmission is the blood feeding pattern. Only mosquito species that feed on vertebrate hosts that amplify a particular mosquito-borne pathogen are considered to be potential vectors of that pathogen. Moreover, previous studies have shown that the microbial communities that inhabit the mosquito body can influence vector susceptibility to pathogens. Here we describe the development and application of Illumina Miseq next-generation sequencing for simultaneous identification of mosquito species, their microbiota and host blood meal source. Our results show that PCR amplification and Miseq sequencing targeting the mitochondrial cytochrome c oxidase 1 (mosquito identification), 12S rRNA (blood meal source), and 16S rRNA (microbiota) genes can successfully be used for simultaneous identification of mosquito species, their microbiota and host blood meal sources. These findings demonstrate the capability of next-generation sequencing to improve the efficiency of mosquito-borne disease surveillance systems.

The role of plant nutrient quality on the survival and reproductive fitness of dengue vector Aedes aegypti

Authors: Tchouassi David P[1], Torto Baldwyn[2] and O Nyasembe Vincent[2], [1]International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology, Kenya

Abstract: Overwhelming evidence indicate that female mosquitoes, including those of highly anthropophilic Aedes aegypti and Anopheles gambiae, intermittently forage on plant sources for nutrition. However, the role of these plant nutrients on their reproductive fitness is scarcely known. Recent advances have seen the advent of more robust analytical techniques such as DNA barcoding and mass spectrometry which allow identification of plant sources fed upon and their trophic interactions. Taking advantage these advances, we recently identified plant sources of four afro-tropical mosquito species that vector dengue, malaria and Rift Valley fever. Here, we further investigated the role of three of the identified plants on survival and reproductive fitness of dengue vector Ae. aegypti. Newly emerged adult male and female Ae. aegypti were fed on Leonotis nepetifolia, Pithecellobium dulce or Opuntia ficus-indica with females receiving an initial three rations of blood meal on day 3, 5 and 7 from anaesthised mice. The controls included those fed on 6 % glucose solution with the initial three blood meals and those fed on blood meal only provided on alternate days throughout the experimental period. We collected data over 30-day period on daily mortality, oviposition and eggs hatching rates. The mosquitoes, plant sources and mice blood were also analysed for sugar and amino acid content. Our results show that survival was strongest on glucose solution and P. dulce with L. nepetifolia and blood meal having comparable survival rates and O. ficus-indica having the least survival. On the other hand, fecundity was strongest on L. nepetifolia and least on O. ficus-indica. Hatching rate was least in eggs laid by females fed on O. ficus-indica but comparable among the rest of nutrient sources. Nutritional analysis revealed qualitative and quantitative similarities and differences between the different nutrient sources that may explain the observed differences in the fitness matrices of Ae. aegypti. Our findings highlight the central role of plant nutrients in the reproductive fitness of dengue vectors which may impact their disease transmission potential.

Semiochemical basis of Aedes mosquito attraction to Non-human primate and human hosts

Authors: Tchouassi David P[1], Torto Baldwyn[1] and W Jacob Juliah[1], [1]International Centre of Insect Physiology and Ecology (icipe), Kenya

Abstract: Non-human primates (NHP) are important in the epidemiology of the Aedes-borne pathogens, dengue, Zika, Yellow fever and chikungunya viruses where they serve as reservoir hosts. However, they have been neglected in studies of Aedes odour-guided host-seeking behaviors, which have largely focused on human volatiles. We explored how host-derived skin odours from the NHP baboon, sykes, vervet, and humans influence Aedes mosquito responses in domestic and sylvatic environments where these viruses circulate. We found that the ketones cyclohexanone and sulcatone are i) important signature cues for Aedes mosquitoes to detect the NHP and humans, respectively, and ii) attractants to Aedes mosquitoes including Aedes aegypti in sylvatic and domestic settings. Both compounds have potential practical applications as lures for improved monitoring Aedes disease vectors as a critical component of risk assessment for transmission of these viruses.

Exploring sand fly plant feeding behaviour for development of nectar- based vector control strategies

Authors: Tchouassi David P[3], Torto Baldwyn[4], Hassaballa Iman[2] and Sole Catherine[1], [3]International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya, [4]International Centre of Insect Physiology and Ecology, Kenya, [2]International Centre of Insect Physiology and Ecology (icipe) Nairobi, Kenya, University of Pretoria, South Africa, University of Kordofan, Sudan, Kenya, [1]Department of Zoology and Entomology, University of Pretoria, Hatfield, South Africa

Abstract: Knowledge of plant feeding behavior is being exploited in vector control including sand flies. However, we have little understanding of this trait for Afrotropical sand fly species. Focusing in an endemic site for leishmaniasis in Kenya, we applied biochemical and molecular methods to i) compare the extent of plant feeding among different sand fly species/sexes belonging to Sergentomyia and Phlebotomus genera) from different habitat, ii) identify specific plants fed upon in nature, and iii) identity signature cues mediating sand fly attraction to the identified plants. We found variation in the proportion of sugar fed males and females with generally no significant difference within sand fly species. Identified plant species fed upon in nature mainly belong to the family Fabaceae. Chemical profiling of host plant odors identified specific volatile organic compounds (VOCs) that can be developed into lures for surveillance of sand fly vectors of Leishmania parasites and phleboviruses.

Exploiting chemical ecology of mosquito-plant interactions to develop surveillance tools for the dengue vector Aedes aegypti

Authors: Tchouassi David P[4], Torto Baldwyn[5], Kungu Caroline Wanjiku[1], Sole Catherine[2], Pirk Christian[6] and Nyasembe Vincent[3], [1]1. International Centre of Insect Physiology and Ecology (icipe), Kenya 2. Department of Zoology and Entomology, University of Pretoria, Hatfield, South Africa, Kenya, [2]Department of Zoology and Entomology, University of Pretoria, Hatfield, South Africa, [3]Emerging Pathogens Institute, College of Medicine, University of Florida, Gainesville, FL, United States, [4]International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya, [5]International Centre of Insect Physiology and Ecology, Kenya, [6]University of Pretoria, South Africa

Abstract: Plants are important in the bioecology of mosquitoes as they provide breeding and resting sites, as well as nectar for energy metabolism. Plant feeding in mosquitoes is largely odor guided and therefore plant-derived odors represent candidate mosquito attractants. One example is (E)-linalool oxide (LO), an attractive plant volatile organic compound (VOC) for both malaria and dengue vectors. In addition to LO, plants produce a plethora of other VOCs, some of which have been found to elicit electrophysiological responses in the antennae of the dengue vector Ae. aegypti. In this presentation, we describe the performance of a blend of LO and two other antennally- active VOCs in field trapping of Ae. aegypti. We also share our findings on the nectar-feeding patterns of this vector in three ecologies of Kenya, additional candidate attractants identified, and the prospects thereof for targeting plant feeding behaviours for vector surveillance.

Advances in the management of the transmission of phytoplasmas: from the field to the lab

Authors: Tedeschi Rosemarie[1], Alma Alberto[1] and Gonella Elena[1], [1]University of Torino - Department of Agricultural, Forest and Food Sciences (DISAFA), Italy

Abstract: Phytoplasmas are a severe threat for several crops in the world and new control strategies are required to better prevent their occurrence and spreading.

Recent studies focusing on the vector transmission efficiency and on the potential of microbial symbionts to reduce vector competence will be presented opening new scenarios in the epidemiology of phytoplasma diseases and for their management.

For instance, new evidences on the infective risk of newly emerged adults of the psyllid Cacopsylla melanoneura when the migration to conifers is delayed for some reason, or on the ability of the leafhopper Scaphoideus titanus to acquire FD-C phytoplasma as an adult too, and to, successively, inoculate it in a short window of time impose a revision of the vector management strategiesMoreover, new tools for the analysis of the interactions between phytoplasmas and their vectors come from the analysis of the immunity system of these latters. An in vitro model based on immunocyte cultures has been developed enabling the study of their structure and activity in particular in relation to the synthesis of antimicrobial peptides. The knowledge of the presence/absence of the most common molecules involved in the immunity of the insect vectors may clarify if the phytoplasmas induce or modulate the insect immune responses, providing potential targets for the management of the insect vectors or of their vector competence.

Another interesting approach to reduce the vector competence comes from bacterial symbionts of insects. In particular, the acetic acid bacteria Asaia sp. induced a reduction of phytoplasma acquisition by the leafhopper vector model Euscelidius variegatus Kirschbaum, mediated by the production of and air-liquid interface biofilm. Moreover, the expression of immune genes in the leafhopper after exposure to Asaia symbiotic bacteria, revealed a specific activation of the Raf gene (a known component involved in the response to septic injury and in immunocyte proliferation and survival) in midguts after double infection by Asaia and flavescence dorée phytoplasma. This particular interplay can suggest the elicitation of a basal host immune activity by Asaia against other microrganisms, including phytoplasma. All these new findings provided evidence of the potential for Asaia to be used as a biocontrol agent capable of reducing phytoplasma infection in leafhopper vectors.

Biopesticides and botanical extracts as an IPM options against rice stem borers in Eastern Africa

Authors: Tefera Tadele[1] and January Bonaventure[2], [1]International Center of Insect Physiology, Ethiopia, [2]Sokoine University, Tanzania

Abstract: The demand for rice has increased sharply in Sub-Saharan Africa (SSA) and is growing more rapidly than in any other continent. SSA has huge production potential for both upland and irrigated rice; however, availability improved varieties, fertilizer, farm mechanization, weeds, diseases and insect pests are the major limiting factors. The major insect pests of rice in Africa include stem borer complex, African rice gall midge, leaf hoppers, flea beetle and termites. The estimated rice yield loss due to insect pests in Africa range between 15% and 25%. Efficacy of two commercial biopesticides: Beauveria bassiana and Metarhizium anisopliae, two botanical extracts (Neorautanenia mitis and Derris elliptica), one synthetic insecticide Cypermethrin (144g/L) + Imidacloprid (200g/L, and untreated control, were evaluated against rice stem borers in Tanzania. The results show that both biopesticides and botanical extracts reduced damages and yield losses caused by rice stem borers as compared to control. Higher grain yield and higher stem borer mortality were also observed in the treated than un-treated control suggesting that biopesticides and botanical extracts can control rice stem borers as efficiently as chemical insecticides. The efficacy and compatibility of biopesticides and botanical extracts with other control options should be evaluated.

Attractiveness of yeast species, strains and combinations to Drosophila suzukii

Authors: Tempest Hayden[3], Jones Rory[1], Günther Catrin[2], Eady Paul[2], Fountain Michelle[3], Goddard Matthew[2], [1]University of Lincoln/NIAB EMR, United Kingdom, [2]University of Lincoln, United Kingdom, [3]NIAB EMR, United Kingdom

Abstract: Some herbivorous species can suppress plant defences. Plants in which defences are suppressed are beneficial for suppressors, as well as for their competitors, hence suppression can be considered a form of niche construction. Tetranychus spider mites are important pests of several crops. Within this genus, T. urticae induce whereas T. evansi suppress tomato plant (Solanum lycopersicum) defences of the jasmonic acid (JA) and salicylic acid (SA) pathways. Defence suppression is beneficial for both species. However, the degree of intraspecific variation for both suppression and induction within species is as yet unclear. Here, we characterize two highly variable outbred populations of T. urticae and T. evansi, regarding their ability to suppress defences. We also test defence suppression in the 7 populations used to found these outbred populations. To this aim, we infested tomato plants with 25 mites of each population during 4 days, then measured (i) the suppression of plant defences through differential expression of plant marker genes for JA and SA pathways and (ii) the consequences of defence suppression for the suppressing mites by recording their fecundity during the period of plant infestation. To assess whether defence suppression can also benefit the competing species, we measured the performance of individual of that species, for 2 days, on plants previously infested with populations of the other species. We found that outbred populations of both species and their founder populations suppressed defences with equivalent beneficial effects across populations. These results show that suppression is not uncommon in T. urticae. Only in some populations did suppression benefit the competitor. This suggests different degrees/pathways of defence suppression or that the suppressors interact differently with different and competitor populations. Thus, our results indicate that defence suppression is a form of niche construction. However, the ecological and evolutionary consequences of within-species variation for this form of niche construction remain to be elucidated.

Defence suppression by phytophagous spider mite as a form of niche constrution

Authors: Teodoro-Paulo Jéssica[3], Duncan Alison[2] and Magalhães Sara[1], [1]Centre for Ecology, Evolution and Environmental Changes, Faculty of Sciences, University of Lisbon, Portugal, [2]Institute of Evolutionary Sciences, University of Montpellier, CNRS, IRD, EPHE, France, [3]Universidade do Porto - Faculdade de Ciências, Portugal

Thus, our results indicate that defence suppression is a form of niche construction. However, the ecological and evolutionary consequences of within-species variation for this form of niche construction remain to be elucidated.

Does climate change contribute to the rise of super pests?

Authors: Teodoro-Paulo Jéssica[4], Alba Juan M.[3], Valeriano-Santos João, Charlesworth Steven[1], Duncan Alison B.[2] and Kant Merijn R.[3], [1]Center for Ecology, Evolution and Environmental Changes, University of Lisbon, [2]Institut des Sciences de l'Évolution, University of Montpellier, CNRS, IRD, EPHE, [3]Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, [4]Universidade do Porto - Faculdade de Ciências, Portugal

Abstract: Rising temperatures due to climate change are predicted to accelerate the life cycle of arthropod herbivores thereby exacerbating pest formation of invasive species already adapted to warm conditions. Notorious pests such as Tetranychus spider mites thrive at higher temperatures, with some species suppressing defences by interfering with the plant's signalling pathways. This promotes mite performance but also that of co-occurring competitors. In this study, we investigated the effect of higher temperatures on plant-eating mites that either induce or suppress plant defences and the impact on their population growth. We found that survival of adults and their offspring was similar for inducer and suppressor mites under moderate temperature (25ºC). At 32ºC, mite damage and fecundity were increased, but survival of adults and their offspring decreased severely, especially for inducer mites. However, the overall pattern of defence induction and suppression was not affected by high temperatures. These results may be particularly relevant to sectors of plant breeding and biological control as they are expected to provide the alternatives that prevent an increase in pesticide use due to climate change. Finally, our results provide novel insights into how climate change could lead to the selection of super pests, such as suppressor mites.

Killers and competitors: the effect of invasive ants on the food web of Round Island, Mauritius, as revealed by dietary DNA metabarcoding

Authors: Tercel Maximillian, Cardiff University

Abstract: Invasive ants are highly damaging introduced species capable of significantly reducing native species richness and abundance. Our knowledge of how they mechanistically impact native ecological communities, however, is lacking. Here, we present the results of an island-wide dietary analysis of twelve species of introduced ants present on Round Island, Mauritius, a supposedly “pristine” island nature reserve supporting numerous endemic animals and plants found nowhere else. Using dietary DNA metabarcoding, we reveal the trophic interactions of the entire ant community of Round Island, representing one of the most complete dietary analyses to date in any system. We found that introduced ants are both predating upon and competing with native species of vertebrate and invertebrate. We also show how they rely on both introduced and native plants. For the first time, this describes the species-level interactions and mechanistic ecological underpinnings of how invasive ants can be so damaging to native species. Results are further discussed in the context of fragile island ecosystems and the increasing prevalence of introduced ants globally.

The Medicinal Use of Insects in Northern Vietnam

Authors: Teräväinen Marianna[1], Long Khuat Dang[2] and Muona Jyrki[1], [1]Finnish Museum of Natural History & University of Helsinki, [2]Institute Of Ecology and Biological Resources, Vietnam

Abstract: Animal-based traditional remedies have received less attention in pharmacological research than botanical ones. However, it is known that especially insects contain medicinally useful compounds. Such practices are found among northern Vietnamese ethnic minority groups, who continue to rely on self-made remedies, often preferring insects over plants because they are considered more potent. Traditional healers from ten ethnic minority groups (Cao Lan, Green/Blue H’Mong, Flower H’Mong, Muong, Nung, Dao, Red Dao, San Diu, Tay, and Thai) spread out across four provinces in northern Vietnam were interviewed about their use of insects for medicinal purposes. These practices and the pharmacological rationale for their use is discussed.

Applications of population genomics to fall armyworm integrative pest management

Authors: Tessnow Ashley[1], Sword Gregory[2] and Raszick Tyler[3], [1]Department of Entomology Texas A&M University College Station, Texas, United States, [2]Texas A&M University Department of Entomology Interdisciplinary Research Program in Ecology and Evolutionary Biology College Station, United States, [3]Texas A&M University, United States

Abstract: The fall armyworm (Spodoptera frugiperda) is a highly polyphagous agricultural pest that is currently of global concern. Although primarily a pest on grass and cereal crops such as corn and sorghum, this generalist insect can opportunistically feed on over 80 different host plants. Within the fall armyworm, there are two morphologically identical but genetically distinct host associated strains, commonly referred to as the corn-strain and the rice-strain. These host strains have a sympatric distribution in the New World, but show a slight difference in their host plant preferences and responses to chemical insecticides. The aim of this study was to use population genomics to characterize the spatiotemporal population structure and host strain hybridization patterns of fall armyworms in their central United States native range. To do this, we collected moths from five locations across the central US at three time points during the growing season, and used ddRADseq to identify genome-wide single nucleotide polymorphisms (SNPs). Using the SNPs, we gained new insights into fall armyworm population structure, and identified novel patterns of host strain hybridization Additionally, we identified new, high-resolution genetic markers that can be used to rapidly differentiate between host strains and their hybrids. Enhancing our understanding of fall armyworm population structure and host strain hybridization patterns will enable more targeted pest management strategies for this species both in the US and globally.

Imperatives for mass trapping thrips. What we know and what we don’t know

Authors: Teulon David[2], Arias Andres[1], Brochero Elena[1] and Nielsen Mette[2], [1]Facultad de Agronomía, Universidad Nacional de Colombia, Colombia, [2]The New Zealand Institute for Plant & Food Research Limited, New Zealand

Abstract: Mass trapping is a recognised tactic for the management of a range of insect pests including thrips. Despite the many references to the apparent successful use of mass trapping for thrips pest management in commercial and industry literature, the scientific literature supporting this approach is scarce. This paper summarises the available literature on this subject and identifies the building blocks necessary to develop a successful thrips mass trapping approach including aspects such as trap size and density, and the use of visual and odour cues. Finally, an experimental scenario is proposed where the scientific basis for mass trapping can be best demonstrated.

A cholesterol-sensing mechanism promotes growth and maturation through insulin and ecdysone signaling

Authors: Texada Michael[1], Rewitz Kim[1], Lassen Mette[1], Pedersen Lisa[1], Koyama Takashi[1] and Malita Alina[1], [1]University of Copenhagen

Abstract: Nutritional inputs strongly govern animal growth and developmental transitions, both as building blocks for metabolism as well as regulators of hormonal signaling. In particular, nutrient intake influences insulin-like signaling systems that drive systemic growth, while also promoting the timely activation of steroid-signaling axes that trigger maturation into a reproductive adult. We have found that the dietary lipid cholesterol promotes larval growth and maturation in Drosophila by inducing the expression and release of insulin-like peptides. Cholesterol absorbed from the diet activates the nutrient sensor Target of Rapamycin (TOR) in the cells of the fat body and the subperineurial glia of the blood-brain barrier, which remotely upregulate insulin production; the cholesterol transporter Npc1a, which removes cholesterol from the lysosome, regulates this cholesterol sensing. Furthermore, cholesterol signaling within the cells of the prothoracic gland strongly promotes TOR activity in this tissue as well, leading to increased endoreduplication and acceleration or bypass of the critical-weight checkpoint. Thus, Npc1/TOR-mediated signaling links cholesterol availability to cellular and systemic growth control as well as developmental timing, which may underlie aspects of associations between cancer and cholesterol as well as the connection between obesity and early puberty.

Second green revolution in India: Issues and challenges

Authors: Thakur D R, Department Of Biosciences, Himachal Pradesh University, Summer Hill, Shimla, India

Abstract: India has achieved the 1st Green Revolution in late 60s with the benevolent efforts of Prof. M S Swaminathan and Prof. Norman Borlaug, USA, “Father of the Green Revolution”, who received Nobel Peace Prize in 1970. This was package of industrial agriculture technologies, such as hybrid seeds, fertilizers, pesticides, and irrigation. Our Hon’ble Prime Minister, Shri Narinder Modi is dreaming to have second green revolution in India because to feed the ever increasing human population against the constant land mass. United Nations declared 2016 as “International Year of Pulses” with the aim to popularize the vegetarian food full of proteins and to eliminate the social evil of malnutrition. But even after the three years of the International Year of Pulses, UNICEF revealed the malnutrition behind 69% deaths among children below five year of age in India. Pulses have 20-27% proteins which is 2- 3 times higher than traditional cereals and constitute the main source of proteins for developing countries, like India where per capita consumption of the animal protein is low, thus pulses are rightly considered the poor man’s meat. Insects belonging to the family Bruchidae (Coleoptera: Chrysomalidae) commonly called “pulse weevils” or bruchids are cosmopolitan in distribution and cause serious loss to legumes both in fields and stores worth million dollars every year. Callosobruchus maculatus (F.), C. chinensis (L.), C. analis (F.), C. theobromae (L.), C. pisorum (L.) etc. infest Phaseolus mungo, P. aureus, Vigna sinensis, Cajanus cajan, Cicer arietinum, Pisum sativum, Glycine max, Dolichos biflorus, D. lablab and many more legumes both in stores and fields and spoil this valuable share of the legume proteins which otherwise be eaten by human being. No doubt chemical control results quick knock down of the pests but unfortunately leave behind many hazardous effects on biodiversity in general and human health in particular. Therefore, the present work has been carried out to explore the reproductive strategy and life history traits of idiobiont and koinobiont parasitoids on some bruchid species under laboratory conditions along with botanicals. Egg endoparasitoid, parasitized the 0-84 hours old eggs and rendered them unviable for future development. Both idiobiont and koinobiont parasitoids could be exploited as potential bio-controlling agents for legume and other stored grain pests after detailed investigations and field trials. In botanical management the use of natural plant products is an important alternative of chemical pesticides to keep the pest population below the economic injury level. Acetone and methanol extracts of leaves, stem, roots etc. were prepared and employed at concentrations of 5, 10 and 20% with three replicas each. Efficacy of extracts was observed on adult mortality, fecundity and F1 adult emergence and 100% adult mortality egg deterrence was observed on second and third day treatment at 20% concentration.

Systematics and Ecology of Southeast Asian Bumblebees

Authors: Thanoosing Chawatat[2], Vogler Alfried[1] and H. Williams Paul[3], [1]Imperial College London, United Kingdom, [2]Natural History Museum, London Imperial College London, London, United Kingdom, [3]Natural History Museum, London, United Kingdom

Abstract: Tropical ecosystems contain high biological diversity including bees which are vital in ecosystem services on pollination. Bumblebees (Apidea: Bombus) show a different pattern as they are predominantly temperate in distribution and rarely occur in the tropics. In tropical Southeast Asia, mountains provide the most suitable habitats for bumblebees. There are approximately twenty-two species in this region. A question is whether these bumblebees are truly tropical species or whether they are restricted to temperate-like refuges at high elevation. Due to their rarity and the inaccessibility of their habitats, the bumblebees in this region are poorly known. This study aims to clarify their systematics, climatic distribution and ecological interactions from museum collections, ecological models and molecular analyses of field samples. This is a first step towards generating an improved understanding of these tropical bumblebees, which is ultimately directed towards pollinator conservation in this region.

Targeting insect synaptic and extrasynaptic nicotinic acetylcholine receptors

Authors: Thany Steeve, University of Orleans, France

Abstract: In insects, nicotinic acetylcholine receptors (nAChRs) are ligand-gated ion channels permeable to sodium (Na+), potassium (K+) and calcium (Ca2+). But, the pharmacological profile of native nAChR subtypes are limited and correlated to hybrid receptors. Insect nAChR remains of fundamental importance because they are the main target of neonicotinoids, sulfoximines and recently introduced pesticides. Several nAChR subunits have been cloned in insects such as the cockroach Periplaneta americana which is currently used to study the mode of action of pesticides. Pharmacological studies demonstrate that synaptic and extrasynaptic receptors may have different pharmacological properties against pesticides. Indeed, imidacloprid and clothianidin activate both synaptic and extrasynaptic nicotinic receptors whereas thiamethoxam activates synaptic receptors. In addition, clothianidin is a full agonist and imidacloprid a partial agonist of nAChRs expressed on the cell bodies. These results suggest that nAChR expressed on synaptic ganglia are distincts to receptors expressed on isolated cell bodies. Moreover, clothianidin effects on isolated cell bodies could involve internal regulation of Ca2+ pathways through the activation of cAMP activity. Comparative studies between nAChRs expressed on the synapses between afferents sensory neurons and giant interneurons, and isolated cell bodies could improve our understanding on the mode of action of pesticides on insect nAChRs.

LIFE “Patches & Corridors” - Development of a habitat network for the Violet Copper to promote a sustainable metapopulation in the northern Eifel (LIFE15 NAT/DE/000745)

Authors: Theissen Bernhard, Biological station Aachen, Germany

Abstract: The violet copper Lycaena helle (Lepidoptera: Lycaenidae) is protected by the European Habitats Directive as ‘a species in need of strict protection’. This project aims to improve the conversation status of this butterfly and its supporting habitat in the northern Eifel mountains in western Germany. A number of projects have targeted this species in this region in the past, however a key barrier to the long term maintenance of this species has been dispersal between sites supporting sub-populations. This project focuses on establishing a habitat network to facilitate migratory movement within and between different Natura 2000 sites through the restoration of mountain hay meadows, wet meadows and alluvial. To monitor the success different endpoints are used e.g. the diversity of vegetation, butterflies, moths, carabid beetles and ground dwelling spiders as well as the dispersal and egg deposition of L. helle.

Tongue length evolution in Prosoeca (Nemestrinidae), a group of specialised flower-feeding flies

Authors: Theron Genevieve[2], Ellis Allan[1], Pauw Anton[1], Anderson Bruce[1], Johnson Steve[2] and van der Niet Timotheus[2], [1]Stellenbosch University, South Africa, [2]The University of KwaZulu-Natal, South Africa

Abstract: Differentiation of traits involved in resource acquisition may be a key-innovation causing rapid radiation in some animal groups. In plant-pollinator mutualisms, morphology of interacting traits such as proboscis length and nectar tube length, may covary, especially in specialized systems. While nectar tubes have long been considered a key-innovation, almost nothing is known about the diversification of proboscis length in most groups of pollinators. In this study we use the Southern African Nemestrinidae, which have proboscides that vary between 5mm – 90 mm and are important pollinators of several dozen plants in the Southern African flora, to reconstruct tongue length evolution. Prosoeca is the most speciose and diverse genus of Nemestrinidae in Southern Africa with 37 described species. Species in this genus are almost always engaged in highly asymmetrical mutualistic interaction networks, in which multiple plant species rely on it as the primary pollinator species for reproduction. We evaluated two alternative scenarios for tongue length evolution. In particular we tested whether long proboscides evolved repeatedly, possibly as an adaptive response to host plant diversity or whether the evolution of a long proboscis occurred once as a key-innovation, followed by rapid radiation. To do this we generated a molecular phylogeny for Prosoeca using two mitochondrial (CO1 and 16S) and two nuclear (28S and CAD) genes. This phylogeny was then used to reconstruct the evolution of absolute proboscis length, which represents the trait with which pollinators interact with flowers, as well as proboscis length relative to body size to correct for allometric effects. An average of proboscis length relative to body length was determined by measuring multiple specimens of a species. Our study provides insight into the factors that influence the evolution of these flies and their unique proboscides.

Understanding the incidence and severity of fall armyworm (Spodoptera frugiperda J.E. Smith) infestations and exploring low-cost management practices in cropping systems of Southern Africa

Authors: Thierfelder Christian[2] and Baudron Frédéric[1], [2]International Maize and Wheat Improvement Centre (CIMMYT), Zimbabwe, Zimbabwe, [1]International Maize and Wheat Improvement Centre (CIMMYT), Zimbabwe

Abstract: Fall armyworm (FAW, Spodoptera frugiperda J.E. Smith), a voracious agricultural pest native to Latin America, was first detected on the African continent in 2016, has subsequently spread throughout Africa and then across Asia. National African Governments immediately responded with purchasing synthetic pesticides for widespread control without much success. Throughout the last three years, we researched how FAW has affected smallholder farmers in Zimbabwe and explored different low-cost pest management practices adapted to the context of smallholder farmers using climate-adapted “push-pull systems”. These practices are based on plant semiochemicals affecting pest behavior and pest-predator interactions to control this invasive pest. The objectives are: a) to provide smallholder farmers with more viable and economical feasible options that are safer for their health and the environment, b) to better understand control processes and foster biological control through agro-ecological management. We found that: i) maize-legume intercropping strategies were effective in reducing FAW damage; ii) the strongest effect was found in cropping systems that are based on the principles of Conservation Agriculture due to increase in biological control; iii) there is evidence that the use of Conservation Agriculture, different maize-legume intercropping strategies and their combination foster increases the abundance of alternative preys for FAW natural enemies; iv) some legume intercrops (e.g. velvet beans (Mucuna pruriens L.) in our trials had a direct effect on reducing FAW damage. The resulting cropping systems from this research can be well integrated into already existing initiatives of fostering sustainable agriculture intensification which include cereal-legume rotations and green manure cover crops. They will enhance greater resilience against this pest besides the other co-benefits of food- and nutrition security for smallholder farmers over time.

Parasitism and competition as structuring forces within host communities, and their sensitivity to experimental warming

Authors: Thierry Melanie[3], Ximenez-Embun Miguel G.[3], Hua Lue Chia[1], Hrcek Jan[2] and Lewis Owen[4], [3]Biology Centre, Czech Academy of Science, Czech Republic, [1]Biology Centre of the Czech Academy of Sciences, Czech Republic, [2]Biology centre, Czech academy of Science, [4]Department of Zoology, University of Oxford, United Kingdom

Abstract: To understand how host-parasitoid networks will respond to global warming, it is important to recognize how trophic and non-trophic interactions act together to structure ecological networks, and how parasitoids can control host populations. To do this, we used laboratory experiments on a co-evolved, tropical Drosophila-parasitoid community at two temperatures – 23°C and 27°C – to test if the mechanisms observed change with increased temperature.

We first investigated how the relative influence of competition and parasitism on host communities change in response to warming temperatures, looking at host community composition and parasitism rates in a co-infection experiment over one generation using different community configurations of three Drosophila species and two parasitic wasp species. Host communities were structured most strongly by trophic interactions with parasitoids. Increased temperatures reduced host community evenness and increased overall host abundances, without significant changes in parasitism rates. Climate change may therefore result in marked changes to the structure of host-parasitoid communities, and increasing the potential for host outbreaks.

We then investigated the stabilizing role of parasitoid on host communities, and if this role will change in response to warming temperatures in a multi-generational experiment using three different community composition of four Drosophila species and two parasitic wasp species. We identified trophic links from the pupae.

The interaction between parasitism and competition is essential for the stability of entire host-parasitoid networks by allowing host species to coexist, but global warming could weaken those interactions and destabilize entire networks. We show that parasitoid control of host population might be compromised with progressing climate change.

Competition for resources impacts phenological asynchrony in host-parasitoid interactions

Authors: Thierry Melanie[3], Ximenez-Embun Miguel G.[3], Hua Lue Chia[1], Souto-Vilaros Daniel[4] and Hrcek Jan[2], [1]Biology Centre of the Czech Academy of Sciences, Czech Republic, [2]Biology centre, Czech academy of Science, [3]Biology Centre, Czech Academy of Science, Czech Republic, [4]Faculty of Science, Charles University, Prague, CZ, Czech Republic

Abstract: One of the most apparent ecological consequences of climate change has been the ongoing phenological shift in important life-history events among species. Given that species within the same community typically show dissimilar phenological responses to climate change, such phenological shifts are altering the timing of species interactions. Thus, some of the most profound effects of climate change on communities will likely be though changes in the timing of species interactions. One way that climate change can alter the phenology of interacting species is by accelerating or decelerating the developmental rates of species. We examined how temperature and resource competition alter the outcomes of phenological mismatches in Drosophila-parasitoid food webs, by modifying the developmental rates of the Drosophila host community. Specifically we set out to address the following questions: 1) To what extent does increased temperature modify foraging success of parasitoids that are phenologically mismatched with their hosts? 2) Are the consequences of phenological mismatch between a host and parasitoid similar in pairwise and multispecies contexts? 3) Does competition among hosts mitigate the adverse impacts of phenological asynchrony by extending the development time of the host community? We found that the degree of wasp infestation was greater in higher temperatures, but successful rate of parasitism (e.g. those infestation events that resulted in adult wasp) was significantly less in the warmer environment. The effects of phenological mismatch on wasp fitness were lessened in the multispecies treatments, suggesting that pairwise investigations may overestimate the effects of phenological asynchrony on host-parasitoid species interactions. Finally, while competition among hosts did extend and increase the rate of infestation, hosts in competition resulted in fewer adult wasps. We suggest that host quality is significantly reduced in high resource competition environments, which limits the successful development of wasps. These results highlight the importance of inspecting the consequences of phenological mismatch in a multispecies context, and reveal that both abiotic and biotic environments can significantly alter the outcomes of phenologically mismatched communities.

Near-infrared optical sensors to monitor flying insects

Authors: Thomas Benjamin[1], Genoud Adrien[1] and Saha Topu[2], [1]New Jersey Institute of Technology, United States, [2]PhD Student, United States

Abstract: In this contribution, we present the results obtained using entomological optical sensors during both laboratory and field experiments. The optical and morphological properties of insects are probed from a distance using near-infrared optical sensors measuring either backscattered light or optical extinction. From optical signals, predicator variables are derived and used in supervised machine learning algorithms such as support vector machine algorithm with the objective to classify insects and specifically mosquitoes. These predictor variables include the wingbeat frequency, Mel Frequency Cepstral Coefficient of the wing signals, body and wing depolarization ratios, and body and wing spectral cross-sections. We present the identification accuracy obtained for various scenarios, such as the classification of the insect family, genus, species, sex group, or gravidity. In addition, we conducted two field campaigns, where we monitored insect's aerial density (# of flying insects/m3) continuously for 80 days in 2020 and 189 days in 2021 and over a range of approximately 50m. During both campaigns, a co-located weather station was used to record several key environmental parameters. The collected data allowed for the study of the circadian rhythm and daily activities as well as the aerial density dynamic over the whole campaign for each cluster individually.

A novel house-based intervention for malaria control: insights from a large-scale cluster randomized controlled trial

Authors: Thomas Matthew[7], Koffi Alphonsine[2], Doudou Dimi[8], Sternberg Eleanore[1], Worrall Eve[5], Cook Jackie[6], N'Guessan Raphael[3] and Assi Serge[4], [1]Department of Entomology and Center for Infectious Disease Dynamics, The Pennsylvania State University, PA, United States, [2]Institue Pierre Richet, Ivory Coast, [3]Institut Pierre Richet (IPR) / Institut National de Santé Publique (INSP), Bouaké, Côte d'Ivoire, Ivory Coast, [4]Institut Pierre Richet, Ivory Coast, [5]Liverpool School of Tropical Medicine, United Kingdom, [6]London School of Tropical Hygiene and Medicine, United Kingdom, [7]Penn State University, United States, [8]Université Alassane Ouattara, Ivory Coast

Abstract: Current malaria vector control relies heavily on the core technologies of Long Lasting Insecticide Treated Nets (LLINs) and Indoor Residual Spraying (IRS). These tools have contributed to substantial declines in malaria burden. However, it is now widely recognized that new tools are required to complement these existing technologies if future control targets, such as those set out in the WHO Global Technical Strategy, are to be achieved.

Over the last few years a group of researchers have been working to develop and evaluate a novel control tool involving fitting sections of PVC pipe into the closed eaves of a house, with an insecticide-treated mosquito-screen insert placed inside the tubes. The tubes maintain airflow through the eaves and can be combined with housing improvements such as screening windows, closing eaves and sealing any other cracks, to make the house more "mosquito proof". The screening component alone should provide some protection for the household, as a physical barrier to mosquito entry. However, relying on cues that typically draw malaria mosquitoes into houses, the insecticide-treated tubes turn the house into a "lethal lure" and could provide community level protection at sufficiently high coverage.

Here we report the results of a large cluster randomized controlled trial conducted over 2 years in 40 villages in central Cote d'Ivoire to determine whether the combination of insecticide-treated tubes plus screening provides protection against malaria, on top of the current best practice of universal coverage of LLINs. We present data on efficacy, acceptability, and cost-effectiveness to provide an interdisciplinary evaluation of the "lethal house lure" approach.

The road to perfect immunity: absence of diseases in fungus-farming termites?

Authors: Thomas-Poulsen Michael, University of Copenhagen, Denmark

Abstract: Social insects have to protect both themselves and their obligate symbionts from specialised diseases. Research in this field has identified a number of specialised and general defence mechanisms that play pivotal roles in protecting social insect symbioses. Fungus-growing termites have coevolved with a basidiomycete fungal cultivar (genus Termitomyces) that is maintained in external fungus gardens (combs) on a substrate of plant material that passes through the termite gut before it is deposited in the fungus comb. This association originated 30 MYA in sub-Saharan Africa and has diversified to include more than 330 described termite species, 40 described Termitomyces spp., and complex and specific core gut microbial communities. Fungus-growing termites manure their fungus on harvested decaying wood, which is expected to contain a rich diversity of microbes that could compromise termite fungiculture, either by competing with or parasitizing Termitomyces or by infecting the termites themselves. However, efforts to identify whether specialised diseases have evolved to exploit farming termite nests have turned up empty handed. Here I review recent progress in our understanding of how these termites maintain high-efficiency monoculture farming to accomplish complete decomposition of any plant substrate without being compromised by pathogens.

Understanding how bumblebees interact with herbicide treated plants

Authors: Thompson Linzi Jay[3], Smith Stephen[2], Stout Jane[1] and Stanley Dara[2], [1]Trinity College Dublin, [2]University College Dublin, [3]University College Dublin, Ireland

Abstract: Herbicides are the most applied pesticides globally, and are used to kill weeds. Some herbicides, such as glyphosate, can be applied to flowering plants, meaning that bees could be exposed to these when foraging. Bumblebees may avoid plants treated with herbicide, since they die shortly after application, especially if there are untreated plants available.

Individual bees were presented with four plants in an exclusion cage; two treated with glyphosate and two controls. We recorded the number and duration of interactions with each plant. Observations were repeated when plants were freshly treated (within 24 hours) and again when they begun to die from glyphosate treatment (after 48 hours). We also collected corbicular pollen and tested for the presence of glyphosate.

We found that bees spent significantly less time collecting nectar from glyphosate treated flowers. However this effect was not strong enough to change their choice to forage overall, where we saw no significant effect on the number or duration of all other foraging and investigative interactions. We found glyphosate was present in pollen at both time periods tested. Therefore, we conclude that bees indiscriminately forage on glyphosate treated plants. This demonstrates a potential exposure route to herbicides in the wild.

Poorly understood effects of plant sessility on pollination success

Authors: Thomson James, University of Toronto Department of Ecology and Evolutionary Biology, Canada, United States

Abstract: The book Cognitive Ecology of Pollination arose from an invitation to organize a symposium on pollination for the International Botanical Congress; I decided that an audience of botanists could benefit from a more sophisticated, up-to-date view of the behavioural ecology of flower-visiting animals. At this anniversary, I will reverse that model by focusing on aspects of plant biology that tend to be overlooked by entomologists, particularly the consequences of plants' sessility. Most comparisons of the "pollination values" of different flower visitors tend to stress an animal's morphology, behaviour, and its morphological "fit" to the flower. It is less appreciated that pollination success also depends on a plant's spatial location—not only what neighbours are present at the time of visitation, but also the composition of the local community in the preceding days. Drawing upon field and lab studies, I will show how site fidelity and trapline holdover affect both the quantity (visitation rates) and the quality (heterospecific pollen deposition) of pollination service delivered by bumble bees.

Can non-crop habitat support biocontrol of the diamondback moth in organic Australian Brassica crops?

Authors: Thurman Jessa[2] and Furlong Michael[1], [1]School of Biological Sciences, The University of Queensland, Australia, [2]University of Queensland, Australia

Abstract: It has been suggested that non-crop habitat benefits biocontrol programs as natural vegetation can promote natural enemies of pests on farms. In-field surveys of arthropod communities were paired with natural enemy exclusion experiments to measure the potential indirect impact of adjacent, unmodified non-crop habitat on larval mortality of the diamondback moth (Plutella xylostella L.). Natural enemy diversity was higher in non-crop habitat, but the composition of the natural enemy communities in non-crop habitat was significantly different from that found within the crop, suggesting that non-crop habitat does not serve as a reservoir for natural enemies on farms. Predation of larvae was high throughout the crop, with significantly higher rates for neonate larvae on the crop edge compared to the middle of the crop. Diversity of natural enemies did not predict this increased predation rate, but there was a positive correlation between increased diversity and predation of second to third instar larvae. These results suggest that unmodified non-crop habitat does not support conservation biocontrol on farms, but that predation by natural enemies plays a significant role in the suppression the diamondback moth populations on farms. When considering these relationships, natural enemy diversity and mortality across life stages must be considered as these interactions vary between the life stages of the pest.

Development of cabbage stem flea beetle rearing to identify resistance in white mustard (Sinapis alba)

Authors: Thursfield Lucy[2], Wells Rachel[2], Penfield Steve[2], Mitrousia Georgia[3] and Faure Sebastien[1], [1]Innolea SAS, [2]John Innes Centre, United Kingdom, [3]Limagrain UK Ltd,

Abstract: The cabbage stem flea beetle, Psylliodes chrysocephala, is major pest of oilseed rapein Europe. Since the ban of neonicotinoid insecticides in the European Union, flea beetle pressure has been severe, and the area of oilseed rape sown has decreased significantly in response. Alternative control measures are desperately needed, and host plant resistance is a promising option. Resistance genes can be sourced from within Brassica napus germplasm, or introgressed from relatives such as white mustard, Sinapis alba.

Currently, no cabbage stem flea beetle resistant varieties of Brassica napus are commercially available. Identification of resistance genes is hampered by challenges with typical phenotyping methodologies using field trials, due to unpredictable infestation rates and difficulty identifying nuanced resistance. In addition, no published rearing methods for this non-model insect currently exist for experimentation in a controlled laboratory setting.

This work optimised methodology for rearing the cabbage stem flea beetle to obtain a consistent source of insects. In addition, a novel phenotyping methodology was used to screen for resistance in the laboratory. Accessions of both Brassica napus and Sinapis alba were phenotyped, and two genotypes of Sinapis alba with contrasting antixenotic (deterrent) resistance were identified. Investigation of quantitative trait loci is underway.

Exploring Biomechanics of Water-Walking Arthropods according to Updated Archimedes' Principle

Authors: Tian Yu, State Key Laboratory of Tribology,Tsinghua University, China

Abstract: Water-walking insects, such as water striders and water spiders, have become the recent burgeoning interest subject. The swift locomotion of water striders and water spiders primarily relies on their hairy super-hydrophobic legs, which allow them to be supported by water surface and to achieve the motion momenton. Exploring the physical mechanisms behind this water-walking capability has become a considerably interesting topic for bioinspired areas. The elegant bright-edged leg shadows of water striders are used to make the tiny forces visible and measurable based on the updated Archimedes' principle. The leg shadows could be used to reconstruct the in situ three-dimensional topographies water surface dimples to achieve the corresponding supporting forces acted on legs. The mechanics of water striders in self-cleaning, swimming forward, jumping forward have been revealed. These results are helpful for understanding the locomotion principles of water walking insects and the design of biomimetic aquatic devices. Visually measure tiny forces applied on the top surface of a circular plate has been invented with a high stability and sensitivity.

An experimental test on the relative role of natural enemy diversity and intraguild predation on herbivore dynamics

Authors: Tighiouart Karim[3], Frago Enric[2], Sanders Dirk[4], Montoya José [5] and Montoya Daniel[1], [1]Basque Centre for Climate Change (BC3), Bilbao, Spain., [2]Centre for Biology and Management of Populations, Montpellier, France, [3]CIRAD-3P, UMR PVBMT, Saint Pierre, La Réunion, France, [4]Environment and Sustainability Institute, University of Exeter, United Kingdom., [5]Theoretical and Experimental Ecology Station (SETE-CNRS), Moulis, France.

Abstract: Natural enemy diversity usually relates positively with herbivore suppression, but this effect can be dampened when natural enemies engage in intraguild predation (i.e. when two predators feed on each other and on a shared resource). The mechanisms behind these effects are poorly understood, and experimental studies are lacking. We worked with a trophic web composed of four herbivores and four enemies, some engaging in intraguild predation. We manipulated this assemblage to create replicated webs following a gradient of natural enemy diversity, that we monitored over several months. Our results showed that community dynamics weakly depended on enemy diversity or intraguild predation because it was mostly driven by a highly-influential polyphagous predator. Our work reveals experimentally how the structure of natural enemy networks determines the dynamics of terrestrial communities, and the services these communities provide, particularly pest biocontrol.

Bacteriophages as tools to dissect mosquito-microbiome interactions

Authors: Tikhe Chinmay[1] and Dimopoulos George[1], [1]Johns Hopkins University, United States

Abstract: Mosquitoes are important vectors of arboviruses and plasmodium parasites globally. Mosquito microbiome plays an important role in larval development, metabolism and vector competence. Multiples studies have deciphered the taxonomic diversity of bacterial community associated with various mosquito species. However, little is known about the functional role of individual bacterial taxa and their interactions with each other within the mosquito microbiota. Targeted modulation of mosquito microbiota can provide insights into the functional role of individual bacterial taxa. Bacteriophages; viruses that infect bacteria, provide a target specific tool for the selective modulation of the mosquito microbiota. In this study we isolated three novel lytic bacteriophages that specifically target Enterobacter spp., Serratia spp. Elizabethkingia spp., three common members of the mosquito microbiota. We assessed the utility of theses bacteriophages to alter the larval development of monoxenic Aedes aegypti and Anopheles gambiae larvae. Our results showed that addition of lytic bacteriophages to the water altered the development of monoxenic Aedes aegypti and Anopheles gambiae larvae. These results provide a proof of principle that bacteriophages can be utilized as a tool to modulate the mosquito microbiota and can in-turn affect mosquito life history traits. We intend to utilize these bacteriophages further to study the effect of targeted microbiome modulation on mosquito life span, fecundity and vector competence. This is the first use of bacteriophages to modulate the mosquito microbiome and has the potential to be developed into a novel strategy to curb mosquito-borne diseases.

Insect Outreach in the UK with the Royal Entomological Society

Authors: Tilley Luke[1], Sconce Francisca[1], [1]Royal Entomological Society, United Kingdom

Abstract: The Royal Entomological Society aims to promote and improve entomology. Entomological outreach is important to increase wider public understanding of insect science and contributes to our charitable purposes.
For almost 15 years, the Society has coordinated a series of major outreach activities in the UK including National Insect Week, Insect Festivals and EntoSci. This has been achieved through collaboration with partners such as specialist insect societies, as well as those working with wildlife and natural history.
In this talk we will share some of the successes of these campaigns and events, and the lessons learned from these activities.

Arthropod community response to abnormal precipitation in Ohio agroecosystems

Authors: Tilmon Kelley[1], Pekarcik Adrian[1], Raudenbush Amy[1] and Richer Eric[1], [1]Ohio State University, United States

Abstract: Annual precipitation in Ohio was nearly 16 cm above normal in 2019. The excessive rainfall delayed or even prevented planting in an unprecedented number of cases. By June 9 only 38% of soybean and 50% of corn was planted which is well below the average of 89% and 96% for these crops, respectively. Additionally, oversaturated soils are known to cause yield losses, especially when planted late. While the negative impact of saturated soils on plants was obvious, it is unknown how the arthropod communities that co-inhabit these soils were affected. When soils are saturated, ground-dwelling insects can move onto the soil surface to escape oversaturation, which in turn may leave them vulnerable to predators they would not generally encounter. Otherwise, insects that remain in the saturated soils may drown. In 2018 and 2019 we monitored X fields in northern Ohio for Asiatic garden beetle, and there was a 3-fold reduction in beetle populations in 2019. We used pitfall traps for this sampling and also collected invertebrate bycatch. The goal of this study is to assess how oversaturated soils in 2019 impacted arthropod communities of corn-soybean rotated fields. Arthropods were sampled weekly throughout the summers of 2018 and 2019 from 20 plots established in a 5x4 grid over a 5-acre area of corn-soybean rotated fields in northern Ohio with a field history of Asiatic garden beetle infestation. All bycatch was identified to the Family level and various aspects of the communities were compared between the two years. We hypothesize that excessive rainfall in 2019 reduced the arthropod communities, particularly for species that are strictly ground-dwelling.

Harmonia axyridis Immigration and Oviposition in Response to Variable Aphid Density

Authors: Tilmon Kelley[1], Pekarcik Adrian[1] and Raudenbush Amy[1], [1]Ohio State University, United States

Abstract: The multicolored Asian lady beetle, Harmonia axyridis, shows a remarkable ability to respond positively to soybean aphid (Aphis glycines) prey density in soybean. We performed both field and greenhouse choice and no-choice studies examining the response of H. axyridis to variable prey density. H. axyridis showed a density dependent response attributable to both increased adult immigration and increased reproductive recruitment (oviposition) in response to higher prey density. This density-dependent response helps explain the success of H. axyridis as both a biological control agent and an invasive species.

Genomic approaches to characterize Wolbachia in arthropod communities of soil

Authors: Tischer Marta[2] and Bleidorn Christoph[1], [2]Georg-August-University Göttingen, Germany, [1]Georg-August-University Göttingen, Dept. Animal Evolution and Biodiversity

Abstract: Wolbachia is a widespread, intracellular, endosymbiotic Alphaproteobacteria known to infect arthropods and several groups of filamentous nematodes. The most important effects of Wolbachia on hosts include manipulation of reproduction, vitamin supplementation, and pathogen restriction.

Wolbachia distribution and diversity among soil arthropods are still poorly studied. There are many representants of soil arthropod hosts caring diverse and possibly new Wolbachia supergroups or strains that require precise examination. Most of the phylogenetic analyses and co-phylogenies made so far for Wolbachia were based on the multilocus sequence typing system (MLST), which comprises up to 5 conserved housekeeping genes. However, while supergroups can be well-distinguished by this system, it often result in a lack of resolution of strains. Currently, there are 16 identified and classified supergroups of Wolbachia, from different hosts and habitats, including nematodes, hexapods and other pancrustaceans, or arachnids. As an alternative for strain typing approaches sequencing and annotating draft genomes have been proposed.

In this project, we aim to investigate the molecular diversity of arthropod communities from the soil environment. After screening for the presence of Wolbachia, we used Illumina-based short-read sequencing to generate draft genomes of Wolbachia from soil organisms. Using phylogenomic approaches, we phylogenetically place the Wolbachia genome sequences, including putatively new supergroups. The diversity of Wolbachia in soil arthropods is discussed and we interpret the results in the light of the evolution of Wolbachia-arthropod symbiotic relationships.

A review of the social insect inquilinism in Histeridae (Coleoptera)

Authors: Tishechkin Alexey, Plant Pest Diagnostics Center, CDFA, Sacramento, CA, United States

Abstract: Histeridae along with Staphylinidae are two leading groups of inquilinous beetles in terms of taxonomic diversity and occurrence. There are two major obligate inquilinous lineages (subfamilies) in the family as well as numerous additional cases of inquilinism evolution in the rest of Histeridae. Distriobution, diversity, host taxa and specificity, integration mechanisms and other natural history features of inqulinous Histeridae are reviewed.

The ‘Cost’ of Wolbachia infections in Nasonia vitripennis

Authors: Tiwary Alok[2] and Raychoudhury Rhitoban[1], [1]Indian Institute of Science Education and Research Mohali Knowledge city, Sector 81, Manauli, PO, Sahibzada Ajit Singh Nagar, Punjab, India, [2]Indian Institute of Science Education and Research(IISER), Mohali, India

Abstract: Wolbachia is known to alter its host reproductive biology for its benefit. It also introduces both positive and negative fitness effects in the vast majority of its host population. The present study describes the effect of maintenance of Wolbachia infection in the parasitoid host Nasonia vitripennis. We have separated the two Wolbachia infections in N. vitripennis to get single lines of Wolbachia supergroup A and supergroup B infections. We compare the effect of Wolbachia infection on life-history traits between uninfected, single A, single B, and double infection strains. Contrary to the previous reports, our results suggest that there is a “cost” associated with the maintenance of Wolbachia infection where life-history traits like adult progeny family size, fecundity, longevity, and male mating potential are compromised in Wolbachia infected strains. The double infection of Wolbachia has more detrimental impacts on the host as compared to single infections. The findings of the study raise important questions on the mechanism of survival and maintenance of these reproductive parasites in arthropod hosts

Wolbachia infections in Nasonia vitripennis: A Host-Pathogen interaction study

Authors: Tiwary Alok[2] and Raychoudhury Rhitoban[1], [1]Indian Institute of Science Education and Research Mohali Knowledge city, Sector 81, Manauli, PO, Sahibzada Ajit Singh Nagar, Punjab, India, [2]Indian Institute of Science Education and Research(IISER), Mohali, India

Abstract: Wolbachia is a maternally inherited endosymbiont that alters its host's reproductive biology to increase the number of Wolbachia-infected females in the population. One of these alterations includes sperm-egg incompatibility known as Cytoplasmic Incompatibility (CI). CI leads to a Wolbachia infected male produce viable offspring only with a female having the same Wolbachia type infection.

Wolbachia induces CI in the parasitoid host Nasonia vitripennis (Hymenoptera: Pteromalidae). The worldwide population of Nasonia vitripennis is infected with two Wolbachia infections, one each from the supergroups of A and B. In case of multiple infections in a single host, several unanswered questions remain. How these infections are being maintained over a long evolutionary time scale even though the two supergroups show CI between each other? To address these questions, we have separated the two infections in Nasonia vitripennis and have generated single lines for Wolbachia supergroup A and supergroup B infections. We have studied the dynamics of these infections at the different developmental stages of its host Nasonia vitripennis. The study demonstrates a trade-off in life-history traits like fecundity, longevity, male mating potential, etc, and the maintenance of Wolbachia infection.

Even though Wolbachia-induced CI has been an area of attraction in recent times, the genetic basis of CI remains poorly understood. Using Nasonia vitripennis as a model system, we are also trying to understand how Wolbachia alters its host reproductive behavior? We have identified the stage of Nasonia vitripennis male development where CI is introduced by Wolbachia. We intend to find out the genes playing a role in this alteration by doing stage-specific transcriptome studies. Our study will lead to deeper insights into the biology of Wolbachia-host interaction.

Understanding how oilseed rape crops are colonised by one of its main pests, the cabbage stem flea beetle Psylliodes chrysocephala

Authors: Tixeront Margot, Université Rennes 1, France

Abstract: Integrated pest management is an emerging solution to protect crops using less or no insecticides. However, predicting crop colonisation and the pest's spatial distribution is essential for effective control. The cabbage stem flea beetle Psylliodes chrysocephala (CSFB) can cause complete destruction of oilseed rape crops (Brassica napus, OSR). In the present study, the colonisation process of OSR fields by the CSFB was studied using sticky traps placed at the border and in the centre of the fields at different heights. Results show that more individuals were caught on the outer side of the traps, suggesting that more beetles were entering than leaving the crop, and beetles were moving into the centre quickly. Catches were more important at the bottom of the trap near the crop, and they were more important during the day than during the night. The sex-ratio of individuals caught was both equilibrated and stable over the study period. Dissections of female's genitalia showed that sexual maturity occurred during the experimentation. Finally, the integration of sampling data with local meteorological data showed that the caught depends on temperature, humidity, and wind speed. The information provided by this study could contribute to implement IPM strategies against this pest.

Establishment of clock gene knockout strains and analysis of diapause phenotype in the silkworm, Bombyx mori

Authors: Tobita Hisashi[1], Katsuma Susumu[1] and Kiuchi Takashi[1], [1]The University of Tokyo, Japan

Abstract: Insects endure unfavorable seasons by entering diapause, physiologically dormant state, and photoperiod is a major environmental cue for the diapause induction. It is well known that disruption of clock gene expression prevents diapause induction in several insect species. In the silkworm, Bombyx mori, several studies have revealed that clock genes are involved in the diapause induction. However, it is controversial how clock genes are involved in the photoperiodic and temperature-dependent diapause induction. We report here the results of knockout (KO) of positive regulators Clock and cycle, and negative regulators period and timeless, in B. mori to investigate their involvement in the diapause induction. We established each clock gene KO strain using CRISPR/Cas9 system in a bivoltine strain p50T (Daizo). In embryonic or larval stage, KO lines were kept under photoperiodic conditions that the wild type moths oviposit diapause eggs. As a result, all KO strains produced non-diapause eggs regardless of the embryonic and larval photoperiod. On the other hands, KO strains tend to oviposit diapause eggs when kept under high temperature conditions in the embryonic stage. These results suggest that clock genes are involved in the photoperiodic-dependent diapause induction in B. mori as a circadian clock.

Unraveling the trophic effects of cover crops on predatory communities in a cotton agroecosystem

Authors: Toews Michael[1], Schmidt Jason[1], Bowers Carson[1], [1]University of Georgia, United States

Abstract: Providing resource stability for natural enemy communities when crop habitat is low should lead to more stable arthropod communities and service provisioning by predatory arthropods in the form of biological control. Here we use molecular gut content analysis to investigate the response of predator communities and interaction networks to rye and crimson clover cover crop use as compared to conventional tillage practices in a cotton system. Predators were collected from the field during each major cotton development stage in 2017 and 2018, and PCR was used to screen predators for the presence of primary cotton pests, incidental pests, and alternative prey. Cotton strip-tilled into cover crop residue promoted unique predator communities in the early and mid-season as compared to cotton using conventional tillage (clean till), with correspondingly dissimilar prey consumption among cover crop treatments. Temporal dynamics observed in predator communities and their interactions with prey suggested higher stability in the late growing season. We identify limitations for biological control of some key pests in this system and discuss potential mechanisms for altered predator communities and their function in the early season.

Rye cover crops replace insecticide applications for sustainable cotton production

Authors: Toews Michael[3], Lahiri Sriyanka[1] and Roberts Phillip[2], [1]Gulf Coast Research and Education Center, Department of Entomology and Nematology, University of Florida, Wimauma, FL, United States, [2]University of Georgia Department of Entomology, United States, [3]University of Georgia, United States

Abstract: Thrips infestations on seedling cotton are a predictable impediment to cotton production in the southeastern US. Common thrips species in this region include Frankliniella fusca, Frankliniella occidentalis, and Frankliniella tritici. As early season thrips can cause stand and yield losses if not managed, growers utilize prophylactic insecticide applications including seed treatments, in-furrow liquid and granular insecticides, and foliar applied insecticides. Field trials were conducted to understand how to better manage these insect pests in the absence of insecticide availability. Responses included counts of immature and adult thrips, visual plant damage ratings, dry biomass estimates at 42 days after planting and lint yield. On conventionally tilled plots, an insecticide seed treatment followed by a foliar insecticide application were necessary for maximizing yield. However, studies also demonstrated that utilizing alternatives including strip tillage into a cereal cover crop minimized thrips infestations and plant damage, while maintaining plant biomass and lint yield. Additionally, utilization of starter fertilizer [93.5 liters of 10-34-0 (N P K) per hectare] complemented thrips mitigation efforts by enabling rapid plant growth that shortened the window of time when seedlings were most susceptible to thrips injury. Although there are no drop in replacements for the convenience of a seed treatment, these data suggest that growers could adapt practices that provide adequate levels of early season thrips protection to preserve lint yield.

Bioinformatics and ecological theory for understanding/designing complex webs of species interactions

Authors: Toju Hirokazu, Kyoto University, Japan

Abstract: In the Anthropocene, countless species are at the unprecedented risk of extinction, while we still have limited knowledge of biological dynamics in nature. Developing interdisciplinary platforms for drastically increasing the information of entangled webs of species interactions is an urgent task. By integrating high-throughput DNA metabarcoding, bioinformatics, and several mathematical tools, we have revealed how hundreds or thousands of species are associated in various types of natural and experimental ecosystems. In an analysis of terrestrial arthropod communities, for example, we have selected Hexapoda-specific PCR primers for detecting gut contents of spiders and then identified a number of prey species with Illumina sequencing. The data were subsequently used to examine how network structure of predator-prey interactions changes through time and how spiders link above- and below-ground food webs. The technical platform was also applied to plant-microbiome and microbe-microbe interactions, allowing us to explore “core species”, which were expected to have great impacts on whole ecosystem dynamics. Furthermore, with the aid of recently developed methods for time-series data analyses (e.g., empirical dynamic modeling), we inferred how the direction/strength of species interactions could change and how the stability of whole communities could fluctuate through time. Such time series datasets also provide a basis for predicting critical transitions between alternative stable states of biological community compositions. Based on these new lines of results on community structure and dynamics, we are now trying to build frameworks for designing complex webs of species interactions for the restoration of degraded ecosystems and the management of sustainable agroecosystems.

Microsporidia as pathogens of Lepidoptera and their parasitoids

Authors: Tokarev Yuri[1], Malysh Svetlana[1], Ignatieva Anastasia[1], Inna Grushevaya[1], Issi Irma[1] and Tyurin Maksim[2], [1]All-Russian Institute of Plant Protection, Russia, [2]Institute of Systematics and Ecology SB RAS, Russia

Abstract: Microsporidia, obligate intracellular parasites, are widespread in arthropod hosts and play an important role in population dynamics of agricultural and forest lepidopteran pests, such as beet webworm, corn borer, cabbage white, green tortrix, spruce budworm, gypsy moth, winter moth etc. (Franz, Huger, 1971; Wilson, 1973; Hill, Gary, 1979; Canning, Wigley, 1983; Issi, 1986; McManus, Solter, 2003; Frolov et al., 2008). Presence of microsporidia in lepidopteran hosts of hymenopteran and dipteran parasitoids may adversely affect the latter due to premature death of the host, decreased host attractiveness for oviposition, physiological alteration of the host or direct infection of the parasitoids (Brooks, 1993; Hoch et al., 2002; Down et al., 2005; Malysh et al., 2013; Paes et al., 2019). On the other hand, parasitoids may facilitate the transmission of microsporidia among the Lepidoptera. In cabbage white Pieris brassicae, two endoparasitic wasps, Cotesia glomerata and Pteromalus puparum, become infected with a microsporidium Vairimorpha mesnili when the parasitoid larvae develop within the host larvae. The pathogen completes its life cycle both in P. brassicae and C. glomerata and the emerged parasitoids transmit V. mesnili to new hosts (Issi, Maslennikova, 1964). Dybrachys cavum, a hyperparasitoid of C. glomerata, may also become infected. Moreover, the wasps may transmit microsporidia mechanically from diseased to healthy larvae during repeated attacks (unsuccessful oviposition attempts) due to ovipositor contamination with the spores (Issi, 1986). Notably, epizootics of microsporidiosis in cabbage white followed the outbreaks of braconid parasitoids (Lipa, 1963), indirectly suggesting an important role of the latter in pathogen dissemination. Additionally, V. mesnili disrupted winter diapause in P. brassicae and C. glomerata causing death of both insects during hibernation (Issi, Maslennikova, 1966).

Ectoparasitic wasp Habrobracon hebetor is widely exploited in pest control (Brower et al., 1996). To understand its interactions with a microsporidium Nosema pyrausta from corn borer Ostrinia nubilalis, we have designed a laboratory model. A continuous laboratory culture of O. nubilalis infected with N. pyrausta has been established. The microsporidia-infected larvae were exposed to adult H. hebetor for oviposition. Development of ectoparasitic larvae was successful, ending up in pupation. However, no adults emerged from the cocoons. Microscopic examination showed that pupal tissues of the wasp were tightly packed with microsporidia spores, and molecular genetic analysis confirmed its identity to N. pyrausta. On the contrary, adult wasps successfully emerged when maintained on control (microsporidia-free) host larvae. Thus, the microsporidium from O. nubilalis is highly infective to H. hebetor larvae and cause fatal disease in its pupae. This may limit H. hebetor efficiency against corn borer populations extensively infected with N. pyrausta.

Increased mutation rate is linked to genome reduction in insect endosymbionts and other prokaryotes

Authors: Tokuda Gaku[10], Lo Nathan[7], Arab Daej[7], Yukihiro Kinjo[4], Ohkuma Moriya[5], Coleman Nicholas[9], Villa-Martin Paula[2], Ho Simon[9], Pigolotti Simone[2], Qian Tang[1], Bourguignon Thomas[3], Hongoh Yuichi[8] and Wang Zongqing[6], [1]National University of Singapore, Singapore, [2]OIST, Japan, [3]Okinawa Institute of Science & Technology Graduate University, Japan, [4]Okinawa Institute of Science and Technology Graduate University, Japan, [5]RIKEN, Japan, [6]Southwest University, China, [7]The University of Sydney, Australia, [8]Tokyo Institute of Technology, Japan, [9]University of Sydney, Australia, [10]University of the Ryukyus, Japan

Abstract: The evolutionary processes that drive variation in genome size across the tree of life remain unresolved. Effective population size (Ne) is thought to play an important role in shaping genome size, a key example being the reduced genomes of insect endosymbionts, which undergo population bottlenecks during transmission. However, the existence of reduced genomes in marine and terrestrial prokaryote species with large Ne demand an alternative explanation. One such alternative is enhanced mutation rate, which might increase an organism's ability to adapt to novel environments, but might also promote gene loss. We analysed the reduced genomes of bacteria from three divergent phyla: Blattabacterium endosymbionts of cockroaches (Bacteroidetes), Buchnera endosymbionts of aphids (Proteobacteria), and free-living marine Prochlorococcus and Synechococcus (Cyanobacteria). We found that rates of gene loss strongly correlate with mutation rates in all of these groups, and show weak or no correlation with the ratio of nonsynonymous/synonymous substitution rates (dN / dS). This indicates that genome reduction is largely associated with increased mutation rate, while the association between gene loss and changes in Ne is less well defined. Lineages with relatively high dS and dN, as well as smaller genomes, lacked multiple DNA repair genes, providing a proximate cause for increased mutation rates. Our findings suggest that similar underlying mechanisms drive genome reduction in both intracellular and free-living prokaryotes, with implications for developing a comprehensive theory of prokaryote genome size evolution.

Metabolome profiles in the hindguts of the wood-feeding cockroaches collected from East Asia and North America

Authors: Tokuda Gaku[4], Kihara Kumiko[3], Kitade Osamu[1] and Fukuda Shinji[2], [1]Graduate School of Science and Engineering, Ibaraki University, Japan, [2]Institute for Advanced Biosciences, Keio University, Japan, [3]National Institute of Technology, Kumamoto College, Japan, [4]University of the Ryukyus, Japan

Abstract: Wood-feeding subsocial cockroaches of the genus Cryptocercus (wood roaches) are close relatives of termites, which sparsely distribute in East Asia and North America. The wood roaches harbor numerous unicellular eukaryotic flagellates in the hindgut as is the case of termites. These flagellates contribute to digestion of recalcitrant lignocellulose, which contains only a trace amount of nitrogen. Previous studies suggested that some bacterial endosymbionts in the hindgut flagellates fix atmospheric nitrogen to produce amino acids. On the other hand, almost all cockroaches including the wood roaches harbor the bacterial endosymbionts Blattabacterium cuenoti in the fat bodies, which play a role in recycling nitrogen wastes of their hosts to produce amino acids and cofactors. Thus, it appears that there is functional redundancy between the bacterial endosymbionts in the gut flagellates and in the host tissue. Our previous studies indicated that the genome sizes in Blattabacterium inhabiting the wood roaches in North America were markedly reduced compared to those in East Asia and that Blattabacterium in the wood roaches in North America lost several genes involved in essential amino acid biosynthesis. Based on these results, we hypothesized that the hindgut microbiota in North America acquired ability to synthesize essential amino acids more efficiently. To address this issue, we performed capillary electrophoresis-mass spectrometry to analyze metabolome profiles in the hindguts of Cryprocercus punctulatus and C. kyebangensis, which were collected in the United States and South Korea, respectively. As a result, we identified 209 distinct metabolites in the hindguts of these Cryptocercus species. There were considerable differences of normalized quantities of the metabolites between these species, whereas the amounts of most essential amino acids in the hindgut were larger in C. punctulatus than in C. kyebangensis. These results suggest that the hindgut flagellates in the wood roaches of North America acquired bacterial symbionts that can efficiently produce essential amino acids, which might have led to relaxed selection of genes involved in essential amino acids biosynthesis in Blattabacterium.

Ecological divergence among morphologically and genetically related Asphondylia species (Diptera: Cecidomyiidae)

Authors: Tokuda Makoto[4], Yukawa Junichi[3], Yamaguchi Daisuke[2], Matsuo Kazunori[1], Yasuda Keiji[7], Uechi Nami[5], Ganaha-Kikumura Tomoko[8] and Shimizu Yuko[6], [1]Biosystematics Laboratory, Faculty of Social and Cultural Studies, Kyushu University, Japan, [2]Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan, [3]Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan, [4]Faculty of Agriculture, Saga University, Japan, [5]Institute of Fruit Tree and Tea Science, National Agriculture and Food Research Organization, Japan, [6]Nago Branch, Okinawa Prefectural Agricultural Research Center, Japan, [7]Okinawa Prefectural Forest Resources Research Center, Japan, [8]Okinawa Prefectural Hokubu Agriculture, Forestry and Fisheries Promotion Center, Japan

Abstract: Ecological data is crucial for determining the degree of reproductive isolation among closely related species, and in identifying the factors that have produced this divergence. We compared the ecological divergence among ten morphologically and genetically closely related Japanese Asphondylia (Diptera: Cecidomyiidae) species in Japan. We found that the ten species were significantly differentiated in important life history traits, such as host range, galling-host organ, voltinism, lower developmental threshold temperature, thermal constant and diapausing season. The data support the hypothesis that ecological divergence evolves early in speciation as the result of divergent natural selection, and that it may drives the evolution of reproductive isolation. We present scenarios on how host range expansion, host plant shift and host-organ shift for galling initiate the early stages of speciation.

Morphological characters of the pupal dorsal thorax of gall midges (Diptera: Cecidomyiidae), with reconstructions of their ancestral states within the family

Authors: Tokuda Makoto[1], Elsayed Ayman[2], [1]Faculty of Agriculture, Saga University, Japan, [2]The Botanical Gardens, Graduate School of Science, The University of Tokyo, Japan.

Abstract: Gall midges (Diptera: Cecidomyiidae) are the largest group of gall-inducing arthropods and are expected to be the most specious taxon of flies on Earth. Their fascinating, diverse, and species-specific shapes of plant-galls have attracted the attention of taxonomists to collect them to obtain immature stages as well as to rear adults. Thus, gall midge systematics is based on the descriptions of larvae, pupae and adults, in addition to the biological information, such as host plants and gall structures. In pupae of gall midges, characters of anterior and ventral parts of head and dorsal tergites of abdomen have been described, but the dorsal thorax remains totally undescribed, except the prothoracic spiracles. This is because the dorsal thorax is usually unclear and folded in the traditional slide-mounting techniques in which the ventrally situated antennae, wings, and leg sheaths prevent from observing its characters comfortably. Scanning electron micrographs can partially help us to observe its general morphology, but usually insufficient to precisely examine the number and position of tiny papillae. In the present study, a new dissecting technique was adopted for pupal exuviae and it enabled us for the first time to examine the detailed morphology of the dorsal thorax in slide-mounted specimens of Cecidomyiidae. We described the morphological features of pupal dorsal thorax of 35 species of 14 genera belonging to several tribes of Cecidomyiinae, two species of two genera of Porricondylinae, and one species of Micromyinae. A new set of terms is provided for the newly found characters, and reconstructions of their ancestral states were inferred.

Unexpected broad existence of endogenous phytohormones in arthropods: implications for the evolution of phytophagy and gall-inducing habits in insects

Authors: Tokuda Makoto[1], Elsayed Ayman[5], Matsuda Hiroki[4], Fujita Shohei[4], Adachi-Fukunaga Shuhei[3] and Suzuki Yoshihito[2], [1]Faculty of Agriculture, Saga University, Japan, [2]Ibaraki University, Japan, [3]NARO Kyushu Okinawa Agricultural Research Center, Japan, [4]Saga University, Japan, [5]The Botanical Gardens, Graduate School of Science, The University of Tokyo, Japan

Abstract: Recent studies have shown that some insects including non-gall inducers have an ability to synthesize auxin (IAA) in their bodies. These facts suggest that a wide range of insects have the auxin-synthesizing ability for some reason, and it might be involved in the evolution of phytophagous and gall-inducing habits as a preadaptive trait. To confirm the origins of phytohormone synthetic abilities in insects, we analyzed endogenous levels of IAA as well as cytokinins (iP and tZ) and their ribosides (iPR and tZR) in various terrestrial arthropods. Surprisingly, certain concentrations of IAA were detected in all terrestrial arthropods analyzed. In addition, iP and/or iPR were detected in most insect orders and the common ancestor of insects was supposed to have possessed its synthesizing ability. In contrast, tZ and/or tZR were detected only in some orders belonging to Condylognatha and Holometabola in Insecta and the synthesizing ability was supposed to have acquired independently in these taxa. Endogenous levels of IAA were not significantly different among higher taxa and feeding habit, but gall inducers possessed significantly higher levels of iPR, tZ and tZR, suggesting that these phytohormones are critically related to the evolution of gall-inducing habit in insects. In conclusion, we revealed that unexpectedly a broad range of arthropod taxa, regardless of phytophagy, possess certain concentrations of endogenous IAA, implying that IAA is not merely used as hormones in plants but has some important function in terrestrial arthropods. Furthermore, the tZ and/or tZR synthesizing ability is likely to be acquired in limited insect taxa containing gall inducers, suggesting its critical role, as in microorganisms, in the acquisition of gall inducing habit.

Environmental factors affecting dragonfly diversity in the Saga Plain, Japan

Authors: Tokuda Makoto[1], Tazunoki Yuhei[4], Oishi Hiroki[3], Goka Koichi[2], Nakanishi Kousuke[2], Ikegami Makihiko[2], Hayashi Takehiko[2] and Oba Yutaro[3], [1]Faculty of Agriculture, Saga University, Japan, [2]National Institute for Environmental Studies, Japan, [3]Saga University, Japan, [4]Saga University, Japan

Abstract: Odonata species are important indicators of freshwater environments. In recent years, several Sympetrum species have declined in Japan and systemic insecticides used for rice nursery-box were suspected as their causes. However, to conclude the causal relationship, we need to discriminate direct and confounding factors affecting Odonata densities in the field. In this study, we investigated Odonata diversity and abundance in ten localities in the Saga Plain, Kyushu, Japan from 2017 to 2019. In addition, we surveyed environmental factors including aquatic vegetation cover (emergent plants, floating-leaved plants, submerged plants), water quality, concentrations of various insecticides, and land use patterns around the census cites. To exclude confounding factors, we analyzed factors affecting the subtractions between generations or years for each species. The abundance of most species belonging to the suborder Anisoptera was negatively related to coverage of aquatic vegetation. The abundance of Sympetrum eroticum eroticum was negatively related to concentrations of a systemic insecticide (fipronil), which consistent with previous studies. Moreover, the spring generation of Ischnura senegalensis seldom occurred at localities surrounded by paddy fields and the concentrations of fipronil negatively affected the abundance of spring generation, which strongly suggest that the insecticides causes population decline of this species.

A revision of the birch-associated genus Massalongia (Diptera: Cecidomyiidae), with discovery of an unidentified species from Japan

Authors: Tokuda Makoto[2], Elsayed Ayman[5], Ohta Kazuki[3], Skuhravá Marcela[1] and Yoshida Satoshi[4], [1]Bítovská 1227, Praha 4, Czech Republic, [2]Faculty of Agriculture, Saga University, Japan, [3]Laboratory of Systems Ecology, Faculty of Agriculture, Saga University, Japan. The United Graduate School of Agricultural Sciences, Kagoshima Un, [4]Laboratory of Systems Ecology, Faculty of Agriculture, Saga University, Japan, [5]The Botanical Gardens, Graduate School of Science, The University of Tokyo, Japan.

Abstract: Betula L. (Betulaceae), or birch, is a Holarctic genus of trees and shrubs, and its species have ornamental, industrial and medical importance. Gall midges of the genus Massalongia Kieffer (Diptera: Cecidomyiidae: Cecidomyiidi) are known to be exclusively associated with birches in the Palearctic region. In 2018, we discovered an unidentified Massalongia species heavily forming leaf galls on midveins of B. grossa Siebold & Zucc. on Mount Tara, Saga Prefecture, Kyushu, Japan. In this study, we consider the taxonomic status of the unidentified species and review the genus Massalongia. In addition, we compared Massalongia with other known genera of Cecidomyiidi, and found that the Nearctic genus Apagodiplosis Gagné, containing a single species A. papyriferae (Gagné) associated with paper birch B. papyrifera, has no synapomorphic differences from Massalongia. Thus, we synonymize Apagodiplosis under Massalongia, and the genus Massalongia becomes a Holarctic genus as their host plant genus. All known Massalongia species are univoltine, and their third instars drop from galls in Autumn, crawl into the ground, and construct unique hyaline bottle-shaped cocoons on the leaf litter. These cocoons does not let the water get inside, thus we suggest they play an important role in the protection of the overwintering larvae against rain water and snow in winter.

Oregon’s experience with a Japanese Beetle Eradication

Authors: Toland Ashley[1], Bodart Jake and Rogg Helmuth[1], [1]Oregon Department of Agriculture, United States

Abstract: In 2016, the Oregon Department of Agriculture (ODA) detected 369 Japanese Beetles, Popillia japonica, in the Portland Metro area. This was the largest detection ever in the state. The following year ODA detected over 23,000 beetles, and initiated a multi-year project with the goal of containing and eradicating Japanese beetle. The project has grown in size and scope each year, but has also seen many successes. Since the project began, there has been an 85% decrease in Japanese beetle detections, over 20,000 acres have been treated, over 22,000 tons of potentially infested yard debris has been quarantined, and over 90% of residents within the treatment boundary have consented to treatment each year. ODA will outline their steps to the eradication program including planning, treatment methods, communications, maintaining public support, and lessons learned along the way.

First evidence of N1575Y mutation in pyrethroid resistant Anopheles gambiae in Nigeria

Authors: Tolulope Oyeniyi[2], Olakiigbe Biodun[4], Oboh Bola[1], Adeogun Olufemi[5], Adesalu Oluwakemi[4], Awolola Samson[4], Idowu Taiwo[3] and Jimoh Tawakalitu[4], [1]Department of Cell Biology and Genetics, University of Lagos, Lagos, Nigeria, [2]Department of Cell Biology and Genetics, University of Lagos. Nigerian Institute of Medical Research, Lagos, Nigeria, [3]Department of Zoology, University of Lagos, Lagos, Nigeria, [4]Nigerian Institute of Medical Research, Lagos, Nigeria, [5]Nigerian Institute of Medical Research, Lagos, Nigeria

Abstract: In view of recent findings that codon 1575 mutation increases the L1014F mediated resistance in Anopheles mosquitoes, we investigated the presence of this mutation in four sites with intense pyrethroid resistance in Nigeria. Pyrethroid: permethrin and deltamethrin susceptibility test was carried out using 2-3 days old adult Anopheles from larval collections. Based on the susceptibility test result, intensity test with 5x and 10x concentrations were carried out at sites with high resistance (% mortality>85). Resistant specimen from each insecticide concentration were identified to species level by PCR and screened for the presence of L1014F and N1575Y mutations using allele specific PCR and Taqman assay respectively. The frequency of kdr mutation for permethrin varied from 0.71-0.75 for 5x and 0.73-0.75 for 10x. The kdr frequency for deltamethrin was significantly low: 0.54-0.60 for 5x and 0.66-0.71 for 10x. Anopheles gambiae resistant to 5x and 10x concentrations of permethrin showed the presence of homozygous mutant allele (Y) and heterozygous mutant allele (NY) in two sites. This is the first detection of N1575Y mutation in Nigeria. From this study, there was no significant association with resistance intensity (?2=0.8, P=0.3711). It may take time for such mutation to reach significant frequency. However, there is need for frequent monitoring, to forestall the effect this may have on national malaria vector control programs

Conditions for collapse: chronic nutrient enrichment increases native insect density linked to salt marsh dieback

Authors: Tomasula Jewel[1], Wimp Gina[1], Murphy Shannon[2], Arab Ali, Rippel Tyler, Maguire Billie, Lopez Eddie and Perez Stephanie, [1]Georgetown University, [2]United States

Abstract: We examined how different conditions of nutrient enrichment affect densities of a native insect that feeds upon a salt marsh foundation plant species with subsequent effects on salt marsh dieback. Dieback is the abrupt death of salt marsh vegetation, leaving barren mudflats. In a natural salt marsh in the mid-Atlantic United States, we set up a full factorial experiment in which we crossed the amount (low, medium, high) with duration (one-year pulse or a two-year press) of nitrogen addition. We recorded stem-boring insect larvae densities, plant tissue percent nitrogen, and percent dieback within each plot. When we compared the effects of nitrogen amount and duration on dieback, we found an effect of nitrogen amount and a marginal effect of press/pulse. By comparing linked and independent Bayesian hierarchical models, we determined both plant percent nitrogen and stem-boring larvae densities contributed to salt marsh dieback. Our findings link nutrient enrichment with an increase in native insect herbivory as a cause of salt marsh dieback, whereas previous studies considered nutrients and herbivory as separate factors. Broadly, we provide evidence that high levels of nutrient enrichment that persist for multiple years amplifies native herbivory and is a condition leading to salt marsh dieback.

Deciphering Adult Behavior the Black Soldier Fly to Optimize Egg Production in Colony

Authors: Tomberlin Jeffery, Department of Entomology Texas A&M University, United States

Abstract: Black soldier fly adults have a unique lekking behavior that drives mating and resulting fertilized egg production. Various abiotic and biotic factors impact such behavior and egg production. During this presentation, those attending will updated on what is known about the impact of temperature, microbiology, and body size on adult mating behavior and resulting egg production.

Photic entrainment mechanism of the circadian clock in the cricket, Gryllus bimaculatus

Authors: Tomioka Kenji, Graduate School of Natural Science and Technology, Okayama University, Japan

Abstract: In insects, the circadian clock governs daily rhythms in various physiological functions, including behavioral activity, hormonal secretion, and sensitivity of visual system. One of the essential properties of the clock is the synchronization to the daily environmental cycle. Light is the primary cue for this synchronization or entrainment. However, the molecular mechanism of the photic entrainment is still largely unknown in insects and our goal is to understand the mechanism. We investigated the mechanism using the cricket Gryllus bimaculatus. Molecular and behavioral experiments revealed that it includes two separate pathways: one resets the clock by delayed light-off and the other resets the clock by light exposure in darkness. The former includes Pdp1 as the first responder to delayed light-off which is followed by upregulation of Clock, then of period and timeless (tim). In this pathway, tim plays an important role because its knocking-down by RNAi mediated gene silencing often prevented resynchronization of locomotor rhythm to 6 h delayed light-dark cycle. The latter mechanism includes c-fos and two cryptochrome genes (cry1 and cry2). Light exposure upregulated the c-fos mRNA levels within 60 min at both early subjective night (CT12) and late subjective night (CT20), while no significant changes were observed when light was given at the mid subjective day. RNAi of c-fos gene significantly decelerated resynchronization to both 6 h advanced and delayed light-dark cycles. Although single RNAi of cry1 or cry2 rather accelerated the resynchronization, double RNAi of cry1 and cry2 often prevented the resynchronization. No significant changes were induced by light exposure in cry1 and cry2 mRNA levels. Thus, post-transcriptional modification may be involved in the c-fos/cry pathway. Based on these results the entrainment mechanism of the cricket circadian clock will be discussed.

The first insights into the Colorado Potato Beetle (Leptinotarsa decemlineata Say) circadian rhythm

Authors: Toprak Umut[1], Foerster Charlotte[2], Cedden Doga[1], Senthilan Pingkalai[3], [1]Ankara University, Molecular Entomology Lab., Faculty of Agriculture, Dept. of Plant Protection Ankara, Turkey, [2]Biocenter - University of Würzburg, Germany, [3]Julius-Maximilians Universitity of Würzburg, Department of Neurobiology and Genetics, Germany

Abstract: It has been unambiguously established over the past decades that almost all of the animals investigated thus far contain endogenous clocks that help them to adapt to the Earth's punctual daily cycle. They accomplish this task by tracking the time using intricate protein feedback loops and then giving output to the organism which ensures the correct timing of complex behaviors such as mating, foraging, molting, and sleeping. Colorado potato beetle (Leptinotarsa decemlineata Say) which is a serious pest of the plants in the Solanaceae family that can devour entire potato fields if left uncontrolled, exhibits an explicit photosensitive response when it comes to the diapause induction which might indicate the existence of a robust circadian clock in this beetle. We were interested in this insect's putative circadian clock and the hypothetical correlation between this clock and diapause behavior as the literature on this topic is still hazy. Clock genes have been studied extensively using the Drosophila melanogaster as a study model. In this study, the mRNA levels of major clock gene homologs isolated from the brains of adult beetles that were reared either under short(light/dark 8h:16h) or long day(light/dark 16h:8h) conditions were evaluated using Rt-qPCR technique at different Zeitgeber times throughout the day. In order to complement the Q-pcr data, we also studied the daily activity pattern of the beetle by monitoring them under different light/dark cycles. Lastly, we tried to locate the neurons that might be implicated in the circadian rhythm of this beetle by staining Diuretic hormone 31 and another neuropeptide, Allatostatin-C, which might be playing a role in the diapause induction.

Evolution of parasitism in Calliphoridae

Authors: Torres Tatiana T[2], Cardoso Gisele A[2], Faria Gustavo A[1], Karunaratne Inoka[3], Thyssen Patricia J[1] and Tharindu B Bambaradeniya Y[3], [2]Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, Brazil, [1]Department of Animal Biology, Institute f Biology, State University of Campinas, Brazil, [3]Faculty of Science, Department of Zoology, University of Peradeniya, Kandy, Sri Lanka

Parasites are attractive models for the study of the evolution of the parasitic habit, and the molecular mechanisms underlying adaptive changes. The Calliphoridae family, for example, is a good candidate for such a study. In this family of flies, different species have been recorded feeding on: living tissues of a vertebrate host; living tissues of an invertebrate host; decomposing matter; and blood. Considering the feeding habits of their larvae, califorids are classified in: saprophagous species, which feed on decomposing tissue; facultative parasites, which feed on decaying organic matter, or infest necrotic or living tissues of vertebrates; and obligate parasites, which feed only on the living tissues of their hosts. We combined three dimensions of information to try and understand the origins of the parasitic habit in this family of flies: (1) phylogenetic, mapping the transitions of habits that occurred in history of the family; (2) phenotypic, quantifying the index of preference for different food sources, and (3) genetic, comparing patterns of gene expression among different species. |The stochastic character mapping in the phylogeny of the family, revealed the most likely ancestral habit as saprophagy. Obligate parasitism and facultative parasitism evolved later, independently. Two-choice essays with females allowed the precise classification of the species regarding their feeding habits. Essays with larvae showed that both, saprophagous and facultative parasites, feed on decaying flesh and fresh meat. On the other hand, C. hominivorax, an obligate parasite, showed an aversive behaviour to decaying meat. These results led to the hypothesis that parasitism arose from a shift in the attraction of the female to new oviposition sites, followed by the specialisation of the parasitic larvae. The search for the genes involved in the specific feeding habits was done with a comparative gene expression analysis of RNA-seq data from six Calliphoridae species. We found 230 potential candidate genes for future research. In addition, we found that both, regulatory and coding regions, have predominantly undergone the action of purifying selection.

Subtle subterfuge: Parasite manipulation of underlying phenotypic plasticity in social insect hosts

Authors: Toth Amy, Iowa State University, United States

Abstract: Parasite and pathogen manipulation of host phenotypes is a dramatic phenomenon, often leading to aberrant, unusual, or even novel host behavior. However, in other cases host manipulation may take a subtler form, resulting in shifts in normal host phenotypes in a direction that benefits the parasite or pathogen. Here, I discuss two cases from social insects, a group widely known for possessing high levels of phenotypic plasticity. The first study suggests strepsipteran endoparasites can alter the social caste of their paper wasp hosts, leading would-be workers to show gene expression patterns that are more queen-like. The second study suggests viruses can alter social behavior in honey bee hosts, allowing infected bees to more easily be accepted into foreign colonies. Both of these examples illustrate cases in which alterations of host social plasticity may result in potential advantages in transmission for the parasite or pathogen. I suggest host manipulation via alterations of underlying phenotypic plasticity may be a common and under-appreciated phenomenon in the study of host-pathogen interactions.

How temperature affects the outcomes of protective aphid-bacterium mutualisms?

Authors: Tougeron Kévin[2], Iltis Corentin[1], Thierry Hance[1], [1]UCLouvain, [2]Université catholique de Louvain Earth and Life Institute, Belgium

Abstract: Many research efforts are being invested with the aim to identify the ecological and evolutionary drivers of insect-symbiont mutualisms in a rapidly changing world. Among these drivers are temperature fluctuations, which shape the cost-benefit fitness balance of hosting certain symbiont species or genotypes and their spread within insect populations. To provide a synthetical view on this topic, we first propose a meta-analysis to quantify the impacts of microbial symbionts on the phenotype of their insect hosts in different thermal contexts (benign or stressful heat conditions). We found that fitness traits (survival, development, morphology, reproduction, and defense against natural enemies) are unevenly protected from acute heat stress by the symbionts (or that hosting a symbiont may or may not be advantageous under heat stress, depending on the trait studied). We distinguish three groups of traits: those that are strongly enhanced by symbionts but poorly affected by temperature (defensive traits), those whose expression is strongly dependent on symbionts and temperature in an interactive manner (development and reproduction), and those that are negatively affected by symbionts independently of temperature (morphology, survival). From this literature survey, it appeared that the fitness impacts of heat-protective symbionts on their hosts have usually been examined under constant temperatures or acute heat pulse, whereas these interacting organisms experience more complex fluctuating temperatures in nature. Empirically, we then examined the joint effects of mean temperature and thermal variability (diurnal thermal range) on the tripartite interaction between an aphid host, its obligate bacterial symbiont, and a facultative heat-protective bacterium. We highlight complex trait-environment relationships that could help drawing a more integrative and nuanced picture about the eco-evolutionary trajectories of insect-symbiont partnerships in the era of climate change.

Loss of winter diapause expression in aphid parasitoids from mild winter climates

Authors: Tougeron Kévin[3], van Baaren Joan[2], Le Lann Cécile[2] and Brodeur Jacques[1], [1]Department of Biological Sciences, University of Montreal, Canada, [2]UMR-CNRS 6553 ECOBIO, Univ Rennes 1, France, [3]Université catholique de Louvain Earth and Life Institute, Belgium

Abstract: Temperature is both a selective pressure and a modulator of the diapause expression in insects from temperate regions. Thus, with climate warming, an alteration of the response to seasonal changes is expected, either through genetic adaptations to novel climatic conditions or phenotypic plasticity. We compared the capacity of four parasitoid species to enter winter diapause under nine different photoperiod and temperature conditions in the laboratory. Our results suggest rapid shifts over the last three decades in the overwintering strategies of aphid parasitoids in Western France, probably due to climate warming. Species that have very recently (last 10 years) invaded winter trophic networks in this region show a low proportion of winter diapause. Parasitoids not entering diapause but developing under short day-lengths had increased developmental time and higher weight than non-diapausing parasitoids compared to those developing under long day-length, at a similar temperature. Responses to novel day-length conditions may thus affect phenological adaptations in a changing climate. Our results overall imply that diapause can be replaced by active adult overwintering, with potential consequences for life-histories, species interactions (host-exploitation throughout winter, increased competition), insect community composition, and natural pest control. In cereal fields of Western France, we report that the host-parasitoid community structure and composition that were stable and prevailed before 2011 have recently shifted toward a more diversified community, with the presence of two new braconid parasitoid species, a few hyperparasitoid species and one aphid species. Modifications in minimal winter temperatures and frequency of frost events across the winter partially explain observed community changes.

Museomics of ground beetles using HyRAD-X exome capture

Authors: Toussaint Emmanuel[1], Munoz Ramirez Carlos[3], GAUTHIER Jeremy[2], Bilat Julia[1], Blanc Mickael[2] and Alvarez Nadir[1], [1]Natural History Museum of Geneva, Switzerland, [2]Switzerland, [3]Universidad Católica de la Santísima Concepción, Chile

Abstract: Museomics is a comparatively recent field allowing the inclusion of Museum-preserved specimens into molecular studies often using a combination of phylogenomics and high-throughput sequencing. Such studies are revolutionary because they permit, for instance, the placement of extinct species in a phylogenetic framework using an unprecedented amount of data. In this study, we investigate the performance of a new phylogenomic method in generating a robust evolutionary tree allowing to place a presumably extinct endemic species from Saint Helena island. Within Carabinae (ca. 1500 species), four tribes are recognized, the flightless Holarctic Cychrini (four genera, ca. 230 species), the flightless South American Ceroglossini (one genus, ca. 10 species), the flightless Pamborini (two genera, ca. 20 species), and the mostly flightless Carabini (two genera, ca. 1100 species). An additional genus comprising the unique species Haplothorax burchelli remains enigmatic because the placement of this Saint Helena endemic is highly uncertain. Using Hy-RAD-X, a recently developed exome capture method, we aim to generate genomic data for representatives of all tribes and most genera within Carabinae to place Museum specimens of Haplothorax in a phylogenomic framework. The phylogenetic implications as well as methodological aspects of this approach will be detailed in this presentation along with perspectives of development in the field of Museomics and in the study of ground beetle evolution.

Belowground battles in Brassicaceae. Molecular mechanisms of optimal glucosinolate allocation in roots under herbivore attack

Authors: Touw Axel[2], Sontowski Rebekka[3], Tsunoda Tomonori[1], Uthe Henriette[2] and van Dam Nicole[3], [1]Faculty of Biotechnology, Department of Bioscience, Fukui Prefectural University, [2]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, [3]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany

Abstract: Optimal defense theory (ODT) predicts that organs with highest value to plant fitness and highest vulnerability to herbivores should have highest levels of chemical defenses. Until recently, ODT was mostly tested for defense allocation over aboveground plant organs. We extended ODT to roots by studying constitutive and herbivore-induced defense allocation patterns over taproots, lateral roots and fine roots of glucosinolate (GSL)-containing plant species. We found that taproots contained highest overall levels of constitutive GSLs, followed by lateral roots and fine roots. In line with these findings, the generalist beetle Amphimallon solstitiale preferred feeding on fine roots, whereas larvae of the specialist Delia radicum (cabbage root fly) preferred feeding on taproots. Herbivory always induced strongest GSL increases in the taproot, independent of which root class was damaged. This induction coincided with upregulation of biosynthesis and transporter genes in taproot tissues, but not in fine roots. Since GSL levels in fine roots or aboveground organs did not decrease, we hypothesize that GSL transporters mainly help to retain GSLs in the taproot during root-herbivory. Future research will include structurally related defense compounds, in particular phytoalexins such as brassinins, which will be related to herbivore feeding patterns and risk of infection by soil-borne pathogens.

The role of cryoprotectants in insect freeze tolerance: lessons from crickets, butterflies, and other animals

Authors: Toxopeus Jantina, St. Francis Xavier University, Canada, United States

Abstract: Many terrestrial insects encounter temperatures low and sustained enough to freeze their body fluids. Remarkably, some temperate and polar insects are freeze-tolerant, surviving conversion of as much as 82 % of their body water into internal ice. However, although insect freeze tolerance was first described almost 300 years ago, we have a limited understanding of the mechanisms underlying this cold tolerance strategy. Many freeze-tolerant insects accumulate low molecular weight cryoprotectants (e.g. amino acids, polyols, sugars) prior to winter. However, many of these molecules are not unique to freeze tolerance (e.g. are accumulated by insects that survive low temperatures but not freezing), and no cryoprotectant (or group of cryoprotectants) is accumulated by all freeze-tolerant insects. Here, I discuss studies on a variety of cryoprotectants in three freeze-tolerant species: the spring field cricket Gryllus veletis, the small cabbage white butterfly Pieris rapae, and the great grig Cyphoderris monstrosa. Using a combination of metabolomics and targeted assays, I show that these insects accumulate moderate concentrations (< 100 mM in the hemolymph) of low molecular weight cryoprotectants in response to a range of treatments, including acclimation to typical autumn-like conditions, prolonged supercooling, and freezing. Through laboratory manipulations, I demonstrate that even small increases (c. 20 mM) increases in hemolymph cryoprotectant concentrations can improve freeze tolerance of G. veletis, likely through non-colligative mechanisms. I discuss whether plasticity in cryoprotectant composition is important for surviving freezing, and how these results inform our understanding of the mechanisms underlying insect freeze tolerance.

The incompatible insect technique: elimination of isolated Aedes aegypti populations is possible and why evaluations of field interventions should focus on the vector itself

Authors: Trewin Brendan[1], Pagendam Daniel[1], Griffin Lachlan[2] and Beebe Nigel[3], [1]CSIRO, Australia, [2]Queensland University of Technology CSIRO, Australia, [3]University of Queensland CSIRO, Australia

Abstract: The incompatible insect technique (IIT) is a new method of control that can effectively suppress populations of medically important vectors such as mosquitoes. This novel technique applies the symbiotic bacteria Wolbachia as the sterilising agent and has recently been applied to successfully suppress populations of Aedes aegypti and Aedes albopictus. Here we show results on how it may be possible for IIT to suppress an Aedes aegypti beyond detection from an isolated urban area in north Queensland, Australia. During the experiment over three million Wolbachia infected Aedes aegypti males were released into three treatment landscapes of 200+ houses, while three control areas with similar characteristics were also monitored. During the 20 week experiment the adult population was suppressed by over 80% across the three treatment areas. However, during subsequent monitoring over the next season, we observed one productive treatment area that did not yield adults until well into the summer, suggesting the standing egg bank had been depleted and the endemic population had been suppressed below detection.

Although randomized control trials (RCT) are the gold standard in evaluating field studies, their size, complexity and costs delay or prevent the implementation of potentially life-saving tools. Alternative and potentially simpler methods are required if we are to efficiently fund novel vector control interventions within human communities. Furthermore, epidemiological endpoints are important when mosquitoes are still present in treatment areas, as is the case when Wolbachia is used as a virus blocking mechanism, however, it may not be optimal to design RCTs when mosquito populations can be removed entirely. With assistance from next generation modelling and genomic surveillance approaches, it will be possible to design interventions that focus entirely on the vector itself. Direct measurements of the mosquito population are cost effective, while modern technologies such as biosensors or LAMP assays have the potential to directly measure viral prevalence within these populations. Given the evidence available for the power of IIT, an epidemiological endpoint of local disease elimination is certainly possible. This will be particularly important as we enter the fourth great era of vector control - the era of area-wide rear-and-release strategies.

SciComics! Biology and Entomology education through comics

Authors: Tribull Carly, Farmingdale State College (State University of New York), United States

Abstract: Comics often bring to mind images of overly muscled superheroes and stories of villains cavorting around with world-ending weapons. However, this is an incredibly limited view of what comics can accomplish and their ever-growing role as tools for science communication! This presentation will provide a justification for why comics should be used in science communication and entomology education - namely for their motivating qualities, ability to bridge difficult concepts through a combination of art and writing, and concept comprehension driven by the reader's personal pace. Along with a growing popularity in the production of biology and entomology comics, there have been a number of studies examining STEM comic successes in primary and secondary science education and as a tool for scientific communication. These studies, along with a survey of the comics themselves, will be discussed in order to encourage symposium participants' adoption of these materials in SciComm work. Additionally, Biology Comics (www.biologycomics.com), an Open Educational Resource that translates the standard introductory biology textbook into a freely accessible webcomic for college students, will be discussed. As many entomology professors also teach general biology at their institutes, Biology Comics can be used as a novel teaching tool, especially for reluctant students. For two semesters, Biology Comics and a traditional biology textbook have been used in a controlled study at Farmingdale State College (SUNY). Preliminary results covering introductory topics like the characteristics of life and atomic properties show that there is no significant difference in learning assessment performance, but a significant difference in attitude towards the material: As with other science comic studies, students receiving the comic reported a more positive attitude towards course materials. Finally, a new project specifically geared at General Entomology students will be presented: A comic guide to insect collecting and collection building as a way of reducing common student mistakes in introductory entomology courses.

A century of phytoplasma-host association records: possible implications for overlooked phytoplasmas in natural habitats

Authors: Trivellone Valeria[1] and Dietrich Christopher[1], [1]Illinois Natural History Survey, Prairie Research Institute, University of Illinois at Urbana-Champaign, United States

Abstract: Phytoplasmas are a diverse lineage of uncultured bacteria strictly associated with the phloem of vascular plants and internal organs of hemipteran insects. Because phytoplasmas often cause severe diseases of economically important plants, study of their diversity and host (vector and plant) ranges has focused almost entirely on agroecosystems. Earlier studies reported that non-crop plants and insect vectors not associated with cultivated plants may serve as inoculum sources that enable phytoplasmas to persist locally through alternative transmission routes. However, despite these efforts, new outbreaks involving previously known or new strains continue to occur regularly. Routes of transmission may involve bridge-vectors and a wider range of plant hosts in natural habitats interspersed with other habitat types. A few studies attempted to detect possible sources of inoculum in specific plants in forests and grasslands that surround crops to estimate the risk of emerging diseases. However, the broader ecological and evolutionary context remains poorly investigated, and available data may suffer from sampling bias; e.g., failure to systematically screen for phytoplasmas and potential vectors in the wild. Insect species that are restricted to natural habitats should be compared with known vectors in terms of their functional traits to detect alternative routes of transmission and bridge-vectors. Network analysis of a global Hemiptera-Phytoplasma-Plant associations database showed that plant- and vector-phytoplasma associations are significantly modular and nested, suggesting stability of communities and increase in numbers of coexisting species associated with lower competition. However, the nested pattern might become non-nested if further plant and/or insect hosts are discovered for one or more phytoplasmas in natural habitats. To examine whether observed patterns might be altered by including data from natural habitats of understudied areas we carried out a pilot study analysing 215 specimens representing 8 tribes of leafhoppers. The specimens were previously collected during several field expeditions to 3 biogeographic regions worldwide. Six specimens of Deltocephalinae tested positive. Among them, 4 species (Leofa dispar, Pravistylus exquadratus, Acharis n. sp., Mayawa n. sp.) belong to genera never reported as phytoplasma vectors and none are normally associated with crops. The sequenced phytoplasmas are related to the 16SrXI phytoplasma group. Another undescribed species of Macrostelini from Australia tested positive for a phytoplasma closely related to the 16SrII-E phytoplasma group. Macrosteles sordidipennis from Kyrgyzstan was infected by a phytoplasma belonging to the 16SrI group; the only phytoplasma group reported previously from Kyrgyzstan belongs to 16SrXII. A better understanding of phytoplasma-associated plant diseases can be achieved by documenting phytoplasma-host associations in natural habitats and screening of potential vectors.

Drivers of true fruit fly (Diptera: Tephritidae) invasions

Authors: Trombik Jiří[1] and Liebhold Andrew [2], [1]Czech University of Life Sciences Prague, Czech Republic, [2]USDA Forest Service

Abstract: Given the high costs associated with fruit fly (Tephritidae) invasions, there is a need to better understand and predict the risks of future invasions. We assembled a global database of historical Tephritidae invasions with the objective to identify the biological and socioeconomic drivers that explain these invasions.

We used various published sources and online databases to assemble a database documenting the occurrence (presence/absence) and status (native/non-native) of individual species for each country in the world. Values of several socio-economic and environmental variables were also assembled and considered as explanatory variables. A generalized linear mixed-effects model framework was used to evaluate the utility of these variables for predicting the country-level occurrence of each species outside of its native range.

A total 44 species were identified as having been accidentally introduced in the world. The number of invasions has rapidly increased since the 1950s. Climatic similarity between native and invaded countries, gross domestic product of the invaded country and distance from the native range are significant predictors of tephritid invasions.

Chinmo is the Larval Member of the Molecular Trinity that Directs Drosophila Metamorphosis

Authors: Truman James[1] and Riddiford Lynn, University of Washington, United States

Abstract: The molecular control of insect metamorphosis from larva to pupa to adult has long been a mystery. The Broad and E93 transcription factors, which can modify chromatin domains, are known to direct the production of the pupa and the adult respectively. We now show that chinmo, a gene related to broad, is essential for the repression of these metamorphic genes. Chinmo is strongly expressed during the formation and growth of the larva and its removal results in the precocious expression of broad and E93 in the first stage larva, causing a shift from larval to premetamorphic functions. This trinity of Chinmo, Broad and E93 regulatory factors are mutually inhibitory. The interaction of this network with regulatory hormones likely ensures the orderly progression through the insect life history.

Genetic structure of stable fly, Stomoxys calcitrans (Diptera: Muscidae): a reference for the quarantine management in Taiwan

Authors: Tsai Cheng-Lung[1], Lu Chia-Ning[1], Yeh Wen-Bin[1] and Tu Wu-Chun[1], [1]Department of Entomology, National Chung Hsing University, Taiwan

Abstract: The stable fly, Stomoxys calcitrans (Diptera: Musidae, Stomoxyini), a blood sucking species with global distribution, is considered as an economically important medical and veterinary pest. It could cause enormous economic loss of cattle by reducing the milk production, losing body weight, and arresting development. Thus, the clarification of genetic structure of S. calcitrans is crucial for its management. To understand the genetic composition of S. calcitrans in Taiwan, two mitochondrial genes, cytochrome oxidase subunit I (COI) and 16S rDNA, and one nuclear internal transcribed spacer 2 (ITS2) of 110 specimens representing 13 localities are analyzed. Moreover, a total of 593 COI sequences from 22 countries including six zoogeographical regions are further applied to resolve the possible origin of Taiwanese population. Phylogenetic inference based on COI gene revealed that a specific genetic lineage was found in Ethiopian Region. For the two Taiwanese lineages, i.e. one from Palearctic/Oriental Regions and the other is associated with the worldwide populations including Nearctic, Neotropical, and Palearctic Regions, might have represented two possible origins for S. calcitrans in Taiwan. A calibration estimation showed that these two lineages were diverged in the middle Pleistocene approximately 0.35 million years ago. However, intermingled ITS2 sequences of the two lineages and low differentiation index (FST) informed that gene flow might have occurred frequently either in Taiwan or among countries. The prevalence of livestock industries and human activities might be the possible explanation for current differentiated pattern. Genetic exchange among populations which belong to the two lineages may change the genetic composition and cause severe impact on livestock industries. Thus, the prevention of foreign populations exhibiting peculiar genetic composition such as Ethiopian Region is important for quarantine task in the world.

Where do apple pollinators live? Understanding nest-site selection of solitary ground-nesting bees in UK orchards

Authors: Tsiolis Konstantinos[4], Fountain Michelle[2], Potts Simon[4], Garratt Michae [4], Tilston Emma[3], Burman Joseph[1] and Rintoul Naomi[1], [1]Canterbury Christ Church University, [2]NIAB EMR, [3]NIAB EMR / Enviresearch Ltd, [4]University of Reading, United Kingdom

Abstract: In the UK, ground nesting bees are the most economically important pollinators of apple crops. However, very little is known about where they nest in orchard landscapes and what their specific habitat preferences are. This presentation will provide novel insights into the habitat preferences of ground-nesting andrenid bees and show how simple management interventions can be used enhance populations several ground-nesting bee species. The findings shared here will underpin more general implications for the sustainable management of a largely overlooked pollinating taxa which have a central role in food security.

The molecular basis of chemosensory receptors in the olive fruit fly, Bactrocera oleae (Diptera: Tephritidae) and manipulation of the reproductive behavior by Orco knock down

Authors: Tsoumani Konstantina[1], Spanomitrou Antonia[4], Gaitanidis Alexandros[3], Skoulakis Efthimios[3], Mathiopoulos Kostas D[1], Belavilas-Trovas Alexandros[1] and Gregoriou Maria-Eleni[2], [1]Department of Biochemistry and Biotechnology University of Thessaly, Greece, [2]Department of Biochemistry and Biotechnology, University of Thessaly, Larissa, Greece, [3]Division of Neuroscience, Biomedical Sciences Research Centre “Alexander Fleming”, [4]University of Thessaly, Greece

Abstract: The olfactory and gustatory systems of an animal possess central roles in several physiological functions, including food localization and choice, mate search or oviposition selection. For insect pests, the ability to manipulate such systems could lead to efficient and species-specific reduction of the insect’s reproductive capacity and damaging ability. To achieve this, however, a profound knowledge and understanding of these systems is a prerequisite. The olive fruit fly, Bactrocera oleae, (Diptera: Tephritidae) is the most destructive pest of the olive tree worldwide. Its specialist larvae feed exclusively on the olive pulp, causing significant production losses and olive fruit impoverishment.

In this study we have identified and explored the families of receptor proteins involved in olfactory perception and taste, including odorant receptors (ORs), ionotropic receptors (IRs) and carbon dioxide-sensing gustatory receptors (GRs) on the B. oleae genome. Gene structure analysis was performed, functional and structural characteristics were determined, and basic phylogenetic clustering were examined. Further phylogenetic comparisons with relative species were also performed based on sequence similarities to uncover the diversity among these receptors and determine divergence or species-specific expansions that might have facilitated the adaptation of the olive fruit fly to its unique plant-host.

We further knocked down the expression of the olfactory co-receptor Orco by RNAi through dsRNA injections. Disruption of Orco expression impaired the copulation and reduced oviposition rates. These results demonstrated that both pre- and/or post- mating processes were affected. The observed changes in the reproductive behavior of B. oleae render Orco a critical key gene that could be considered a potential pest control target for the development of environmentally friendly insect management strategies of the olive fruit fly populations.

We are currently deorphanizing odorant receptors which would allow the design of novel and species-specific pest control agents and set new perspectives towards the improvement of the olive fruit fly control approaches.

Effects of photoperiod on the induction of dormancy in Glaucias subpunctatus (Walker) (Heteroptera: Pentatomidae)

Authors: Tsunashima Ayaka[2] and Itoyama Kyo, Meiji University, Japan, [2]Meiji University, Japan

Abstract: The fruit-piercing stink bug, Glaucias subpunctatus (Walker) (Heteroptera: Pentatomidae) is a pest attacking various fruits in the southwestern area of Japan. In recent years, it has been reported that their distribution has gradually expanded northward and the incidence has tended to increase in some areas. The basis of forecasting is the ecological characteristics of target pests, especially understanding of phenology and life cycle is necessary. Although the expansion of the damage of this bug in the future is concerned as mentioned above, its ecological characteristics remain largely unknown. For overwintering, G. subpunctatus adults are known to enter reproductive dormancy in temperate climates. However, G. subpunctatus winter dormancy has not been explicitly evaluated to determine whether it is a diapause or a quiescence state. Therefore, the objective of this study was to clarify effects of photoperiod on the induction of dormancy in G. subpunctatus. We investigated the critical day length and the sensitive developmental stage to photoperiod of G. subpunctatus under laboratory conditions. In the first experiment, bugs were reared from eggs to adults under five photoperiodic conditions ranging from 12L12D to 16L8D at 25 ± 1°C. In the second experiment, egg masses were first placed in long-day condition (16L8D) and then moved to short-day condition (12L12D) at each developmental stages. The results of these experiments suggested that the critical day length was between 13 h and 14 h and that it may not had a clear sensitive developmental stage to photoperiod. We discuss the expansion of the distribution of southern insects based on the dormancy characteristics of G. subpunctatus.

Evolution of the repeat-rich Y chromosomes in mosquitoes: new insights from long read sequencing

Authors: Tu Zhijian, Department of Biochemistry, Virginia Tech Blacksburg, VA, United States

Abstract: Sex is critical to the survival and evolution of sexually reproducing organisms including mosquitoes. Only female mosquitoes feed on blood and transmit disease-causing parasites or viruses while the non-biting males are harmless in this context. A dominant male-determining factor (M factor) from the Y chromosome or the male-determining locus (M locus) provides the master switch that initiates male development in mosquitoes. Such male-determining factors have been recently discovered in a few mosquito species (Hall et al., 2015; Criscione et al., 2016; Krzywinska et al., 2016). However, Y chromosomes are still very difficult to study due to their repeat-rich characteristics (Hall et al., 2016). Y chromosomes were entirely missed when the 16 Anopheles mosquito genomes were published in 2015 (Neafsey et al., 2015). Towards the goals of improving our understanding of the function and evolution of the Y chromosomes in mosquitoes, we have recently sequenced the males from divergent Anopheles species using Oxford Nanopore and other platforms. In this presentation, I will describe the various methods that we are developing to facilitate Y gene discovery and Y chromosome assembly. These methods include coverage-based informatic analysis, targeted assembly, and sequencing of hybrid F1 progeny followed by trio binning. Experimental verification of these genomic analyses will also be presented. I will also present comparative genomics analysis of the distribution and turnover of M-locus and Y-chromosome genes among divergent mosquito species. The potential for using “Y”-linked “maleness” genes to control mosquito-borne infectious diseases will be also discussed.

Demographic comparison of rearing media (or meridic diets) for the predator Orius strigicollis (Hemiptera: Anthocoridae)

Authors: Tuan Shu-Jen[1], Chen Yeuh-Wen[1] and Hung Yi-Ting[1], [1]Department of Entomology, National Chung Hsing University, Taiwan

Abstract: The generalist predator Orius strigicollis (Poppius) (Hemiptera: Anthocoridae) is commonly used in the biological control of minute pests because of its high searching ability and high predation rate. In order to develop a cost-effective mass-rearing medium for O. strigicollis, thirteen meridic diet recipes with different proportions of egg yolk, honey, sucrose, beef extract, yeast extract, milk powder and eggs of Ephestia kuehniella Zeller were evaluated for rearing nymphs and adults of O. strigicollis at 25°C by comparing life table data derived from using the age-stage, two-sex life table. Two artificial diets (10YE+5MK and LarvaC, composed mainly of yeast extract, milk, and egg yolk) proved to be outstanding replacements for the two most commonly used natural prey species (i.e., deutonymphs of the mite Tetranychus urticae Koch and 3-day-old nymphs of Rhopalosiphum padi (L.) aphids). The fecundities of O. strigicollis reared on the two meridic diets were at least 20% above those reared on mites and >7+ times higher than when reared on aphids. Our results demonstrated that the artificial medium 10YE+5MK appears to be an effective substitute for mass rearing of O. strigicollis. The sustainable mass-rearing system was constructed based on life table analysis and rearing costs.

Halyomorpha halys (Hemiptera: Pentatomidae), a new alternative host for egg parasitoid Ooencyrtus kuvanae (Hymenoptera: Encyrtidae)

Authors: Tunca Hilal[1], Venard Marine[2], Tabone Elisabeth[3], Cosic Benjamin[3], Colombel Etty-Ambre[3] and Capelli Mathilde[2], [1]Ankara University, Agriculture Faculty, Dept. of Plant protection, Turkey, [2]Biocontrol laboratory, Experimental Unit of Entomology and Mediterranean Forest from the National Institute of Agronomic Research (INRA), France, [3]INRA, UEFM site Villa Thuret, Laboratoire BioContrôle, France

Abstract: One of the most important egg parasitoids of gypsy moth is Ooencyrtus kuvanae (Howard) (Hymenoptera: Encyrtidae). We have already developed a method to rear O. kuvanae on the laboratory host Philosamia ricini (Danovan) (Lepidoptera: Saturniidae). In order to try to optimize the rearing of this oophagous parasitoid, we used an alternative host Halyomorpha halys (Heteroptera: Pentatomidae). However, H. halys has rapidly become an important pest of several crops in many countries. The study was conducted at the INRAE-PACA Mediterranean Forest and Entomology Unit, Laboratory of Biological Control located in Antibes, France. The laboratory conditions were 25 ± 1°C, 60 ± 5% RH and a photoperiod of 18:6 hr L:D. Halyomorpha halys was successfully reared in our biocontrol laboratory . The reproduction of the parasitoid is arrhenotoky and O. kuvane was reared for more than ten generations on the eggs of H. halys. O. kuvanae could be a candidate for future research as a biological control agent against an important pest, H. halys, and that insect may be a suitable alternative host for rearing of egg parasitoid O kuvanae.

Development of a biocontrol program against the Box Tree Moth Cydalima perspectalis (Walker, 1859)

Authors: Tunca Hilal[1], Venard Marine[2], Tabone Elisabeth[3], Colombel Etty-Ambre[3], Thévenet Jean[2] and Capelli Mathilde[2], [1]Ankara University, Agriculture Faculty, Dept. of Plant protection, Turkey, [2]Biocontrol laboratory, Experimental Unit of Entomology and Mediterranean Forest from the National Institute of Agronomic Research (INRA), France, [3]INRA, UEFM site Villa Thuret, Laboratoire BioContrôle, France, [6]INRA, UEFM site Villa Thuret, Laboratoire BioContrôle, France

Abstract: The Box Tree Moth (BTM), Cydalima perspectalis (Walker, 1859), an invasive East-Asian pest, spread out in Europe and in France since 2008. These Lepidopteran Moths caused serious damages by defoliating box trees. Strategies have to be setting up in order to limit pest impact. In preparation for this control, the aim of the researchers is to evaluate and to develop biocontrol solutions. In Antibes, INRA laboratory goal is to improve moth biology knowledge and to develop a biocontrol strategy with parasites and predators.

With this aim in mind, the team has reared BTM in laboratory (25°C, 75%RH, 16L: 8D). Since 2017, collections were made in situ on damaged box trees of different stages of BTM in order to find indigenous parasites, between May and September, on several sites of five French departments. Then, parasites have to be tested on BTM eggs or larvae to evaluate their efficiency to control the pest. The most present parasite in BTM pupae is a Diptera from the Tachinid family. Some Hymenoptera have also been found.

Other collections of arthropods were made at the same moment in situ by the beating method on box trees with presence of BTM. This study aimed to spot which species consume the moth. For this, the predators' digestive tract content is analyzed to see if there is BTM DNA in it. The most represented orders are the Hemiptera, Hymenoptera (Formicidae), Aranea, Acari, Psocoptera and Colembolla. Each individual is dissected and analyzed by PCR method. The results of this study will be presented.

Box Tree protection against BTM could be effective only by combining several environmental friendly strategies.

Where is the northern limit of the potential range of citrus longhorn beetle (Anoplophora chinensis) in EU based on climate suitability?

Authors: Tuomola Juha[1] and Hannunen Salla[1], [1]Finnish Food Authority

Abstract: To support appropriate use of biosecurity resources, we studied which climatic factors limit the potential range of citrus longhorn beetle (CLB, Anoplophora chinensis) in the EU, and where the northern limit of its potential range is based on these factors. First, we built a Climex model for CLB in Europe. Sensitivity and uncertainty analyses revealed that two Climex parameters, 1) the lower development threshold temperature and 2) the annual growing degree days (GDD) required for establishment, determine the northern limit of the potential range of CLB in the EU. Next, we delineated the northern limit using the annual GDD required for establishment and assuming that CLB needs to complete its life cycle in 3 years. The analysis was done using JRC-MARS climate data for 2000-2020. Our results suggest that the northern limit goes through southern Denmark and Sweden, and south-eastern Estonia. This suggests that CLB surveys, required in the EU legislation, are unlikely to be necessary in areas north from this limit. However, our assessment does not consider the uncertainty in the GDD that CLB needs to complete its life cycle, and that the pest might be able to establish also if its life cycle takes longer than 3 years.

Whiteflies can fool their host plants, but not their parasitoids

Authors: Turlings Ted[1], Zhang Peng-Jun[2] and Yu Xiao-Ping[2], [1]FARCE Laboratory, Institute of Biology, University of Neuchâtel, Switzerland, [2]Zhejiang Provincial Key Laboratory of Biometrology and Inspection & Quarantine, College of Life Sciences, China Jiliang University, Hangzhou, China

Abstract: Herbivorous insects and plant pathogens commonly trigger chemical defenses in plants, which include the release of specific blends of volatiles. Herbivore-induced plant volatiles play a key role in the host searching behavior of many parasitoids. An additional role of inducible volatiles is to alert undamaged plant tissues of incoming attack. When neighboring plants perceive these alert signals, they also prepare themselves in a way that they respond faster and stronger when they themselves are assaulted by the same attacker. This is referred to as defense priming and in the case of chewing insects, priming involves the plant hormone jasmonic acid (JA), but in the case of an attack by a biotrophic pathogen, the enhanced defense responses are usually dependent on salicylic acid (SA).

Phloem-feeding whiteflies appear to manipulate their host plants by making them mobilize SA defense, at the cost of JA-dependent defenses, which makes the plants more suitable for whitefly development. We found that this apparent manipulation extends to the volatiles that are induced by whitefly feeding, which also are similar to volatiles to volatiles released after pathogen attack, for instance the monoterpene ß-myrcene. As a result, neighboring plants that perceive whitefly-induced volatiles wrongly prepare themselves for pathogen attack and become more vulnerable to insects and thus more suitable for the next generation of whiteflies. The specialist parasitoid Encarsia Formosa, which parasutize whitefly nymphs is not misled by this signal manipulation. In greenhouse trials, with various Arabidopsis mutants we showed that the parasitoid uses SA-triggered emission of ß-myrcene for host location. Hence, unlike host plants, the parasitoid is not fooled by the whitefly's signal trickery.

Sequestration of cucurbitacins by Diabrotica balteata larvae and their protective role against natural enemies

Authors: Turlings Ted[2], Bruno Pamela[6], Benrey Betty[7], Besomi Gaia[7], Spescha Anna[1], Jaccard Charlyne[7], CM Arce Carla[4], Glauser Gaëtan[5] and A. R. Machado Ricardo[3], [1]ETH Zürich, Switzerland, [2]FARCE Laboratory, Institute of Biology, University of Neuchâtel, Switzerland, [3]Institute of Plant Sciences,University of Bern, Switzerland, [4]Laboratory of Fundamental and Applied Research in Chemical Ecology, University of Neuchâtel, Switzerland, [5]Neuchâtel Platform of Analytical Chemistry, University of Neuchâtel, Neuchâtel, Switzerland, [6]University of Göttingen, Germany, [7]University of Neuchatel, Switzerland

Abstract: Cucurbitaceae plants produce cucurbitacins, bitter triterpenoids, to protect themselves against various insects and pathogens. Adult banded cucumber beetles (Diabrotica balteata), a common pest of maize and cucurbits, sequester cucurbitacins, presumably as a defensive mechanism against their natural enemies, which might reduce the efficacy of biological control agents. Whether the larvae also sequester and are protected by cucurbitacins is unclear. We profiled cucurbitacin levels in four varieties of cucumber, Cucumis sativus, and in larvae fed on these varieties. Then, we evaluated larval growth and resistance against common biocontrol organisms including insect predators, entomopathogenic nematodes, fungi and bacteria. We found considerable qualitative and quantitative differences in the cucurbitacin levels of the four cucumber varieties. While two varieties were fully impaired in their production, the other two accumulated high levels of cucurbitacins. We also observed that D. balteata larvae sequester and metabolize cucurbitacins, and although the larvae fed extensively on both belowground and aboveground tissues, the sequestered cucurbitacins were mainly derived from belowground tissues. Cucurbitacins had no detrimental effects on larval performance and, surprisingly, did not provide protection against any of the natural enemies evaluated. Our results show that D. balteata larvae can indeed sequester and transform cucurbitacins, but sequestered cucurbitacins do not impact the biocontrol potential of common natural enemies used in biocontrol. Hence, this plant trait should be conserved in plant breeding programs, as it will provide protection against plant pathogens and generalist insects.

Development of microsatellite markers for the endangered butterfly, Luehdorfia japonica (Lepidoptera: Papilionidae)

Authors: Ueda Shouhei[3], Nakasuji Chiaki[1], Nakahama Naoyuki[2], Hirai Norio[3] and Ishii Minoru[1], [1]Graduate School of Life and Environmental Science, Osaka Prefecture University, [2]Institute of Natural and Environmental Sciences, University of Hyogo, [3]Osaka Metropolitan University, Japan

Abstract: An endangered butterfly species, Luehdorfia japonica Leech, 1889 (Lepidoptera, Papilionidae), is endemically distributed in the central and western parts of Honshu, Japan. This species inhabits the Satoyama landscape neighboring deciduous forests populated with an evergreen wild ginger species of the genus Asarum sect. Heterotropa on which the larvae feed. However, habitat loss due to the development and the abandonment of regular forest management has caused L. japonica to be classified as “Vulnerable” in the latest version of the Japanese Red List. Here, we developed 17 microsatellite loci for L. japonica based on de novo genome sequence data and observed that 16 loci exhibited polymorphisms in four populations of L. japonica among Osaka, Hyogo, Fukui and Yamanashi in central Honshu, Japan. A principal coordinate analysis based on this genetic information revealed genetic differentiation among geographic populations of L. japonica. The genetic diversity of the Osaka population was found to be lower than that of other populations, suggesting that this population should quickly be targeted for conservation. The developed markers can potentially be used to evaluate temporal changes in genetic diversity in a local population of the species over a period of more than 30 years.

Phylogenetic revision of Bedbugs and their relatives, with an emphasis on their evolution of Traumatic insemination

Authors: Ugwuanyi Ifeoma[1], Cassis Gerasimos[1] and Tatarnic Nikolai[2], [1]University of New South Wales, [2]Western Australian Museum, Australia

Abstract: Bedbugs and their relatives are members of the heteropteran superfamily Cimicoidea that comprise economically important species, ranging from predaceous biocontrol agents to ectoparasitic blood feeders. Beyond this lifestyle diversity, cimicoids are best known for practising traumatic insemination (TI), where the male pierces the abdomen of the female and ejaculate directly into the haemoceol. To better understand the evolution of these sexual characters, a robust phylogeny of the superfamily is needed. Currently, knowledge of the relationships within the Cimicoidea is in its infancy, with several alternative phylogenetic hypotheses. Here we present the first combined morphological and molecular analyses that includes data from next-generation sequencing (NGS), targeting ultra-conserved elements (UCEs) and flanking regions. We aim to optimise TI character evolution in a phylogenetic context to determine their origins and diversification.

Molecular Identification of Insect Vectors for Zoonotic Diseases from District Faisalabad, Pakistan

Authors: Ulabdin Zain[5], Arshad Muhammad[3], Asim Mirza Aizaz[3], Khan Rao Sohail Ahmad[1], Hussain Fiaz[2], Hira Hasooba [3] and Abbas Saqi Kosar[2], [1]CABB, University of Agriculture, Faisalabad, Pakistan, [2]College of Agriculture, BZU Sub Campus Bahadur, Pakistan, [3]Department of Entomology, University of Agriculture, Faisalabad, Pakistan

Abstract: Correct identification of insect vector species is a very critical step toward the implementation of successful Integrated vector management programs. Based on molecular data the most important insect species involved as vectors for Zoonotic diseases in Pakistan were identified. The precise and accurate identification of such a type of organism is only possible through molecular-based techniques. Morphological species identification in insects at any life stage is very challenging, therefore, DNA barcoding was used as a tool for rapid and accurate species identification in a wide variety of taxa across the globe and parallel studies revealed that DNA barcoding data can be effectively used in resolving taxonomic ambiguities, detection of cryptic diversity, invasion biology, description of new species, etc. A comprehensive survey was carried out for the collection of insects (both adult and immature stages) in district Faisalabad, Pakistan and their DNA was extracted and mitochondrial cytochrome oxidase subunit 1 barcode sequences were used for molecular identification of immature and adult life stages. This preliminary research work opens new frontiers for developing sustainable insect vector management programs for saving the lives of mankind from fatal diseases.

Effect of Different Temperature regimes on the Development, Survival and parasitization rate of Parasitoids of Phyllocnistis citrella (Gracillariidae; Lepidoptera)

Authors: Ullah Muhammad Irfan[1], Afzal Muhammad[1], Abdullah Asad[1], Riaz Maryam[1], Arshad Muhammad[1], Altaf Nimra[1], Ali Shaukat[2] and Muhammad Ali Zahid Syed[1], [1]Department of Entomology, University of Sargodha; China-Pak Joint Research Centre for Citrus Diseases and Insect Pest Management, University of Sargo, [2]China-Pak Joint Research Centre for Citrus Diseases and Insect Pest Management, University of Sargodha, Sargodha; Department of Entomology, South China Agricultural University

Abstract: We studied the effect of three different temperatures on the development and survival of parasitoids, Citrostichus phyllocnistoides and Cirrospilus ingenuus (Eulophidae; Hymenoptera). The temperature regimes were set to 20, 25 and 30? with 65±2% relative humidity (R.H.) and 16h: 8h (L:D) photoperiod. The longevity of C. phyllocnistoides and C. ingenuus was highest (14.20 and 16.80 days respectively) at 20 ? that gradually decreased with an increase in temperature. The minimum longevity was recorded at the highest temperature (30?) for both parasitoids. The pre-oviposition period was found higher in C. phyllocnistoides and C. ingenuus (2.20 and 2.4 days respectively) at lower temperatures (20?) while this period became shorter by increasing the temperature levels. The oviposition period of both parasitoids was delayed at 20?. The post-oviposition period of C. phyllocnistoides was very short (< 1.5 days) at all the temperatures, as most of the parasitoids died shortly after the final egg-laying. On the other hand, the post-oviposition period of C. ingenuus was prolonged (2.8 days) at 20? while it became shorter at higher temperatures. Maximum fecundity of C. phyllocnistoides (17 eggs) and C. ingenuus (17.6 eggs) was recorded at 25? while minimum fecundity was recoded at 30? (10.60 and 9.4 eggs respectively). The parasitization rate of C. phyllocnistoides and C. ingenuus was highest (42.50 and 29.33% respectively) at 25? while lowest parasitization was recorded at 20? in both parasitoids.

Using dead-end trap plants in the biological control of the spotted-wing drosophila (Drosophila suzukii)

Authors: Ulmer Romain[3], Couty Aude[1], Gabola Fausta[3], Chabrerie Olivier[1] and Eslin Patrice[2], [1]CNRS / University Picardie Jules Verne, France, [2]FRE CNRS 3498 EDYSAN, Université de Picardie Jules Verne, France, [3]University of Picardy Jules Verne CNRS, France

Abstract: Drosophila suzukii, the spotted-wing Drosophila, is an exotic fruit fly from Asia that has recently invaded Europe as well as North and South America in the past decade. Being highly polyphagous, this fly has quickly become one of the major pests of small fleshy fruit crops such as strawberry, raspberry, blueberry, cherry, blackberry, etc. Females lay their eggs in the flesh of ripening fruits, causing them to rot prematurely. The economic damages to fruit production systems are considerable and increasing since few satisfactory means of controlling its populations are available. Indeed, chemicals are not entirely satisfying and their use tends to be reduced in agricultural practices because of their impact on the environment. Biological control technics have been intensively studied but are currently not effective enough to be used in the field. The use so called “dead-end trap plants” has recently shown promising results in the control of various pests. These plants attract the pest and but do not allow the development of its offspring. Previous studies (Poyet et al 2015) allowed us to identify several potential dead-end trap plant species, among which the firethorn Pyracantha coccinea. In our controlled laboratory conditions, the number of eggs laid by D. suzukii in strawberries was reduced by more than 50% in the presence of fruits of P. coccinea compared to a control where the strawberries were the only fruits available. The number of eggs laid by the pest was up to 2 times higher in the fruits of P. coccinea than in the strawberries, even when the distance between the two plant species increased up to 30 cm. Despite this preference shown by the female D. suzukii, the egg-to-adult survival rate of their offspring in P. coccinea was null, while it was approximately 80% in strawberries. A study of the survival of the larvae in the fruits of P. coccinea showed a significant developmental delay and a death happening before the pupation in the 10 days following the egg-laying. Our work shows the promising potential of P. coccinea as a dead-end trap plant that could be used as an alternative and complementary way to reduce the population of D. suzukii. Borders of P. coccinea could be planted around strawberries field or potted individuals could be positioned within greenhouses to provide an efficient IPM tool against D. suzukii that could be used in combination with chemicals or biological control agents such as predatory arthropods.

Population dynamics of Drosophila suzukii throughout the year in urban environment

Authors: Ulmer Romain[1], Couty Aude[1], Samama Alice[1], Spicher Fabien[1], Pavis Justine[1], Lamotte Nicolas[1], Chabrerie Olivier[1] and Eslin Patrice[2], [1]CNRS / University Picardie Jules Verne, France, [2]FRE CNRS 3498 EDYSAN, Université de Picardie Jules Verne, France

Abstract: The spotted-wing drosophila (SWD) Drosophila suzukii is a polyphagous pest of ripening small fleshy fruit (eg. Strawberries, cherries). It is native to Asia and appeared in Europe in 2008. It is the only Drosophila that causes agricultural damage in Europe and it is considered one of the main biological invasions of the 21st century. For instance, in the French region of Dordogne in 2013, D. suzukii caused the loss of 600 tons of strawberries, estimated to a total of 1.8 M€ and a shortfall of 9000 €/ha in cherry crops (Sicoloy 2016).
Despite much research on this insect, its ecology and the temporality of its life cycle (in natural and urban ecosystems) are still little known. In particular, its use of different urban habitats (eg. parks, river banks, buildings) which are warmer than rural habitats, could help it survive during winter time. The aim of this study was to investigate the ecological niche of SWD in urban areas and gather information on the local, landscape and climatic factors that could explain the variation of this invasive insect populations over time. Fly traps were randomly set in the town of Amiens (Haut-de-France, France) from September 2018 to August 2019 in five different habitat types (town centre, shops and houses, river bank, park, wood). For each trapping session, 75 traps were left for one week, fly species were then determined and biometrics measures were taken on SWD flies (winter/summer morph, size and number of eggs in ovaries). Overall, the two most important species were D. suzukii and D. subobscura, but their relative importance (co-occurrence) varies with the seasons. SWD could favor the presence of decaying fruit available for D. subobscura (facilitation). SWD was more common in the less urbanized sites of the city (wood, park and river). Our study gives new insights into the life cycle of SWD in an urban environment. The summer morph, still present in October, would give way to the winter morph in November / December, which would go dormant up to February and leave its place in May to a new summer generation. Wooded areas close to/in towns could be a winter refuge habitat for winter morphs of SWD which could in the spring move to other urban habitats from where it could then colonize agricultural places where small fruits are produced.

Behavioural plasticity in response to the social environment in a clonal ant

Authors: Ulrich Yuko[3], K. Tokita Chris[1], E. Tarnita Corina[1], Kronauer Daniel[2], Saragosti Jonathan[2], Kawakatsu Mari[1] and Chandra Vikram[2], [1]Princeton University, United States, [2]The Rockefeller University, United States, [3]University of Lausanne, The Rockefeller University, Switzerland

Abstract: The composition of social groups can have wide-ranging and profound effects on their behaviour and function by influencing, for example, collective decision-making, foraging efficiency, or mating systems. In social insects, the demographic, genetic, and morphological composition of colonies is expected to affect their behaviour and, in turn, fitness. However, measuring the effect of each of these factors is challenging because they inherently co-vary in many systems. To avoid this issue, we analysed the relationship between group composition, division of labour (DOL), and fitness in the clonal raider ant Ooceraea biroi, a queenless, parthenogenetic species that affords maximum control over several important aspects of colony composition. We manipulated each of these factors independently by setting up experimental colonies with controlled variation in genetic composition (single vs. mixed genotypes), demographic composition (single vs. mixed age cohorts), and morphological composition (mixing workers with low and high ovariole numbers). Automated behavioural tracking of individual ants in 120 colonies allowed us to quantify DOL, and we also measured several fitness components. We find clear effects of age, genotype and morphology on individual behaviour, as well as unexpected effects of mixing individuals of different ages, genotypes, or morphology on colony-level behaviour.

By manipulating the main aspects of colony composition that are proposed to affect DOL and measuring their effects on colony performance, we provide a thorough picture of the causes and consequences of DOL in an emergent model system for social behaviour.

Eco-evolutionary dynamics in a real tangled bank: from genomics to field monitoring

Authors: Utsumi Shunsuke, Field Science Center for Northern Biosphere, Hokkaido University, Japan

Abstract: Researchers have acknowledged that ecological and evolutionary time-scales can converge. Genetic variation and rapid evolution within populations can shape interspecific interactions, which in turn influence population demography, community dynamics, and ecosystem function. The ecological changes also feed back on evolutionary changes in space and time. With a growing number of experiments showing the interactions between ecology and evolution, the field of eco-evolutionary dynamics is developing rapidly.

Most experimental studies have elucidated impacts of phenotypic variation for ecological processes and patterns in highly standardized, simplified environments, using a common gardening design. However, toward an understanding of eco-evolutionary dynamics in nature, we should take into account that species co-occur in diverse communities in real ecosystems. In other words, the challenge remains to transfer the insights from standardized and simplified experiments to natural conditions, where multiple species directly and indirectly interact with each other and the dynamics are far more complex than those studied previously.

Recent advances in genomics and analytical tools can help to overcome difficulties to identify eco-evolutionary dynamics in complex nature. In this study, we took various approaches to elucidate eco-evolutionary dynamics in a community context in a “real tangled bank”, linking genomics approach, large-scale experiment in semi-natural settings, and spatio-temporal monitoring in the field.

The willow leaf beetle (Plagiodera versicolora), which occurs around a riparian “bank”, has a genetic variation in a foraging trait: specialist- and generalist-type. The specialist-type exclusively feeds on new leaves of willows, while the generalist-type displays non-preferential feeding for leaf-age types. We performed restriction-site associated DNA sequencing and genome-wide association study to develop SNP markers for tracking rapid, ongoing evolution in the foraging trait of the non-model organism. Next, we conducted a large-scale experiment in semi-natural settings to investigate real-time eco-evolutionary feedback between evolution and ecological community in the field. We covered a whole mature tree, inoculating leaf beetle populations. We initially manipulated leaf beetle populations in inoculation as follows: 1) specialist-type, 2) generalist-type, and 3) mixed treatment, based on the frequency of the specific marker allele. Effects of initial beetle treatment significantly reverberated in subsequent community dynamics of insects.

And then we detected rapid evolution of the foraging trait of the leaf beetle in response to the changes in arthropod community structure. Finally, we identified rapid, ongoing evolution of the leaf beetle foraging trait on “a real tangled bank”. Multi-spatial convergent cross mapping provides evidence of the rapid, ongoing evolution in a community context.

Sequence of (mtCO1) gene of Chilo partellus Swinhoe (Lepidoptera: pyralidae) by using molecular tools in Lahore Pakistan

Authors: Usman Haider Muhammad[2] and Ahmad Shahbaz[1], [1]Institute of Agricultural Sciences University of the Punjab, Pakistan, [2]PhD Scholar in University of the Punjab Lahore, Pakistan

Abstract: Taxon barcodes using DNA sequencing is the only aspect for an endurable recognition of any biological systems. Molecular studies of an organism are very endorsing in specie diagnosis. Taxonomic knowledge is breaking up due to over reliance on conventional knowledge of identification. Mitochondrial gene Cytochrome C oxidase I (COI) is considered as a major constituent in global identifications of all biological systems. CO1 profiles are constructed temporarily to examine taxa and raw samples of that specific order and phylum. Authentic profiles for CO1 are developed on specie level that will guide and gave knowledge about that specie comprehensively. This knowledge lead towards a good, dependable, gainful analysis of close featured species and one sample is good enough to overcome the recognition crises. Chilo partellus Swinhoe (Lepidoptera: Pyralidae) is one of the major biotic constraints of maize and sorghum production areas of Pakistan. Present study reveals the molecular identification of the mitochondrial cytochrome oxidase (CO1) gene of C. partellus. DNA sequencing and specie identification by using the molecular tools were also parameters of this study. Samples were collected from maize fields in Lahore Pakistan. Molecular characterization of C. partellus was done by using mitochondrial cytochrome oxidase 1 (mtco1) genomic region. The DNA was extracted after performing PCR and sequencing was analyzed from Advance Bioscience International, Pakistan. The 717bp product was obtained, DNA sequencing results identified the specie on molecular level and it showed 100% homology with C. partellus specie present in Kolhapur India upon BLAST search. This homology is also shown with the help of phylogenetic relationship by using different softwares. This is the first report of molecular identification of any lapidopteran in Pakistan. This study reveals the gainful knowledge about molecular advancement. This study also concluded the vitality of CO1 gene is detectable in identification of insect species at molecular level.

Adoption of native parasitoid Habrobracon hebetor Say (Hymenoptera: Braconidae) in biological control of invasive coconut insect pest, Opisina arenosella Walker (Lepidoptera: Oecophoridae)

Authors: Uraichuen Uraichuen[2] and Chomphukhiao Namphueng[1], [1]Department of Entomology, Faculty of Agriculture, Kasetsart University, Kamphaeng Saen Campus, Nakhon Phathom, Thailand, National Biological Control Research, [2]Department of Entomology, Faculty of Agriculture, Kasetsart University, Kamphaeng Saen Campus, Nakhon Phathom, Thailand

Abstract: The coconut black-headed caterpillar (BHC), Opisina arenosella Walker is an invasive insect pest of coconut damaging Thai coconut industry in recent years. Biological control program was then chosen by using 2 BHC's braconid parasitoids including a native parasitoid, Habrobracon hebetor Say and an imported parasitoid, Goniozus nephantidis (Muesebeck). Comparative study on fecundity and parasitization ability of H. hebetor and G. nephantidis on two lepidopterous insect hosts was conducted revealing that the native parasitoid specie could obviously better adopt to its hosts than the imported one either on BHC or rice moth, Corcyra cephalonica Stainton larvae. H. hebetor could be then mass produced on BHC or C. cephalonica depending on availability of its insect hosts. Reproductive study on strains of H. hebetor; Japanese (JPN) and Thai strains proved that the reciprocal crosses of JPN x TOA1 and JPN x TCC4 produced only male's offspring. Economic impact of biological control program of BHC by utilizing H. hebetor in coconut field was finally performed by decreasing of the insect pests from the second months after parasitoid releasing with profit given of 550 USD/acres/year. This indicated that biological control using H. hebetor as biological agent can be well adopted to management program on BHC for sustainable coconut production.

Eliciting plant defenses by exposition to HIPV's: a new sustainable approach to manage agricultural pests

Authors: Urbaneja Alberto[4], Pérez-Hedo Meritxell[4], Granell Antonio[2], Gallego Carolina[3], Pons Clara[2], Luis Rambla Jose[2], Alonso-Valiente Miquel[3], Vacas Sandra[1] and Navarro-Llopis Vicente[1], [1]Centro de Ecología Química Agrícola – Instituto Agroforestal del Mediterráneo. Universitat Politècnica de València. Valencia, Spain, [2]Instituto de Biología Molecular y Celular de Plantas. (IBMCP), Consejo Superior de Investigaciones. Científicas, Universidad Politécnica de Valencia, [3]Instituto Valenciano de Investigaciones Agrarias (IVIA). Centro de Protección Vegetal y Biotecnología, (IVIA), Valencia, Spain, [4]Instituto Valenciano de Investigaciones Agrarias, Spain

Abstract: Plants communicate with each other using specific volatiles to warn of attacks and thus are able to activate defense mechanisms that make them more robust against external aggressions. In this research we have activated defense responses of tomato plants by exposing them to two synthetic Herbivore Induced Plant Volatiles (HIPVs). Tomato plants induced by both volatiles turned out to be less attractive to key tomato pests such as Bemisia tabaci and Tuta absoluta and more attractive to natural enemies. Using transcriptomics we were able to identify how exposure to both HIPVs modified the transcripts genes related with defenses. Under semi-field conditions one of the HIVP-mediated activation reduced the subsequent attack of Tetranychus urticae and T. absoluta to less than half. With this knowledge, dispensers to release this HIPV under field conditions were designed and calibrated. The use of these selected dispensers in commercial tomato greenhouses maintained defensively activated plants throughout the crop and reduced the impact of T. absoluta by almost 60%. Our work demonstrates for the first time under real field conditions how the use of HIPVs as elicitors of plant defenses can be successfully integrated as a new biorational and sustainable tool within pest management programs.

Zoophytophagous predator-induced defences restrict infection of plant viruses

Authors: Urbaneja Alberto[2], Pérez-Hedo Meritxell[2], Rubio Luis[1] and Bouagga Sarra[1], [1]Instituto Valenciano de Investigaciones Agrarias (IVIA). Centro de Protección Vegetal y Biotecnología, (IVIA), Valencia, Spain, [2]Instituto Valenciano de Investigaciones Agrarias, Spain

Abstract: Biological control in protected crops has been widely adopted to manage pests. In recent years, the incidence of plant viruses has decreased in crops using zoophytophagous predators. Because these predators induce plant defences with their plant feeding behaviour, we hypothesized these responses could be, in part, responsible for the decrease in virus occurrence. Here, we investigated whether the plant defence activated by two mirid predators can limit infection and multiplication of the Tomato spotted wilt virus (TSWV) in sweet pepper. Our results revealed TSWV accumulation in mirid-punctured plants to be significantly lower when compared to intact plants; this is probably associated with the upregulation of the JA pathway triggered by mirid phytophagy. We demonstrate for the first time how cultivated plants can be more robust against viral diseases when their induced defence system is activated. This novel approach can offer new control strategies for the management of plant diseases.

Contrasting invasion history in two ambrosia beetles of the Xylosandrus genus

Authors: Urvois Teddy[3], Perrier Charles[6], Roques Alain[4], Sauné Laure[6], Courtin Claudine[4], Kajimura Hisashi[2], Hulcr Jiri[5], Cognato Anthony I.[1], Auger-Rozenberg Marie-Anne[4] and Kerdelhué Carole[6], [1]Department of Entomology, Michigan State University, East Lansing, MI, USA, [2]Graduate School of Bioagricultural Sciences, Nagoya University, Nagoya, Japan, [3]INRAE URZF & UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France, [4]INRAE, URZF, Orleans, France, [5]School of Forest, Fisheries, and Geomatics Sciences, University of Florida, United States, [6]UMR CBGP, INRAE, CIRAD, IRD, Institut Agro, Univ. Montpellier, France

Abstract: Xylosandrus compactus and X. crassiusculus are two ambrosia beetles originating from Southeastern Asia and invasive on several continents.

We used COI and RAD sequencing to disentangle the origin(s) of their non-native populations on the invaded continents and analyse their genetic diversity and pathways within each invaded region.

Our results showed that, despite their ecological and phylogenetic proximity, the two species have different genetic patterns and invasion histories.

For X. compactus, both markers suggested three colonisation events. First, Africa was invaded more than a century ago from Southeastern Asia. Then, the American-Pacific region and Europe were invaded independently from close sources in or near Shanghai, in the mid-XXth century and at the beginning of the XXIst century, respectively.

X. crassiusculus' invasion was more complex. Both markers support the existence of two divergent clusters, mostly allopatric. Cluster 1 independently invaded the Pacific islands and Africa. Cluster 2 invaded the Americas, Europe, Africa and Oceania, with several independent introductions from multiple sources, including through bridgehead scenarios followed by intra-continental dispersion. Hawaii, Papua New-Guinea and South Africa were invaded by both clusters. Our study raises the question of the taxonomical status of the two clusters identified within X. crassiusculus.

OakeyLIFE: Ecological restoration of forest steppe habitats in Hungary benefitting Cucujus cinnaberinus, Bolbelasmus unicornis, Aphydryas maturna (LIFE16 NAT/HU/000599)

Authors: Vadász Csaba[3], Hajagos Gabriella[3], Andrési Dániel[2], Erdélyi Arnold[1], Hadi Barnabás, Peregovits László[4] and Győri Gabriella[1], [1]Hungarian University of Agriculture and Life Sciences, [2]KEFAG Kiskunsági Erdészeti és Faipari Zrt., [3]Kiskunság National Park, [4]PARS Kft.

Abstract: The Peszér-forest Natura2000 site is assigned to the conservation of several species of Community Interest. In the OAKEYLIFE project we aimed to present fine-scale distribution maps; carry out reliable estimations on populations size; determine the local conservation status and restore habitats of particular insect species (Cucujus cinnaberinus, Bolbelasmus unicornis, Aphydryas maturna).

C. cinnaberinus was present in all available/suitable microhabitats, even at isolated forest patches containing little amount of suitable deadwood (both native and alien tree species). By the preparation of dead wood, extent of habitats colonized was increased.

With high effort sampling, B. unicornis was proved to be present at most of those foreststeppic habitats and grasslands, which were never ploughed and were characterized by the mosaics of dry and mesic grassy patches. By increasing the extent of that kind of patches, we targeted to expand the habitats of this species. Within 1-2 years, colonization of restored habitats was not confirmed.

Aiming to increase the extent of habitats of A. maturna, ecological corridors were established, where spawning plants (especially Ligustrum vulgare) secondary host plants and nectar-providing plants were planted/seeded. The occupancy rate of restored habitats was 100%. Also, A. maturna was reintroduced to isolated forests unreachable by spontaneous colonization.

Smart Pheromone Traps for Automatic Remote Monitoring of Genus Osmoderma (Coleoptera, Scarabaeidae, Trichiinae) Species

Authors: Valainis Uldis[2], Mizers Valdis[1], Balalaikins Maksims[1], Balalaikins Maksims[1], Soldans Arvis[1], Bastytė-Cseh Dalia[2], Gintaras Alvidas[2] and Augutis Danas[2], [1]Institute of Life Sciences and Technology, Daugavpils University, Latvia, [2]Lithuanian Fund Fund for Nature, Vilnius, Lithuania

Abstract: The present study shows a novel solution to remote Osmoderma species monitoring using smart traps based on the Linux controller and equipped with an IR night vision video camera and moisture/temperature sensor. The traps take photos at regular intervals and record environmental parameters. All data is stored SD cards and via GPRS modem send to the remote repository (database) accessible through the web. Traps work from the autonomous power source and can work approximately 2 months without charging. Smart traps can be used in any area covered by the GPRS or 3G network. The hermit beetles imago activity is highly dependent on environmental conditions; therefore, monitoring of these species with standard pheromone traps often has situations when the placed pheromone traps are empty for a long period, and in such case, time, as well as financial resources, are unnecessarily spent for surveying. Environmental sensors that are integrated into the traps allows obtaining data on the ecological characteristics of Osmoderma species that are essential for the implementation of conservation measures.

The research was supported by European Union LIFE+ programme project "Ecological network for Osmoderma eremita and other species dependent on veteran trees" LIFE16 NAT/LT/000701.

Herbivory in novel native oak stands: Disentangling the effects of landscape context, leaf defences and tree genotype

Authors: Valdés-Correcher Elena[1], Galmán Andrea[2], Hampe Arndt[1], Bourdin Audrey[1], Castagneyrol Bastien[3], C. González-Martínez Santiago[1] and Moreira Xoaquín[2], [1]BIOGECO, INRA, Univ. Bordeaux, Cestas, France, [2]Biological Mission of Galicia (MBG-CSIC), Pontevedra, Galicia, Spain, [3]Inra, France

Abstract: Forests form a network of patches of woody habitats that can alter the relationships among organisms such as plant-herbivore interactions. However, little is known about how insect herbivores are affected by individual tree scale factors such as functional traits and tree genotype, and by environmental factors such as forest size and isolation. We investigated the effect of landscape and individual scale factors on herbivory in 15 newly established oak forest stands in rural landscapes of SW France. These stands differed in size and isolation. To that aim, we investigated if the patterns of herbivory could be explained by individual scale factors as the leaf defences, tree growth, tree genotype and/or by factors acting at larger scale as stand size and isolation. We found that both scales influenced insect herbivory. The herbivory increases with stand size, but decreases in fast growing trees and trees with high leaf phenolic compounds. The landscape-scale driver stand size has the largest overall effect. Tree genetipe sligly influenced herbivory and leaf defences. Stand isolation did not affect the herbivory. Our study shows that insect herbivory is driven by both landscape and individual tree scales. Overall, our results have important implication for the management of small isolated and expanding forest patches in complex landscapes.

The need for a New IPM, for the management and control of emerging Superpests, as those arthropods (insects and mites), rapidly adapting to Climate Change and Global Warming.

Authors: Valencia Pizo Edinson, University of Saskatchewan University of Lethbridge Ironhide NextGen Corporation, Canada

Abstract: Climate Change represents a major driving force, drastically affecting planet earth, but also many of the human activities and agriculture, is and will be one of the most affected. Several insect pests are exhibiting characteristics of adaptation to Climate Change, that will require a brand-new approach to Pest Management, for us to overcome this new mega-challenge. One of the aspects of Pest Control to be more directly impacted by Climate Change, will certainly be the duration of the Life Cycle of many arthropod pests, which in general trends to be shorter, even under the slightest increases of temperature. A gross estimation of this Adaptive Response of arthropod pests to the increase of temperature, can be that in general, per each degree Celsius augmented, the Life Cycle of many insect pests will be one day shorter. As a result and due to an accumulative response of a pest to Climate Change, the overall Life Cycle can be several days shorter during the crop season. In spite of the apparent severity of this situation, this happens to be only “the tip of the iceberg” of the problem related to Climate Change, due to the following consequences of a shorter life cycle: 1. A significant increase of the potential damage to the host crop, as a result of the higher number of generations of the pest. 2. A more rapid population dynamics of the adaptive pest, which poses more difficulties to achieve its control by biological and chemical insecticides. 3. A minor shortening of the Life Cycle of a host pest, will represent a major challenge for many of the Biological Control Agents and for the Natural Enemies of the pest, which depend on its life cycle and not always are able to adapt to Climate Change at the same pace that the pest does. 4. More generations of the pest per crop season, represent a higher risk of Resistance to insecticides. Due to this situation and maintaining IPM as the Central Paradigm of Pest Control, it is apparent that a New IPM approach, with some important adjustments, might be required for the management of the Global Superpests, as follows: 1. Early Detection of the pests. 2. Emphasis on Preventive Control measures. 3. Priority on Natural Pest Control already existing in the crops. 4. Emphasis on Native Natural Enemies and indigenous entomopathogen species. 5. Use of Bioinsecticides within special-favorable application windows and under specific Action Sub-Thresholds, taking advantage of their Sub-lethal Effects. 6. When necessary, only specific-selective chemical insecticides should be applied under an Action Threshold criteria. 7. Development of Co-formulated mixtures of Biological and Chemical insecticides exhibiting synergism at lower rates and with a longer efficacy and 8. Integration of Technologies for the New IPM, where the additive, synergistic and complementary effects between the technologies applied, will facilitate to achieve an efficient, cost-effective and competitive IPM, on the face of Climate Change globally.

Expressing the Cry10Aa Toxin of Bacillus thuringiensis in transgenic Coffea arabica L. plants: sustainable development for integrated management of the coffee berry borer.

Authors: Valencia-Lozano Eliana[1], Eugenio Ibarra-Rendon Jorge[1], Luis Cabrera Ponce Jose[1] and Angel Gomez-Lim Miguel[1], [1]Center for Research and Advanced Studies of the National Polytechnic Institute, Mexico

Abstract: This report presents an efficient protocol of the stable genetic transformation of coffee plants expressing the Cry10Aa protein of Bacillus thuringiensis. We used Embryogenic cell lines with a high potential of propagation, somatic embryo maturation, and germination. We evaluated Gene expression analysis of cytokinin signaling, homedomains, auxin responsive factor, and the master regulators of somatic embryogenesis genes involved in somatic embryo maturation. We introduced Plasmid pMDC85 containing the cry10Aa gene into a Typica cultivar of C. arabica L. by biobalistic transformation. With this, we achieved a transformation efficiency of 16.7% according to the number of embryogenic aggregates and developed transgenic lines. We proved stable transformation by hygromycin-resistant embryogenic lines, green fluorescent protein (GFP) expression, quantitative analyses of Cry10Aa by mass spectrometry, Western blot, ELISA, and Southern blot analyses. Cry10Aa showed variable expression levels in somatic embryos and the leaf tissue of transgenic plants, ranging from 76% to 90% of coverage of the protein by mass spectrometry and from 3.25 to 13.88 µg/g fresh tissue, with ELISA. qPCR-based 2-??Ct trials revealed high transcription levels of cry10Aa in somatic embryos and leaf tissue. This is the first report about the stable transformation and expression of the Cry10Aa protein in coffee plants with the potential for controlling the coffee berry borer.

Wolbachia in sympatric parasitoid cryptic species

Authors: Valerio Federica[1], Martel Cornelia, Stefanescu Constanti, van Nouhuys Saskya, Kankare Maaria and Duplouy Anne, [1]University of Helsinki

Abstract: Identifying the mechanisms supporting the reproductive isolation between sympatric species often remains challenging, as it may be induced by multiple factors other than geographical distance.

Endosymbiotic bacteria can lead to reproductive isolation between conspecific lineages due to the infection inducing either post-mating incompatibility or pre-mating avoidance. Wolbachia, one of the most common endosymbiotic bacteria of insects worldwide, manipulates its host reproductive system or other life-histories towards its benefit to spread in the host population. Based on this, Wolbachia-induced phenotypes can support partial to complete reproductive isolation between host lineages up to speciation.

The genus Cotesia (Hymenoptera, Braconidae) includes over 1000 species and even more cryptic species, making it one of the most diverse groups of social parasitoids. In North-eastern Spain, several species of Cotesia occur in sympatry and parasitize Melitaeini butterfly species. Previous phylogeographic studies have suggested that local resource partitioning, competitive exclusion, as well as host-specialization may each have contributed to species radiation within this unique Spanish parasitoid community. However, the mechanisms by which gene flow has been restricted remain unclear.

Here, we investigated the biogeography of Wolbachia across European populations of several Cotesia species, including the North-eastern Spanish region. We characterized the mitochondrial diversity associated with infected and uninfected specimens. Moreover, we screened for Wolbachia infection all publicly available Cotesia whole genome sequencing data to gain insights into Wolbachia strain diversity in this genus. Our results proposed that different strains of the symbiotic bacterium might be key-players in the reproductive isolation and radiation of these Cotesia cryptic species.

Towards mass-rearing of Nsenene (Ruspolia differens) in Uganda

Authors: Valtonen Anu[5], Malinga Geoffrey[2], Roininen Heikki[3], Sorjonen Jaana[3], Rutaro Karlmax[1], Nyeko Philip[4], Opoke Robert[2] and Lehtovaara Vilma[3], [1]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland; Department of Biochemistry and Sports Science, Makerere University, Uganda, [2]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland; Department of Biology, Gulu University, Uganda, [3]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland, [4]Department of Forestry, Biodiversity and Tourism, Makerere University, Kampala, Uganda, [5]University of Eastern Finland, Joensuu, Finland

Abstract: Ruspolia differens (Orthoptera: Tettigoniidae), Nsenene, is one of the most consumed insects in East Africa, with high nutritional and cultural value and high economic potential especially in the Lake Victoria region. Currently, they are harvested with powerful lights from the natural populations during the two annual swarming seasons. In order to prevent overexploitation of the natural populations, and to improve food and nutrition security in the region, methods allowing mass-rearing of this species are urgently needed. Mass-rearing could provide a sustainable and a more reliable way to produce valuable proteins and fatty acids for local communities in the future and could bring income to local farmers.

To achieve methods for mass-rearing, understanding on species' basic biology and ecology, optimal feeds, chemical composition, and optimal rearing conditions are essential. We aimed to shed light on these in our Academy of Finland -funded project (2015–2019) entitled "Developing mass rearing technology for the highly valued edible grasshopper, Ruspolia differens". This presentation summarizes the findings of our project.

We showed that it is possible to rear Nsenene successfully in laboratory for several consecutive generations, which means that mass-rearing in captivity is possible in controlled conditions. Nsenene can be reared from newly hatched nymphs to adult in relatively short time (49 d), on artificial diets, and in relatively high densities. The optimal rearing temperature is 28-30°C. Slightly lower temperatures, which slow down the development rate, can be used to synchronise the development of different batches of nymphs in mass-rearing conditions. With rearing densities =36 nymphs per liter, a survival rate of 60% can be expected up to 28 days. The weight of individuals can be modified with rearing duration, so that by rearing the insect up to a week after final moult, up to 50% increase in weight can be achieved. A promising egg-laying medium using folded plastic cloth was developed, enabling large-scale production of eggs in the future.

We found that Nsenene can develop and mature on highly variable feeds including both its natural host plants and artificial feeds. It benefits from diet mixing; more diversified diets result in shorter development time and greater adult fresh weight and female fecundity compared to the single diet or less diversified diets. Also feeds including by-product protein sources from food-industry can sustain its development – this information can be used in future to increase the sustainability of rearing efforts. Finally, the dietary fatty acids alter the content and composition of Nsenene fatty acids. This means that its nutritional value for human can be improved by adding a source of omega-3 fatty acids and proteins in its feeds. We emphasize that there is now enough information on the species' basic biology to start experimenting with mass-rearing of R. differens.

Evolution of life history traits in response to artificial selection for virulence and non virulence in a Drosophilaparasitoid, Asobara tabida

Authors: van Baaren Joan[4], Couty Aude[2], Moiroux Joffrey[1], Prevost Geneviève[3], Eslin Patrice[3] and Leroux Vincent[3], [1]Avignon University, France, [2]CNRS / University Picardie Jules Verne, France, [3]FRE CNRS 3498 EDYSAN, Université de Picardie Jules Verne, France, [4]UMR-CNRS 6553 ECOBIO, Univ Rennes 1, France

Abstract: Co-evolution of host–parasitoid interactions is determined by the costs of hostresistance, which received empirical evidence, and the costs of parasitoid virulence, whichhave been mostly hypothesized. Asobara tabida is a parasitoid, which mainly parasitizesDrosophila melanogaster and D. subobscura, the first species being able to resist tothe parasitoid development while the second species is not. To parasitize resistant hosts,including D. melanogaster, A. tabida develops sticky eggs, which prevent encapsulation,but this virulence mechanismmay be costly. Interindividual and interpopulation variation inthe proportion of sticky eggs respectively allowed us to (i) artificially select and comparelife-history traits of a virulent and a nonvirulent laboratorystrain, and (ii) compare avirulent and a nonvirulent field strain, to investigate the hypothetical costs of virulence.We observed strong differences between the 2 laboratory strains. The nonvirulent straininvested fewer resources in reproduction and walked less than the virulent one but livedlonger. Concerning the field strains, we observed that the nonvirulent strain had largerwings while the virulent one walked more and faster. All together, our results suggest thatvirulence may not always be costly, but rather that different life histories associated withdifferent levels of virulence may coexist at both intra-and interpopulation levels.

Global environmental change may benefit Conservation biological control in temperate-climate areas

Authors: van Baaren Joan[1], Damien Maxime[1], Tougeron Kevin[2], Roudine Sacha[1] and Le Lann Cécile[1], [1]UMR-CNRS 6553 ECOBIO, Univ Rennes 1, France, [2]University Picardie Jules Verne

Abstract: The increase of mean temperatures during winter caused by global warming in temperate climatic regions has induced change in organism phenology and may lead to interactions within and between trophic levels. In agro-ecosystems of the West part of France, aphids and their natural enemies are reproducing during the whole winter. These agro-ecosystems may benefit from a change in plant phenology, such as flowering plants often used in Conservation biological control programs. We investigated the consequences of flowering plants in winter to assess if they may constitute favourable habitats to biological control agents and increase their pressure on aphid pest populations in adjacent cereal crops. We hypothesised that (i) aphid parasitism would increase close to sown flowering cover rather than close to spontaneous grassy margins (SGM) by providing food resources or alternative hosts and (ii) that sown flowering strips would better promote ground predator activity than SGMs, by providing shelters with better micro-climatic conditions. Higher aphid parasitism has been observed close to flowering cultivated plants and the density of activity of ground predators was higher within sown flowering strips. The results suggested that the winter period should constitute the target period for conservation biological control programs under changing environmental conditions.

When additional floral resources fail to enhance aphid control by parasitoids: food web structure reveals increased intraguild competition and predation

Authors: van Baaren Joan[2], Le Lann Cécile[2], Jeavons Emma[3], Le Ralec Anne[1], [1]Institut Agro Rennes-Angers, [2]UMR-CNRS 6553 ECOBIO, Univ Rennes 1, France, [3]University of Rennes 1, UMR ECOBIO 6553, Rennes Agronomic service, Yves Rocher, France

Abstract: Understanding which factors affect ecological community structure is essential to predict resultant ecosystem functioning, but remains a key challenge. For instance, biological control of herbivores by predators and parasitoids is a major ecosystem function, but how it is impacted by community structure modifications remains poorly understood. While trophic theory predicts that increased plant diversity will enhance diversity and abundance of higher trophic levels and increase top down control on herbivores, field results are not often consistent with those predictions. Studying community-level foodwebs could enlight the mechanisms involved in resultant top down effect in multi-natural enemy systems. For instance, it can be expected that increased plant resource provision will increase negative interactions among natural enemies, such as intraguild competition and predation. In that case, top down effect on herbivores may be limited.

In Brittany, intercropping legume plants within cereal fields is a common agroecological practice which provides an interesting model to study the effect of addition of floral resources on cereal aphid-parasitoid-hyperparasitoid foodweb structure. Legume plants provide carbohydrate resources (here, Vicia faba extra-floral nectar) and alternative hosts (such as the pea aphid Acyrthosiphon pisum) which can be used by generalist parasitoids. We conducted a two-year field studycomparing aphid parasitism rate and foodweb structure in cereal monocultures and cereals intercropped with legumes (mixed crops). Generalist parasitoids are more enhanced by additional floral resources than specialists, which probably resulted in increased intraguild competition. Moreover, hyperparasitoids also benefited from the increase in floral resources and the parasitoid community change in mixed crops. The resulting parasitism rate was higher in monocultural crops at the end of the season compared to mixed crops, showing no benefit of additional floral resources on aphid control.

While increasing resource provision is generally assumed to enhance herbivore control, our study showed that it could in fact disrupt top down effect due to a modification of the foodweb structure and the increase of intraguild interactions. Such effects may depend on the studied system, thus enlighting the need to deepen our understanding of additional resources on four-level trophic foodwebs to improve biological control methods.

Are you searching for insects? Here is where to look! - The effect of land use intensity on insect biomass

Authors: van Dam Nicole[6], Svenningsen Cecilie[9], Bonn Aletta[4], Johannes Hansen Anders[2], P. T. Tøttrup Anders[7], Richter Anett[5], Fløjgaard Camilla[1], Eichenberg David[5], Bowler Diana[4], Heilmann-Clausen Jacob[3], Bladt Jesper[1], Colling Larsen Jonas[7], Menger Juliana[6], Bruhn Pedersen Lene[7], Ejrnæs Rasmus[1], R. Dunn Robert[8], Hecker Susanne[5], Guldberg Frøslev Tobias[2] and Grescho Volker[5], [1]Aarhus University, Department of Bioscience - Biodiversity and Conservation, Denmark, [2]Centre for GeoGenetics, GLOBE Institute, University of Copenhagen, Denmark, [3]Centre for Macroecology, Evolution and Climate, GLOBE institute, University of Copenhagen, Denmark, [4]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig Friedrich Schiller University Jena; Institute of Biodiversity Helmholtz Centre for Environmental Research (UFZ), [5]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig; Helmholtz Centre for Environmental Research (UFZ), Department of Ecosystem Service, [6]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany, [7]Natural History Museum of Denmark University of Copenhagen, Denmark, [8]Natural History Museum of Denmark, University of Copenhagen Department of Applied Ecology, North Carolina State University, United States, [9]Natural History Museum of Denmark, Denmark

Abstract: Insect abundance and diversity is declining across the globe. One major contributor to the decline is anthropogenic land use causing degradation of natural areas and essential insect habitats. There is currently a shortage of studies using a standardized sampling strategy across several land use categories, and hence the understanding of drivers that affect insect biomass distributions across multiple land use intensities remain unclear.

In this study, 177 citizen scientists sampled flying insects with rooftop mounted car nets on 278 routes in Denmark and Germany in June 2018. The 462 bulk insect samples were sorted in two size fractions and dry weight was used as a measure of total insect biomass. We incorporated land use categories as explanatory variables for variation in insect biomass, abundance and size structure using linear mixed-effect models lmer and lme (R packages lme4 and nlme). We included fine-scale land use metrics along a buffer zone of each route and accounted for sampling time, weather and spatial structure. Thus, we tested the hypothesis that insect biomass is lower along routes with increased land use intensity e.g. intensive agriculture or urban areas, and higher along heterogeneous and extensive land use types, e.g. forest. The same samples are currently processed with a DNA metabarcoding approach to obtain taxonomy data.

How to survive in the dark - Interactions of root flies with host plant defence compounds and their gut microbiome

Authors: van Dam Nicole[2], Sontowski Rebekka[2], Weinhold Alexander[2], Heintz-Buschart Anna[2] and G. Vassao Daniel[1], [1]Department of Biochemistry, Max Planck Institute for Chemical Ecology, Jena, Germany, [2]German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany

Abstract: Using a plant as a diet source is a major challenge for insects. Next to hard digestible particles, such as lignin, insects are often confronted with toxic plant defence compounds. The agricultural important crop family Brassicaceae evolved a defence system containing glucosinolates (GSLs) and their breakdown products the isothiocyanates (ITCs). Several insects have adapted to this defence system, such as the cabbage (Delia radicum) and turnip root fly (D. floralis). Both species are specialists and frequent pests on Brassicaceae roots. It is currently unknown how these larvae handle the Brassicaceae defence system. Our aim is to disentangle detoxification mechanisms of the GSL-ITC system in both belowground herbivores. We experimentally assess the effect of GLSs and ITCs on Delia performance. Second, we tested the breakdown of GSLs and ITCs in larvae using HPLC-UV and GC-MS. In addition, we compared gut microbial communities in both species using 16S barcoding and their role in detoxification processes. We found that ITC differently affected fly performance in both species. However, both larvae breakdown GSLs as well as ITCs. Although feeding the same, the gut microbial community differed in both species. Despite specialized on their host plant defence system, larvae suffer from defence compounds, even when they developed multiple breakdown pathways. Understanding the detoxification process of these pests is a first step toward the development of sustainable resistance.

The effects of low-dose exposure to Cry proteins on Fall armyworm and its practical implications for IRM in Africa

Authors: Van den Berg Johnnie[1], du Plessis Hannalene[1] and Papa Nini[1], [1]North-West University, South Africa

Abstract: The planting of Bt maize is limited to only a few countries in Africa. In a response to mitigate fall armyworm impact, this expected to increase in the near future. FAW rapidly evolves resistance to Cry toxins, which is exacerbated by exposure to low-dose events, such as those that will be deployed in Africa. We report on effects of low-dose exposure to Bt maize on life history parameters and flight ability of moths reared for eight generations on Bt/non-Bt maize. Larval survival on Cry1Ab and Cry1A.105 + Cry2Ab maize ranged between 16 and 95% over eight generations. F1-larval survival on two-toxin maize was 19% and 82% for the F7-generation. Larval and pupal periods were delayed on Bt maize, resulting in poor synchronization of moth emergence patterns between Bt and refuge plantings. Moth flight ability was reduced and only between 29 – 45% of moths reared on two-toxin maize was able to fly out of a 40 cm high cylinder, compared to 88% for the non-Bt treatment. Limited capacity to fly may limit random mating and contribute to selection pressure, reducing the effect of the high-dose / refuge strategy on smallholder fields where several other IRM challenges also exist.

Vector competence of Belgian Anopheles plumbeus and Culex pipiens mosquitoes for Japanese encephalitis virus

Authors: Van den Eynde Claudia[1], De Regge Nick[2], Sohier Charlotte[2] and Matthijs Severine, [1]Belgium, [2]Sciensano, Belgium

Abstract: Japanese encephalitis virus (JEV) is a mosquito-borne virus that is considered an emerging disease. It is therefore important to know if indigenous mosquitoes would be able to spread JEV upon introduction in a new area. Here we determined the vector competence of Belgian field-collected Anopheles plumbeus and Culex pipiens mosquitoes for JEV. Mosquitoes were orally exposed to an infectious blood meal containing $10^{6'39}$ TCID50/ml JEV (Nakayama strain), followed by a 14-day incubation period at 25°C. Infection and dissemination of JEV was investigated by detection of viral RNA by qRT-PCR in the abdomen and legs/wings/heads, respectively. In Culex pipiens, infection and dissemination rates of 34.7 and 21.3 % were found by qPCR while this was 13.8 and 13.8 % for Anopheles plumbeus. The majority of qPCR positive samples were confirmed positive in virus isolation. These findings suggest the existence of a stronger midgut infection barrier for JEV in Anopheles plumbeus than in Culex pipiens. The latter species also seems to have a midgut escape barrier for JEV. Saliva is currently being tested to determine the transmission ratio and the effect of temperature on the vector competence will be studied in the coming months.

What is the likelihood of entry of Navel orangeworm (Amyelois transitella) into European Union?

Authors: van der Werf Wopke[3], Czwienczek Ewelina[5], MacLeod Alan [1], Zappalà Lucia[2], Tramontini Sara[7], Mosbach-Schulz Olaf[6], Campese Caterina[4], Maiorano Andrea[7] and Stancanelli Giuseppe[7], [1]Department for Environment, Food and Rural Affairs (Defra), [2]Department of Agriculture, Food and Environment, University of Catania, [3]Department of Plant Sciences, Wageningen University, [4]European Food Safety Authority, [5]European Food Safety Authority (EFSA), Italy, [6]MESE Unit, European Food Safety Authority (EFSA), [7]PLANTS Unit, European Food Safety Authority (EFSA)

Abstract: The Navel orangeworm (Amyelois transitella) (Lepidoptera: Pyralidae) is a polyphagous and multivoline pest in Americas, known to occur on nuts, so called ‘mummies’ (walnuts, almonds and pistachios), citrus, plums and other fruits. As a potential threat to EU nut and fruit production the European Commission requested the European Food Safety Authority (EFSA) to provide a quantitative risk assessment. The likelihood of the pest’s entry into EU27 was investigated following EFSA guidance on quantitative risk assessment. Understanding pest biology, crop phenology and industry practices is crucial when building a pathway model to assess the likelihood of pest entry. Taking into consideration pre-and post-harvest industry practices to minimise infestations for the export, we describe how the EFSA process integrates information and data on pest biology with agricultural practices to apply expert knowledge elicitation to quantitatively evaluate the likelihood of Amyelois transitella entering EU27 via the import of host nuts and fruits. Further work on establishment, spread and potential impact in the EU is planned together with the identification and evaluation of risk reduction options.

The European Commission will use the results of this assessment to make future decisions regarding the regulatory status of Amyelois trasnitella in EU27.

Fitness consequences of timing asynchrony at the individual and population level in the winter moth

Authors: van Dis Natalie E.[2], Bansal Vidisha, Sieperda Geert-Jan, Wertheim Bregje[4], Visser Marcel[3] and A. Hut Roelof[1], [1]GELIFES, Groningen University, Netherlands, [2]Netherlands Institute of Ecology (NIOO-KNAW) GELIFES, Groningen University, Netherlands, [3]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [4]University of Groningen, Netherlands

Abstract: Climate change can severely impact species that depend on ephemeral resources because of induced phenological asynchrony: a mismatch between consumer and resource seasonal timing. In the winter moth, climate change induced asynchrony increased selection on the temperature sensitivity of egg development rate. However, we know little about the fine-scale fitness consequences of asynchrony at the individual level and how this affects population dynamics in the winter moth. We determined the fitness curve of timing of egg hatching relative to timing of oak budburst in a feeding experiment and combined this with our long-term data series on relative abundances of four Dutch populations to model the effect of asynchrony on population dynamics. Already one day of mismatch greatly increased mortality rates of freshly hatched caterpillars. This was reflected in our population models in which we found a significant effect of timing mismatch on population growth rates. These severe fitness consequences of asynchrony have driven the rapid genetic adaptation to climate change in the winter moth in the past 20 years. We are now using whole genome sequencing of historic winter moth samples to gain insight into how the selection pressure strength and population dynamics we investigated here have impacted the speed of adaptation in the wild.

Dispersal, population development and symptom development of A. lycopersici and relationship between mite density, visual symptoms and yield loss in a Western European protected tomato crop

Authors: Van Heghe Benedikte[2], Bosmans Lien[2], Vervaet Lore[1], De Groote Stefanie[4], Aussems Evelien[3], De Vis Raf[3], De Clercq Patrick[1] and Van Leeuwen Thomas[1], [1]Laboratory of Agrozoology, Ghent University, Ghent, Belgium., [2]Research Centre Hoogstraten, Meerle, Belgium., [3]Research Station for Vegetable Production, Sint-Katelijne-Waver, Belgium., [4]Vegetable Research Centre, Kruishoutem, Belgium.

Managing the Russian invasion in Australia…

Authors: van Helden Maarten[3], Pirtle Elia[1], Al-Jawahiri Farah[2], Maino James[1], Lye Jess[1] and Heddle Thomas[2], [1]Cesar, Australia, [2]South Australian Research and Development Institute, Australia, [3]South Australian Research and Development Institute, University of Adelaide, Australia

Abstract: Russian wheat aphid, Diuraphis noxia Kurdjumov (Hemiptera: Aphididae) was considered a serious biosecurity risk to Australian grains since the 1980s (Hughes & Maywald 1990). When RWA was first detected in South Australia in May 2016, it had already spread over a large area. It is now (Jan. 2020) established across South Australia, Victoria, Tasmania and most of New South Wales. The front moves hundreds of km northwards each year, and is expected to reach Queensland soon. Western Australia seems protected by the arid Nullarbor Plain. Climex modelling shows that RWA should be able to persist in all cereal-growing regions of Australia (Avila et al 2018).

Since damage was expected, emergency permits were issued and curative insecticide sprays (2016 season) were applied. From then on, neonicotinoid seed treatments were adopted widely (estimated 40% increase in imidacloprid use nationwide).

Subsequent research, incorporating advice from overseas experts (F. Peairs, J. Vitou), focussed on biotype confirmation, varietal susceptibility, population growth, natural enemies, crop damage and yield loss.

Screening RWA populations against cereals with Dn-genes showed that Australian RWA are nearly identical to the American RWA1 biotype. There are currently no commercial cereal varieties with resistance to RWAau1 available in Australia.

The most recent GRDC investment, undertaken by SARDI and cesar, aims to assess the regional pressure of RWA and impact on yield, to provide risk estimates, thresholds and IPM options.

Field observations (2016) and experiments (2016-2020) looked into RWA dynamics and yield loss in relation to cereal commodity, sowing date and regional risks. Over the last (dry) years, regional RWA pressure was low. Infestation levels were higher when crops were sown very early (April) or late (July), when RWA migrate. RWA summer survival is linked to the green bridge: native and introduced grasses and volunteer cereals, requiring summer rainfall.

Inoculated trials show higher RWA development in crops experiencing severe drought stress, and yield loss was observed. In higher rainfall environments, even quite severe infestations of >15% of tillers with RWA did not result in yield loss. Elimination of high infestations at GS35-40 reduced the risk of yield loss. Intervention thresholds are being finalised.

Overall, the risk posed by RWA to cereal production in Australia seems low. Increased risk might occur in low rainfall areas, in years with high summer rainfall. For lower risk situations, the use of prophylactic seed treatments is not warranted, an IPM approach seems more sustainable: Symptom expression is very clear, quantifying RWA through scouting easy and (if needed) an insecticide application before GS40 will avoid yield loss.

Native and invasive wireworm pests of Canada: Increasing threats, and increasing options for their management

Authors: van Herk Wim[1], Vernon Bob[2] and Mitchell Terisha[1], [1]Agriculture and Agri-Food Canada, Canada, [2]Sentinel IPM Consulting, Canada

Abstract: Three invasive Agriotes click beetle species have become significant pests of vegetables and field crops on the west coast of British Columbia and in eastern Canada since the early 1900s. Pest populations of these species are currently increasing and they are continuing to spread to new areas. Populations of native Selatosomus, Limonius, and Hypnoidus pest species have also increased significantly over the last 20 years, and currently cause considerable crop damage in central Canada. However, with the increasing threats these developments pose for crop production, a suite of promising new chemical and semiochemical control approaches are offering hope.

The nutritive value of black soldier fly larvae reared on common organic waste streams in Kenya

Authors: van Huis Arnold[7], Ekesi Sunday[4], Borgemeister Christian[2], Shumo Marwa[1], M. Tanga Chrysantus[4], M. Khamis Fathiya[5], M. Osuga Isaac[3], K. M. Fiaboe Komi[6] and Subramanian Sevgan[4], [1]Center for Development Research (ZEF), Department of Ecology and Natural Resources Management, Bonn, Germany; International Centre of Insect Physiology, [2]Center for Development Research (ZEF), Department of Ecology and Natural Resources Management, Bonn, Germany, [3]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya; Jomo Kenyatta University of Agriculture and Technology, [4]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya, [5]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [6]International Institute of Tropical Agriculture, Cameroon, [7]Laboratory of Entomology Wageningen University @ Research, Netherlands

Abstract: In Africa, livestock production currently accounts for about 30% of the gross value of agricultural production. However, production is struggling to keep up with the demands of expanding human populations, the rise in urbanization and the associated shifts in diet habits. High costs of feed prevent the livestock sector from thriving and to meet the rising demand. Insects have been identified as potential alternatives to the conventionally used protein sources in livestock feed due to their rich nutrients content and the fact that they can be reared on organic side streams. Substrates derived from organic by-products are suitable for industrial large-scale production of insect meal. Thus, a holistic comparison of the nutritive value of Black Soldier Fly larvae (BSFL) reared on three different organic substrates, i.e. chicken manure (CM), brewers' spent grain (SG) and kitchen waste (KW), was conducted. BSFL samples reared on every substrate were collected for chemical analysis after the feeding process. Five-hundred (500) neonatal BSFL were placed in 23 × 15 cm metallic trays on the respective substrates for a period of 3–4 weeks at 28 ± 2 °C and 65 ± 5% relative humidity. The larvae were harvested when the prepupal stage was reached using a 5 mm mesh size sieve. A sample of 200 grams prepupae was taken from each replicate and pooled for every substrate and then frozen at -20 °C for chemical analysis. Samples of BSFL and substrates were analyzed for dry matter (DM), crude protein (CP), ether extracts (EE), ash, acid detergent fibre (ADF), neutral detergent fibre (NDF), amino acids (AA), fatty acids (FA), vitamins, flavonoids, minerals and aflatoxins. The data were then subjected to analysis of variance (ANOVA) using general linear model procedure. BSFL differed in terms of nutrient composition depending on the organic substrates they were reared on. CP, EE, minerals, amino acids, ADF and NDF but not vitamins were affected by the different rearing substrates. BSFL fed on different substrates exhibited different accumulation patterns of minerals, with CM resulting in the largest turnover of minerals. Low concentrations of heavy metals (cadmium and lead) were detected in the BSFL, but no traces of aflatoxins were found. In conclusion, it is possible to take advantage of the readily available organic waste streams in Kenya to produce nutrient-rich BSFL-derived feed.

Widespread loss of formerly dominant insect species and global biodiversity change

Authors: van Klink Roel, iDiv, Germany

Abstract: Widespread declines of terrestrial insect abundances are now well established. What remains unclear, however, is whether other aspects of biodiversity, such as species numbers, evenness and relative abundances, are also changing. We compiled long-term insect monitoring data to study global patterns of biodiversity change. We found that despite declines of terrestrial insect abundances, there is no average decline in species numbers, and no change in evenness. This can be explained by declines of dominant species and high rates of species replacement. In the freshwater realm, we found, apart from increases in abundance, strong increases in species numbers, and an increase in evenness. This could be explained by increases in the number of rare and intermediately common species, whereas the formerly most dominant species declined. The loss of formerly common species has probably already led to the widespread rewiring of food webs, and a change in ecosystem functioning and services, given the ecological importance of abundant species.

Essential and useless ecological knowledge for applied biological control

Authors: van Lenteren Joop, Wageningen University, Netherlands

Abstract: Ecology and biological control are intensely interconnected. Population regulation theory provides an understanding of the working mechanism of natural, inoculative and conservation biocontrol. Information about multitrophic relationships show intricate networks between soil biota, plants, herbivores, their natural enemies and organisms at the fourth trophic level. Ecological insight has helped in finding and evaluating natural enemies for specific types of biocontrol. However, ecologists have also proposed the necessity of certain research approaches for biocontrol that have not contributed to progress and even delayed implementation of biocontrol projects. I will illustrate this with examples related to studies on functional response, attack rate, handling time, host discrimination, associative learning, chemical ecology, etc. Biocontrol researchers would appreciate help from ecologists, for example in the development of reliable and quantifiable criteria to quickly exclude biocontrol agents that might not be effective or cause unacceptable negative effects. Other areas where help would be welcome are the design of quality control, mass production, storage and release methods for natural enemies, a better understanding of host plant resistance to pests and its effect on biocontrol agents etc. etc.

Mapping of resistance traits in diverse arthropods by bulked segregant analysis

Authors: Van Leeuwen Thomas[3], Dermauw Wannes[4], vandenhole Marilou[3], Kurlovs Andre[2], Wybouw Nicky[2], M. Clark Richard[5] and Snoeck Simon[1], [1]Department of Biology, University of Washington, United States, [2]Department of Plants and Crops, Ghent University, Belgium, [3]Department of Plants and Crops, Ghent University, Belgium, [4]Flanders research institute for Agriculture, Fisheries and Food (ILVO), Belgium, [5]School of Biological Sciences, University of Utah, United States

Abstract: The development of resistance to insecticides and acaricides is a major problem in agriculture. It is therefore of crucial importance to understand the mechanisms of resistance. However, these mechanisms of adaptation can be complex. In the past, some major discoveries were made via the genetic tools in model organisms such as Drosophila. As recently more and more good-quality genomes are becoming available and high-throughput short-read sequencing is becoming very cost effective, we present here a population-level Bulked Segregant Analysis (BSA) that can be used to map resistance genes in high resolution and uncover the genetic architecture of both monogenic and polygenic trait variation. Another advantage of population-level BSA is that it can be applied to a wide variety of arthropod species with life histories or physical attributes (as for micro-insects) that render genetic mapping with other methods impractical. Although this technique can be used for any sexual reproducing insect that can easily be crossed and maintained in high population size in the laboratory, we present here the work conducted with the spider mite Tetranychus urticae, an important crop pest. We give an overview of how this technique has resolved a number of complex cases of resistance against some of the major classes of acaricides. These advanced BSA experimental designs can thus resolve causal loci to narrow genomic intervals, facilitating follow-up investigations for a wide variety of arthropod species.

Potential of iolinid predatory mites for the control of tomato russet mite, Aculops lycopersici, in protected tomato cultivation

Authors: Van Leeuwen Thomas[1], De Clercq Patrick[3], Vervaet Lore[2], Vanlommel Wendy[4], Reybroeck Eva[5], Parapurath Gokul[6], Bosmans Lien[4], De Vis Raf[5] and van Havermaet Robin[5], [1]Department of Plants and Crops, Ghent University, Belgium, [2]Laboratory of Agrozoology, Department of Crop Protection, Ghent University, Belgium, [3]Laboratory of Agrozoology, Department of Plants and Crops, Belgium, [4]Research Centre Hoogstraten, Belgium, [5]Research Station for Vegetable Production, Belgium, [6]University of Padova, Italy

Abstract: The tomato russet mite (TRM), Aculops lycopersici (Tryon, 1917), is a key pest in tomato crops and occurs in all countries where tomatoes and related solanaceous crops are grown. The tomato russet mite can be highly destructive to the tomato crop and can cause significant yield losses. Early detection of this pest is difficult due to its minute size and the time-gap between infestation and the first symptoms. TRM is very small and moves easily on the leaf and stem surface, thereby not hindered by the (glandular) trichomes. These glandular trichomes, however, hamper all of the commercially available natural enemies of TRM. Moreover, low efficacy of acaricides against TRM has been reported. Actually, growers control TRM by repetitive sulphur sprayings but this has a negative effect on other biocontrol systems. Lack of successful control sparked a search for new natural enemies that can efficiently feed and reproduce on TRM and that are not hindered by the trichomes of the tomato plant. A survey for potential predators in Europe yielded two iolinid predatory mites. Laboratory experiments were done to compare their predation potential on different life stages of the pest. The value of pollen as a supplementary food for these predators was also tested, as well as its effect on their predation activity.

The contribution to adaptation of cis versus trans gene regulation in a polyphagous arthropod, the spider mite Tetranychus urticae.

Authors: Van Leeuwen Thomas[1], vandenhole Marilou[1], Kurlovs Andre[1], de Beer Berdien[1] and M. Clark Richard[2], [1]Department of Plants and Crops, Ghent University, Belgium, [2]School of Biological Sciences, University of Utah, United States

Abstract: The spider mite Tetranychus urticae is a global pest known to feed on 1,100 different hosts from 140 plant families, including most major crops. Due to a very strong adaptation potential, it is one of the most notorious organisms for insecticide/acaricide resistance development.

We have previously shown how spider mites can mount a strong transcriptional response when challenged with a novel hosts, or after adaptation to acaricides. However, gene regulatory mechanisms underlying this plasticity and adaptation potential are not well studied. We have generated a large collection of fully inbred and resistant mite strains and describe the sampled genomic variation in the context of selection and adaptation. Using dedicated crosses between these inbred lines, we have started to study gene regulation mechanisms on a genome wide scale and unravel the global architecture of gene expression variation in a generalist herbivore.

Development and impact of Environmental Risk Assessments on the use of Biological Control

Authors: van Lenteren Joop C., Wageningen University

Abstract: During the first 100 years of biological control of arthropod pests, natural enemies usually did not undergo environmental risk analyses. This changed in the 1980s after concern was expressed about non-target effects caused by import and release of exotic biocontrol agents. Non-target effect concern was amplified when many amateurs started to mass produce and market new natural enemies as a result of the strongly increasing popularity of augmentative biocontrol,. The development of environmental risk assessment procedures in Europe started with the design of a code of conduct for the import and release of exotic biological control agents in the 1990s. This was followed by devising specific environmental risk assessment protocols that initially were rather complicated, but were refined and simplified, resulting in a comprehensive, stepwise method. Worldwide, protocols for regulation of import and release of exotic biocontrol agents are very different and seriously limit implementation of biocontrol.

Introduction, history of natural enemy evaluation, current challenges and proposal for ecological evaluation criteria for candidate selection.

Authors: van Lenteren Joop C., Wageningen University

Abstract: Ecology and biological control are intensely interconnected. Population regulation theory provides an understanding of the working mechanism of natural, importation (=classical) and conservation biocontrol. Information about multitrophic relationships show intricate networks between soil biota, plants, herbivores, their natural enemies and organisms at the fourth trophic level. Ecological insight has helped in finding and evaluating natural enemies for specific types of biocontrol. However, ecologists have also proposed the necessity of certain research approaches for biocontrol that have not contributed to progress and even delayed implementation of biocontrol projects. I will illustrate this with examples related to studies on functional response, attack rate, handling time, host discrimination, associative learning, chemical ecology, etc. Biocontrol researchers would appreciate help from ecologists, for example in the development of reliable and quantifiable criteria to quickly exclude biocontrol agents that might not be effective or cause unacceptable negative effects. Other areas where help would be welcome are the design of quality control, mass production, storage and release methods for natural enemies, a better understanding of host plant resistance to pests and its effect on biocontrol agents etc.

Exploring the potential of microbial volatiles to enhance biological control of pest insects

Authors: van Neerbos Francine[1], Jacquemyn Hans[2] and Lievens Bart[1], [1]Laboratory for PME&BIM KU Leuven, [2]Laboratory of Plant Conservation and Population Biology KU Leuven

Abstract: Biological control using parasitoids has become an important method of pest management. However, its efficacy may be hampered by parasitoid dispersal from the crop and the occurrence of hyperparasitoids. This low efficacy may be addressed by employing an infochemical-based approach. A growing body of research has identified volatile organic compounds (VOCs) emitted by microorganisms to be an interesting source of these infochemicals. However, to date little is known about the olfactory response to microbial VOCs within and across different trophic levels, and whether they can be exploited as a source to enhance biological control. Here, we used Y-tube bioassays to assess how bacterial VOCs (bVOCs) affect the olfactory response of the aphid-parasitoid-hyperparasitoid food web. Next, using chemical analyses of the bVOC blends and correlation analysis with insect behavior, we identified interesting compounds and created synthetic mixtures which were both evaluated in Y-tubes. Results revealed that linalool was repellent for the hyperparasitoid Dendrocerus aphidum but repellent for the parasitoid Aphidius colemani. Furthermore, we found that a blend of styrene and benzaldehyde had the opposite effect. In subsequent greenhouse experiments, the styrene and benzaldehyde blend was evaluated in different doses and over different distances to attract parasitoids and repel hyperparasitoids.

Luring hyperparasitoids away from their parasitoid host in greenhouses

Authors: van Neerbos Francine, CMPG laboratory of PME&BIM KULeuven, Netherlands

Abstract: Parasitoids are among the best biocontrol agents of aphids but their efficacy may be reduced when hyperparasitoids are present. Hyperparasitoids are natural enemies of parasitoids and are thus in the fourth trophic level. They are often reported to kill virtually all parasitoids of aphids in greenhouse horticulture, impairing sustainable pest management of indoor-grown vegetables. In sweet pepper greenhouses in The Netherlands, a diversity of hyperparasitoids occurs, and they may kill up to 100% of aphid mummies, preventing population establishment of primary parasitoids. In this presentation, I introduce the possibility of managing aphid hyperparasitoids by developing lures (baits) that divert hyperparasitoids away from their beneficial parasitoid host. This strategy requires an understanding of the cues that hyperparasitoids use to find their host. Experimental data suggest that the hyperparasitoid Dendrocerus aphidum may use cues from plants but host-derived cues (the aphid mummy) are most attractive. I will discuss the opportunities and challenges of applying this knowledge to develop a sustainable management strategy for hyperparasitoids.

Host plant availability drives the spatio-temporal dynamics of interacting metapopulations across a fragmented landscape

Authors: van Nouhuys Saskya[2], H. Opedal Øystein[3], Laine Anna-Liisa[5], Saastamoinen Marjo[1], Ovaskainen Otso[4], [1]Helsinki Life Science Institute, University of Helsinki, Finland, [2]Indian Institute of Science, United States, [3]Lund University University of Helsinki, Sweden, [4]University of Helsinki Norwegian University of Science and Technology, Finland, [5]University of Zürich, Switzerland; University of Helsinki, Finland

Abstract: The dynamics of ecological communities are likely to depend on species interactions within and among trophic levels. The Glanville Fritillary butterfly, its specialist parasitoid wasp Cotesia melitaearum, and the specialist fungal pathogen Podosphaera plantaginis infecting Plantago lanceolata, a host plant of the Glanville Fritillary, live as metapopulations in Åland, Finland. These species are known to interact locally directly and indirectly. We assessed the influence of these interactions on their spatio-temporal dynamics. To do this we analysed a 19-year time-series of each species across a network of more than 4000 habitat patches. We first included the presence of potentially interacting species in the previous year as a predictor in models describing the local colonisation and extinction rates of each species. Then, we performed simulations of metacommunity dynamics based on models trained for each species independently, and compared these predictions to the observed dynamics. All focal species responded strongly to variation in plant abundance. Single-species analyses suggested that colonisation and to a lesser extent extinction rates differ depending on the presence of interacting species within patches. However, the directions of most effects differed from expectations, and simulations assuming species independence replicated reasonably well the observed metacommunity dynamics. These results suggest that although local interactions among the butterfly, parasitoid, and mildew occur, their roles in metacommunity spatio-temporal dynamics are weak compared to other environmental drivers. Instead, all species respond to variation in plant abundance, which fluctuates in response to climatic variation. Consequently, changes in climate affect the structure of entire metacommunities.

Historical and transgenerational effects of fungal infected diet for a butterfly

Authors: van Nouhuys Saskya[2], Karlsson Green Kristina[3], Laine Anna-Liisa[5], Saastamoinen Marjo[1] and Rasmussen Pil[4], [1]Helsinki Life Science Institute, University of Helsinki, Finland, [2]Indian Institute of Science, United States, [3]Swedish University of Agricultural Sciences, Sweden, [4]The National Research Centre for the Working Environment, Denmark, [5]University of Zürich University of Helsinki, Switzerland

Abstract: Sharing host plant with a plant pathogen may have important consequences for developing larvae but the degree of plant disease resistance may be difficult for an ovipositing female to evaluate. The Glanville Fritillary butterfly, Melitaea cinxia, inhabits a landscape with variation of risk of powdery mildew infected host plants and feeding on infected plants is detrimental to M. cinxia larvae. Here, we studied if females choose to oviposit on plants that are resistant to powdery mildew, thus minimising the risk their offspring will feed on infected plants, and if this choice depend on whether they came from populations with or without a history of mildew infected diet. We also study whether larvae differentiated between food that is infected or not, and how their efficiency of conversion depends on diet. In addition, we tested the effects of the mothers diet on offspring preference and performance. We found that the adults from both mildew infected and uninfected areas do not select plant genotypes that are resistant to mildew infection. However, larval diet selection and efficiency of conversion depends both on their own feeding experience and their mother's diet. Thus, larval preference is subject both to intra- and transgenerational plasticity depending on earlier experience of mildew infected diet. These results contribute to our understanding of how multitrophic interactions and transgenerational effects mediate insect behaviour.

Increased fluctuation in a butterfly metapopulation leads to diploid males and decline of hyperparasitoid

Authors: van Nouhuys Saskya[1], Nair Abhilash[3] and Nonaka Etsuko[2], [1]Indian Institute of Science, United States, [2]Sweden, [3]University of Helsinki, Finland

Abstract: Climate change can increase spatial synchrony of population dynamics, leading to large-scale fluctuation that destabilizes communities. High trophic level species such as parasitoids are disproportionally affected because they depend on unstable resources. Most parasitoid wasps have complementary sex determination, producing sterile males when inbred, which can theoretically lead to population extinction via the diploid male vortex. We examined this process empirically using a hyperparasitoid population inhabiting a spatially structured host population in a large fragmented landscape. Over four years of high host butterfly metapopulation fluctuation, diploid male production by the wasp increased, and effective population size declined precipitously. Our multitrophic spatially structured model shows that host population fluctuation can cause local extinctions of the hyperparasitoid due to the diploid male vortex. However, regionally it persists because spatial structure allows for efficient local genetic rescue via balancing selection for rare alleles carried by immigrants. This is the first empirically based study of the possibility of the diploid male vortex in a natural host-parasitoid system.

Two decades of temporal genetic changes in an introduced parasitoid population infected by a deleterious Wolbachia strain

Authors: van Nouhuys Saskya[1], Duplouy Anne[2] and Nair Abhilash[2], [1]Indian Institute of Science, United States, [2]University of Helsinki, Finland

Abstract: By influencing their host reproduction, or their host susceptibility to parasitism to favor proliferation of the infected hosts, endosymbiotic micro-organisms, such as the bacterium Wolbachia, can affect the spread of particular host genotypes in natural populations. This might have important consequences for the study of spatio-temporal changes in the genetic structure of introduced populations. and bias our understanding of how such populations establish, persist and disperse across habitats. We used 14 microsatellites and one mitochondrial marker to genotype 323 specimens of the parasitoid wasp Hyposoter horticola collected between 1992 and 2013 from five localities in the highly fragmented Åland archipelago, between the Finish and Swedish coasts in the Baltic Sea. A Wolbachia strain was previously shown to persist at an intermediate prevalence (~50%) in this population, and to affect the susceptibility of the wasps to a hyperparasitoid. We identified that migration occurred between some isolated populations, potentially facilitating the persistence of local introductions, and all island populations, despite occasional local population crashes. We show that the fixation of Wolbachia on some islands due to locally reduced predation pressures by the hyperparasitoid species, has selected for particular host genotypes in those isolated populations. We discuss the importance of including symbiotic partners in the study of trophic networks.

Viruses of mass reared insects – a lot of dark matter

Authors: van Oers Monique, Wageningen University and Research, Laboratory of Virology, the Netherlands

Abstract: Successful application of mass-reared insects heavily relies on healthy insect colonies. However, insect pathogens, including a number of before unknown viruses, easily emerge in large scale cultures, often leading to colony collapse. To be sustainable and cost-effective, insect production urgently needs to become more resilient to a variety of insect pathogens. The major drawback though, is that the knowledge needed to prevent such infectious diseases is very scarce and specific diagnostic tools are hardly available, leaving the insect rearing companies at serious risk for re-occurring outbreaks. To overcome this knowledge gap, develop the necessary techniques for diagnosis and management, and to increase the number of specialized researchers, the European INSECT DOCTORS programme was initiated. In this presentation, I will focus on what we know about viruses occurring in a variety of mass reared insects (e.g. crickets, tsetse, medflies, and caterpillars), thereby highlighting research data from the INSECT DOCTORS programme. I will also include our recent data on the discovery of insect specific viruses in mosquitoes and how the genome properties of these viruses differ from related human and animal viruses vectored by mosquitoes.

Valence-driven feature binding in the fly brain

Authors: van Swinderen Bruno[2] and Grabowska Martyna[1], [1]Queensland Brain Institute The University of Queensland, Australia, [2]Queensland Brain Institute Tee University of Queensland, Australia

Abstract: Selective attention describes the brain's capacity to prioritize one set of related stimuli while ignoring others. What defines a related set is driven in part by valence, or the value assigned to key stimulus features. Animals as dissimilar as insects and primates display valence-driven attention, but it is unclear if similar mechanisms are employed. Here, we used distinct frequency tags to disambiguate attractive and aversive visual objects in fly brain activity and found that valence cues governed the binding of associated visual features. Feature binding was evident even during covert attention and could be redirected by activating a reward circuit in the fly brain. Attended stimuli were phase-locked to endogenous beta (20-30Hz) oscillations, suggesting a conserved function for this frequency range in regulating feature binding.

Haze of glue determines preference of western flower thrips (Frankliniella occidentalis) for yellow or blue traps

Authors: van Tol Rob[3], Tom Jolanda[3], Roher Monika[2], Schreurs Anne[1] and van Dooremalen Coby[3], [1]Bosch, Netherlands, [2]Greb, Croatia, [3]WUR

Abstract: In a wind tunnel we compared the colour preference for western flower thrips to four types of colour plates (clear, white, blue and yellow) applied with two types of glue (diffuse Stikem versus clear D41). Further the results for blue and yellow preference were validated in two greenhouses. In the wind tunnel, we found a clear preference of yellow over blue when a clear glue (D41) was used. However, with a more diffuse (whitish) glue (Stikem) the preference for yellow over blue disappeared, whereby the attraction to yellow decreased (58%) while the attraction to blue increased (65%). In the greenhouses, we found similar effects as in the wind tunnel with a decrease in attraction to yellow (35%) and increase in attraction to blue (32%) for Stikem compared to D41. Light measurements showed an increase of 18% of blue, 21% of violet light, 8% of yellow and 9% of green light reflected

on the yellow Stikem trap versus the yellow D41 trap. On blue plates there was only 4% increase of blue light, 8% decrease of yellow light reflected when Stikem glue was used compared to D41 glue.

Response of the Western flower thrips to blue and yellow varies according to diffused versus specular reflection of glue on the trap

Authors: van Tol Rob[3], Schreurs Anne[1], van Dooremalen Coby[4], Tom Jolanda[4] and Roher Monika[2], [1]bosch, Netherlands, [2]greb, Croatia, [3]Wageningen University and Research, Netherlands, [4]WUR

Abstract: In a wind tunnel and greenhouses we compared the effect of different reflection of glue on the preferred colour for Western flower thrips. We compared colour choices of thrips in a wind tunnel for two types of glue (diffuse Stikem versus specular D41) on four types of colour plates (clear, white, blue and yellow) and repeated this experiment in two greenhouses (Chrysanthemum and Rose).
We found in the wind tunnel a clear preference of yellow over blue when a specular (clear glue) reflective glue (D41) was used. With a more diffuse (whitish) glue (Stikem) the preference for yellow over blue disappeared whereby the attraction to yellow decreased (58%) while the attraction to blue increased (65%). There was no significant effect of glue found for clear or white plates.
In the greenhouses we found similar effects as in the wind tunnel whereby the overall effect was a decrease in attraction to yellow (35%) and increase in attraction to blue (32%) when changing the glue type from specular to diffused. Light measurements showed an increase of 20% of blue light and 8% of yellow light reflected on the yellow Stikem trap versus the yellow D41 trap. On blue plates there was only 3% increase of blue light and 8% decrease of yellow light reflected. It remains to be seen if the change of ratio blue to yellow caused by the glue type plays a role in the change of attraction or whether the diffused particles in the glue itself cause these changes in attraction.
The reflective properties of glue are so far an unknown factor in colour choice and may explain partially the different results on colour preference as found by others.

Advances in studying the role of neuropeptides and their receptors in locust physiology and behavior

Authors: Vanden Broeck Jozef, Catholic University of Leuven, Belgium

Abstract: Despite their diversity, some fundamental characteristics are shared by all animals. Like other metazoans insects are heterotrophs, implicating a need for the intake of food. Many post-embryonic processes depend on this nutritional and energetic input. It is crucial that insects can rely on regulatory mechanisms controlling and integrating their development, physiology and behavior. Hormonal and neuronal signalling systems are playing an important role in this complex regulation.
In this presentation, we will consider neuropeptide-mediated signalling pathways that are implicated in the regulation of developmental-physiological and behavioral processes in insects. In particular, we will discuss recent data obtained in locusts, which are swarming pests that irregularly devastate the agricultural production in large areas of the world. In a physiological and neurobiological context, locusts have proven to be interesting experimental research organisms. We have molecularly characterized several neuropeptide precursors and receptors in locusts, and will report on our recent physiological and molecular biological studies that further illustrate the important role of neuropeptide-mediated signalling systems. We have also evaluated the potential of peptide-mimetic analogues as molecular pharmacological tools to interfere with these signalling systems, as well as with the downstream physiological processes they are controlling. Moreover, RNA interference was employed as a highly efficient and robust method to post-transcriptionally silence the expression of peptide precursors and/or receptors.

The general aim of our work is to contribute to a better understanding of the regulation of insect post-embryonic processes, as well as of the functional networking interactions between different regulatory pathways in an integrative, organismal context.

Knockdown of ecdysone receptor in male desert locusts affects relative weight of accessory glands and mating behavior

Authors: Vanden Broeck Jozef[1], Van Lommel Joachim[3], Lenaerts Cynthia[1] and Delgouffe Charlotte[1], [1]Catholic University of Leuven, Belgium, [3]KULeuven, Belgium

Abstract: Recently (2018–2021) the world has faced the largest swarms of desert locusts, Schistocerca gregaria, in decades and food security in large parts of Africa and Asia was under extreme pressure. We investigated the possible role(s) of the ecdysteroid receptor in the reproductive physiology of male S. gregaria. Ecdysteroids are best known for their role in moulting and exert their function via a heterodimer consisting of the nuclear receptors ecdysone receptor (EcR) and retinoid-X receptor (RXR). To gain insight into the role of SgEcR and/or SgRXR in the male reproductive physiology of S. gregaria we performed RNAi-induced knockdown experiments. A knockdown of SgEcR, but not SgRXR, resulted in an increased relative weight of the male accessory glands (MAG). Furthermore, the knockdown of these genes, either in combination or separately, caused a significant delay in the onset of mating behavior. The high transcript levels of SgEcR in the fat body, especially towards the end of sexual maturation in both males and females, represent a remarkable finding since as of yet the exact role of SgEcR in this tissue in S. gregaria is unknown. Finally, our data suggest that in some cases SgEcR and SgRXR might act independently of each other.

Cryptic Fire Ant Species in South America

Authors: Vander Meer Robert[4], Alberto Calcaterra Luis[1], Ascunce Marina[3] and Porter Sanford[2], [1]Foundation for the Study of Invasive Species, Argentina, [2]United States Department of Agriculture (retired), United States, [3]United States Department of Agriculture, United States, [4]USDA-ARS, United States

Abstract: In South America, the home land of the fire ant, Solenopsis invicta, where their population densities are 5-10 less than they are in the United States. The rationale for this is that they left their natural enemies behind when they arrive in the USA. The search for natural enemies in South America has been going on for decades. The most successful result has been the introduction of several species of parasitic phorid flies. Results with pathogens has been less successful. We propose that the problem is a result of several cryptic species in South America that is confounding the search for pathogens. We use chemical, behavioral, and genetic methods to establish the presence of cryptic fire ant (Solenopsis invicta) species in northern Argentina.

Crosspollinating Urban Community Gardens and Forests: A Network Approach to Conserving native bees in Cities

Authors: Vanderstock Amelie[1] and Latty Tanya[1], [1]The University of Sydney, Australia

Abstract: Conserving native bees in cities involves understanding how they use floral resources across urban habitat types. Community gardens, a form of urban agriculture tended to by the public, are thought to support pollinators by providing diverse flowers all year-round. Native and regenerated urban forest is assumed to not only provide food-flowers, but also habitat including bare ground for nesting as well as cavities and hollows in trees. However, insect conservationists are yet to understand how the location of community gardens and forest sites can influence native bee diversity in an urban context.

We studied how connectivity between these two urban green spaces influences pollinating insect communities and the structure of plant- pollinator networks in Sydney, Australia. Specifically, whether community gardens adjoining urban forest have greater abundance and diversity of native bees compared with isolated gardens. We also compared native bee biodiversity of isolated forest sites with those adjoining community gardens. We surveyed fifty-six sites for characteristics including size and floral density. Insect visitors to all flowering species were caught at each site in time-standardized surveys. Using visitation data, we constructed plant-pollinator networks to explore how the interaction between community gardens and urban forest sites influenced key network metrics.

Our results demonstrate that a greater species richness and abundance of native bees, flies and wasps were found in community gardens compared with bushland sites, regardless of their habitat connectivity. Density and diversity of flowering plants is a more important explanatory factor for native bee biodiversity than their proximity to bushland. Aside from honeybees Apis mellifera, the most abundant bees across sites were Blue Banded bees Amegilla cingulata and Sweat bees, Liptotriches phenerura; both ground nesting species, as well as Leaf cutter bees Megachile Serricauda; who nests in wooden cavities. These native bees are likely finding ample food and nesting resources in the urban environment regardless of immediate proximity to native habitat.

Understanding the interactions between cultivated crops and remnant vegetation in the urban matrix is an important contribution to the research on pollination network and food resilience in global cities.

Who profits from the invasion – a preliminary study towards biological control of mosquitoes

Authors: Vanslembrouck Adwine[3], Scheers Kevin[5], Vermeersch Xavier[1], Hendrickx Rens[4], Deblauwe Isra[2], Schneider Anna[2], De Witte Jacobus[2], Van Bortel Wim[2], Reuß Friederike[6] and Müller Ruth[2], [1]Brussels Environment, [2]Institute of Tropical Medicine, Antwerp, [3]Institute of Tropical Medicine, Belgium, [4]Province of Antwerp, [5]Research Institute Nature and Forest, [6]Senckenberg Biodiversity and Climate Research Center, Frankfurt

Abstract: The spread of mosquito-borne diseases (MBDs) is restricted by the occurrence of competent vectors. In addition to the native Culex pipiens, a vector for West Nile and Usutu virus, invasive species such as Aedes albopictus are flourishing in Europe. Their spread towards more temperate regions poses an increasing threat because of their high vector competences for different viruses. They can establish rapidly in suited regions, reaching high abundances and posing a potential risk for MBDs.

The control of these populations will be necessary to prevent MBDs outbreaks. One possible biological control agent is the use of several species of diving beetles as natural predators of mosquitoes. Twenty-four common dytiscid species were wild-caught in Belgium and kept at insectary for a feeding experiment and prey choice on Cx. pipiens and Ae. albopictus larvae.

First results on the feeding experiment suggest at least five good dytiscid predators that are known to inhabit small, temporal habitats. Further experiments on prey choice reveal a clear preference for the ground dwelling Ae. albopictus rather than Cx. pipiens. A distribution overlap between these good predators is given on the point of entries where Ae. albopictus has been found in Belgium in the past years.

Exploring the parasitoid diversity for viral domestication

Authors: Varaldi Julien, University Lyon 1, France

Abstract: In some endo-parasitoid wasps, viruses have been endogenized within and domesticated by wasp genomes. Those endogenized viral genes are used by the wasps as a delivery tool to inject virulence factors, essential to the development of their offspring. So far, most cases of such viral domestication have been described in the Ichneumonoidea superfamily. First, I will show that convergent evolution led to virus domestication outside this superfamily. Second, we hypothesized that endo-parasitoidism may have favored the domestication of viruses or conversely that virus domestication may have favored the evolution of endo-parasitoidism. By analyzing the genomic composition of 124 Hymenoptera genomes spread over the diversity of Hymenoptera including free-living, ecto and endo-parasitoid species, we tested whether wasp lifestyle correlates with endogenized virus content. First, dsDNA viruses were more often endogenized and domesticated than expected based on their estimated abundance in insect viral communities compared to other virus genomic structures. Second, our analysis revealed that endogenization and domestication of dsDNA viruses was more frequent in lineages with endo-parasitoid lifestyle compared to ecto-parasitoid or free-living species. This result suggests that the evolution of endo-parasitoidism has favored the domestication of dsDNA viruses or conversely that dsDNA virus domestication has favored the evolution of endo-parasitoidism.

Evading invasive ants: investigating an ant repelling fly and its potential as a control method for exotic pest ants.

Authors: Vargo Edward[1], List Fabian[2] and Tarone Aaron[1], [1]Texas A&M University, United States, [2]Texas A&M University, Department of Entomology, United States

Abstract: Many studies have shown that invasive ants can have a devastating effect on the invertebrate environment in areas where they become established. With steadily increasing human trade around the globe, we are creating ever more opportunities for hitchhiking invaders. Increasing, stricter pesticide laws and different regulations around the world call for constant innovation for new control strategies for invasive ants. An unlikely new candidate could come from a fly. While most species of the Diptera are excellent fliers in their adult life stage, during their development however, they are soft-bodied, slow, vermiform packets of nutrients for any predator that might come by. Commonly called maggots, the juvenile life stages of dipterans have to find a method to avoid predation. While many are adapted to a cryptozoic lifestyle, the species used in this study regularly thrives in close proximity to foraging ants. Apparently, these maggots have developed a defensive strategy to prevent this kind of predation. This study used the tawny crazy ant (Nylanderia fulva), the red imported fire ant (Solenopsis invicta) and the Argentine ant (Linepithema humile) as examples to identify the activity and origin of a repellent compound found on these maggots. Survival assays under ant predation were conducted including assays with maggots raised on antibiotics to investigate the origin of the repelling compound. The common fruit fly (Drosophila melanogaster) was used as positive control for predation. Results show a drastic increase in survivorship for the untreated and antibiotics raised maggots, indicating an inherent origin of the repellant. This is strong evidence for a novel strategy of these flies to avoid predation by ants and future results could potentially yield a new natural repellent for ants.

Sexually antagonistic selection promotes genetic divergence between males and females in an ant

Authors: Vargo Edward[2], Blumenfeld Alexander[1] and Eyer Pierre-Andre[2], [1]Department of Entomology 2143 TAMU Texas A&M University College Station, United States, [2]Texas A&M University, United States

Abstract: In Hymenoptera, males and females display striking phenotypic differences despite lacking sex chromosomes. The constraint of a shared gene pool has been thought to prevent them from separately reaching sex-specific fitness optima by fixing different alleles in each sex. However, their entire haplodiploid genomes display an X-linked pattern that predisposes them to sexually antagonistic selection (SAS), whereby an allele is beneficial to one sex but harmful to the other. Here we report the first instance of SAS in a haplodiploid organism, the invasive ant Nylanderia fulva, with distinct alleles across a large portion of the genome differentially selected in each sex. Our findings shed light on a newly described genetic pattern and provide further insight into sexual conflicts in haplodiploids.Genetic diversity acts as a reservoir for potential adaptations, yet selection tends to reduce this diversity over generations. However, sexually antagonistic selection (SAS) may promote diversity by selecting different alleles in each sex. SAS arises when an allele is beneficial to one sex but harmful to the other. Usually, the evolution of sex chromosomes allows each sex to independently reach different optima, thereby circumventing the constraint of a shared autosomal genome. Because the X chromosome is found twice as often in females than males, it represents a hot spot for SAS, offering a refuge for recessive male-beneficial but female-costly alleles. Hymenopteran species do not have sex chromosomes; females are diploid and males are haploid, with sex usually determined by heterozygosity at the complementary sex-determining locus. For this reason, their entire genomes display an X-linked pattern, as every chromosome is found twice as often in females than in males, which theoretically predisposes them to SAS in large parts of their genome. Here we report an instance of sexual divergence in the Hymenoptera, a sexually reproducing group that lacks sex chromosomes. In the invasive ant Nylanderia fulva, a postzygotic SAS leads daughters to preferentially carry alleles from their mothers and sons to preferentially carry alleles from their grandfathers for a substantial region (~3%) of the genome. This mechanism results in nearly all females being heterozygous at these regions and maintains diversity throughout the population, which may mitigate the effects of a genetic bottleneck following introduction to an exotic area and enhance the invasion success of this ant.

Influence of hedgerows on plant and invertebrate diversity in Niagara vineyards

Authors: Vasseur Liette[1] and Hughes Margaret[2], [1]Brock University, UNESCO Chair on Community Sustainability, Department of Biological Sciences, St Catharines, ON, Canada, [2]Department of Biological Sciences, Brock University, St. Catharines, Ontario, Canada

Abstract: Historically perennial agroecosystems, like vineyards, are known for their limited plant diversity, ultimately hindering the potential for the provision of ecosystem services. Due to the fact that plants display bottom-up control, increased plant diversity in the margins of agroecosystems, known as hedgerows, may support local abundance of natural pest-enemies, through increased habitat complexity. This research aims to better understand the interaction between increased plant diversity in various types of perimeter plantings throughout the Niagara region, Ontario, Canada, and the potential impact on a common vineyard pest, leafhoppers (Cicadellidae), and a natural pest enemy, spiders (Arachnids) communities. Plant surveys in the perimeters and interior of vineyards and invertebrate community data was collected in 7 vineyard sites, encompassing a wide range of management practices. It was found that plant communities and functional diversity differed from the hedgerow to the interior and among on-farm managements. Leafhoppers communities were affected by on-farm management but not by the presence of the hedgerow. Spider communities benefitted from the presence of a hedgerow due to the increased structural complexity both within the hedgerow and between the hedgerow and vineyard interior. In conclusion it was found that hedgerows did not increase weed or pest pressure, and did support the maintenance of spider assemblages both within the hedgerows as well as vineyard interiors.

Responses of invertebrate communities in Lettuce (Lactuca Sativa) and Radish (Raphanus Sativus) monocultures and intercrop

Authors: Vasseur Liette[2] and VanVolkenburg Heather[1], [1]Brock University, Department of Biological Sciences, St Catharines, ON, Canada, [2]Brock University, UNESCO Chair on Community Sustainability, Department of Biological Sciences, St Catharines, ON, Canada

Abstract: Agroecosystems are ecosystems that are often vulnerable to diversity loss, which reduces crucial ecosystem services such as pest and weed controls, and resilience in the face of climate or environmental changes. In agroecology and sustainable agriculture, intercropping is a cultivation method that shows promise in its ability to increase diversity at the first trophic level thereby increasing diversity in successive levels (i.e. insects and other invertebrates). There is a need however to better understand how invertebrate assemblages as well as plant yields within the system may respond according to the type of plants being cropped. To try to gain a better understanding of how increasing crop diversity influences subsequent trophic levels, three separate but related experiments were implemented in Southern Ontario, Canada, a region where intercropping is still not very often used, even in organic farming. The experiments included a greenhouse control with no invertebrates present, a controlled field environment at the community garden at Brock University (regular irrigation and mechanical weeding provided), and an operational field setting (an organic farm). The main objectives of this project were to 1) examine responses of insect and other invertebrate assemblages in operational and field-controlled settings of lettuce-radish intercropping and monocultures; and 2) evaluate under controlled greenhouse conditions lettuce-radish intercropping and monoculture yields in the absence of invertebrates. Differences in invertebrate assemblages, and plant growth and herbivory rates were quantified for cultivated monocultures and intercrops of lettuce (Lactuca sativa) and radish (Raphanus sativus). Species diversity (invertebrates) and interactions (plants) were also calculated and compared across treatments. In some cases, herbivore abundance and richness in intercrops was shown to decrease and predator abundance increase in the intercrops compared to monocultures. Intercrop treatments showed significant increase in invertebrate species diversity in a controlled field setting yet little difference was found at the operational farm. For plants, herbivory rates were significantly lower in intercrop treatments relative to monoculture, but radish was a significantly stronger competitor than lettuce in all intercrops and had highest yield in the controlled field location. Lettuce did not appear to benefit in terms of yield when in the presence of radish. Overall, results showed that existing interactions might be site specific. Future research should include a greater number of functional groups such as detritivores and pollinators in novel plant combinations to improve our understanding of how increased biodiversity at the first trophic level influences agroecosystem invertebrate composition and overall productivity.

Integrating nutritional and cognitive ecology to study complex floral rewards

Authors: Vaudo Anthony[1] and Francis Jacob[1], [1]University of Nevada, Reno, United States

Abstract: Our current understanding of the role floral rewards play in pollinator cognition and plant fitness largely revolves around a single currency, nectar. Yet, many plants reward visitors with both nectar and pollen, which are both chemically complex and variable across co-flowering plant species. Embracing the nutritional complexity of floral rewards represents both a challenge and an opportunity for pollination biologists. On one hand, our recent work shows that multiple aspects of reward composition (e.g. pollen alkaloid content vs. nectar sugar concentration) can interact to guide floral choice in bumblebees (Bombus), complicating our ability to predict pollinator preferences based on a single reward trait in isolation. On the other hand, recognition of this nutritional complexity holds promise for understanding what guides floral choice among generalist bees, and thus predicting how co-flowering plants interact via shared pollinators. We share our ongoing research on the nutritional ecology of floral rewards in a community context. To understand how reward composition predicts pollen movement in montane (NV and CA, USA) communities, we quantified the macronutrient content of pollen and nectar offered by Bombus-visited plant species co-flowering in Sierra Nevada meadows. We combined this information with high resolution aerial imagery (10m radius plots around 155 focal plants across 7 species) to identify co-flowering individual plants at pollinator-relevant spatial scales. Further, we apply a network approach to understand how pollen macronutrient ratios link bees and co-flowering plant species. Together, these efforts suggest that a nutritional perspective on the cognitive ecology of pollination may help explain how the drivers of individual bee foraging decisions scale up to a community level.

Dengue superspreading and its impact in surveillance and control strategies

Authors: Vazquez Prokopec Gonzalo, Department of Environmental Sciences. Emory University. Atlanta, GA, United States

Abstract: Abstract. Transmission heterogeneity (TH), whereby a disproportionate proportion of pathogen transmission events aggregates in a small fraction of individuals or geographic locations, is an emerging property of most infectious disease systems. For vector-borne diseases, TH is commonly inferred from the distribution of the number of vectors per host, which could lead to significant biases in situations where vector abundance and transmission risk do not correlate. The combination of human daytime mobility and the low and spatio-temporally heterogeneous density of Aedes aegypti significantly limit the value of entomological measures such as number of females per host as a measure of DENV transmission risk. Longitudinal cohort studies performed in the Amazon city of Iquitos, Peru, since 2007 have identified the activity space (AS), the array of locations that form part of a person’s daily routine, as the unit of DENV transmission. We extended such contact-cluster studies to quantify the distribution of acute DENV cases by AS during two consecutive outbreaks (DENV-4 and DENV-2) that occurred in Iquitos, during 2008-2014. A total of 257 ASs led to the virological detection of 220/1,474 (14.9%) DENV-infected contacts. Significant overdispersion in the distribution of contacts was observed in the presence of subclinical infections, with 34% ASs leading to 64% of all infections. Up to 16% ASs were quantified as super-spreading events. DENV super-spreading was predicted by the non-linear interaction of Ae. aegypti abundance and by host susceptibility to the circulating DENV serotype across the AS. Entomology is, thus, a valuable predictor after considering the intensity of transmission and the susceptibility of the human population. Furthermore, the marked heterogeneity in case distribution, and the role of asymptomatic infections in defining it, highlight important difficulties faced by reactive interventions if those spatial units contributing most to transmission are missed.

Biosurveillance for invasive xylophagous beetles using a DNA metabarcoding approach

Authors: Veillat Loïs[2], Roux Géraldine[1], Roques Alain, Boyer Stéphane and Lopez-Vaamonde Carlos, [1]INRAe, [2]INRAE, France

Abstract: Invasive xylophagous beetles represent a threat to forests worldwide. There is an urgent need to develop a biosurveillance system for early detection of invasive species. New approaches such as DNA metabarcoding allow rapid and accurate identification of species. However, many insects are not detectable with these approaches because they are not referenced in barcode databases. Moreover, these approaches are often expensive, time consuming and based on short DNA sequences, thus limiting taxonomic information.

The aim of this study is to develop an approach based on the MinION long-read sequencer which provides a cheap, direct and fast analysis within the framework of a biomonitoring study of invasive xylophagous insects.

We have used multi-component blends for mass trapping both native and exotic longhorn beetles at several European ports of entry. With this biological material at our disposal, we are developing reference databases of Cerambycides to improve the number of species detectable in metabarcoding analyses. We are also working on the design of beetle-specific primers to amplify short overlapping amplicons and re-construct the entire bracode fragment (658 bp), which would impove the detectability rate of these species using Oxford Nanopore Technology’s MinION portable sequencing platform.

RNA-seq transcriptomics reveals differences in gene expression patterns of Anastrepha obliqua colonizing different fruits: a potential diversification strategy

Authors: Velasco-Cuervo Sandra[1], Galindo-González Leonardo[2], Toro-Perea Nelson[1], [1]Universidad del Valle, Colombia, [2]University of Alberta, Canada

Abstract: Due to the close relationship of phytophagous insects with their host plants, many of them have been specialized in infesting one or several plant species related phylogenetically. In this context, the host-use is considered as a factor that impacts evolutionary trajectories of insects. Despite its importance, research in host-use effect in neotropical insects is scarce, being necessary to identify if the use of different hosts can drive ecological specialization or, if this behavior contributes to formation of generalist species in the Neotropics. One of the main tools to understand plant resources use by phytophagous insects is differential gene expression analysis. In the current study, we propose the fruit fly A. obliqua as a model to understand phenotypic plasticity at the transcriptomic level. since A. obliqua infests host plants from different families that co-exist in sympatry. We sampled fruits from three host-plants: (i) red mombin (Spondias purpurea, Anacardiaceae), their native host; (ii) mango (Mangifera indica, Anacardiaceae), the main host of this pest in the Neotropics; and, (iii) star-fruit (Averrhoa carambola, Oxalidaceae), which belongs to another family also infested by A. obliqua. We assembled the first de novo transcriptome of third stage larvae of this fly using RNA-seq technology. Results identified changes in expression in response to the host plant, which could be indicative of a plastic response of A. obliqua. Preliminary analyses identified an enrichment of serine hydrolase activity in larvae infesting red mombin. These enzymes are commonly associated with digestion in insects, although they have also been reported to be associated with physiological functions of development and the immune system. Other transcripts upregulated in the larvae associated with red mombin included genes of innate immune response, proteolysis and digestion. We also found downregulation on some transcripts associated to inflammatory responses and in the Mariner Mos1 transposase, when larvae of red mombin were compared with mango and start-fruit larvae. Transposons have been suggested to have an adaptive role into the genomes to environmental stresses and can cause rapid evolutionary change in their hosts. This transcriptional plasticity could be related to polyphagy allowing flies to infest new hosts and respond to specific secondary metabolites. We are analyzing if there are SNPs in differentially expressed transcripts, which may indicate genomic differentiation that could contribute to ecological specialization within a continuum of diversification. From the results and data obtained so far, we hope to contribute to the knowledge of metabolic pathways involved in the feeding and survival of A. obliqua and to infer potential strategies of host use diversification.

Role of plant defenses in host-parasitoid interactions

Authors: Venkatesan Radhika[1], Ghosh Enakshi[2] and Aswathi Sasidharan[2], [1]National Centre for Biological Sciences, Bangalore, India, [2]National Centre for Biological Sciences, India

Abstract: Plant defenses play a major role in shaping tri-trophic interactions between plants, insect herbivores, and parasitoid wasps. The characteristic blend of volatiles released by plants upon herbivory, function as attractive cues to parasitoids and as an indirect plant defense. Further, the secondary metabolites in plants alter insect host physiology that might indirectly affect parasitoid choice. This talk will explore the role of glucosinolates, a major class of secondary metabolites found in Brassicaceae in altering parasitoid performance. Using Plutella xylostella as host and two parasitoid wasps, we examine herbivore physiology and parasitoid choice and development. Our study shows that host plant quality mediated changes in insect physiology impacts trophic interactions and parasitoid behavior differentially.

Olfactory perception in elevated ozone: the role of ozone reaction products

Authors: Venkateswaran Vignesh[1], Knaden Markus[1] and Hansson Bill[1], [1]MaxPlanck Institute for Chemical Ecology, Germany

Abstract: Ozone can degrade VOCs mediating insect olfactory perception. How may reaction byproducts affect olfactory perception? Such products may be attractive or aversive or may change blend perception by altering the background. Using Drosophila melanogaster, we target nearly 600 odorants in the DoOR2.0 database (a database of odor-receptor responses), and predict their oxidative breakdown with ozone. We generate a ranked list of the most consistently occurring ozone byproducts and targeted the top ten most occurring products to investigate behavioral and neurophysiological responses. We test the intrinsic valence of flies to compounds, and in the context of the background. We investigate single sensillum responses. Almost all byproducts are perceived as olfactants and range from being attractive to neutral but not aversive when tested individually. When present in the background behavioral change to an attractive, ecologically relevant odour blend of balsamic vinegar was not altered. We observe that most products are perceived by one of the three tested sensilla investigated. Overall, the byproducts of ozone degradation may play only a minor role in disrupting odor perception of ecologically relevant signals. Our study provides a crucial foundation for accounting for ozone degradation of odors by air pollution for insect olfactory perception.

Arthropod assemblages of urban meadows - a multitaxa study

Authors: Venn Stephen, University of Helsinki, Finland

Abstract: Bees, carabid beetles and butterflies were sampled from a set of meadows in the Helsinki capital region. Bees were sampled using coloured pan-traps and netting along transects; carabid beetles were sampled by pitfall trapping and butterflies were sampled using netting along transects. Few meadow butterfly species were recorded, and carabid and bee assemblages were diverse, though did not include threatened species. I recommend that meadow networks are managed by mowing and grazing if possible, and more attention should be given to the management of patches of supplementary open habitat to support meadow assemblages. I suggest that species and taxa traits, particularly relating to dispersal, determine their capacity to persist in an urban environment.

Carabid species structure in grassland habitats is determined by soil and moisture conditions

Authors: Venn Stephen, University of Helsinki, Finland

Abstract: Carabid beetles are a speciose taxon that has been widely used in empirical ecological research studies. I sampled the carabid fauna of diverse grassland habitats in the capital region of Helsinki during the period 2007-2009, to characterize the assemblages of threatened habitat types, such as rocky dry meadows and sheep fescue (Festuca ovina) dry meadows and to determine how urbanization affects the carabid assemblage. Carabid beetles were sampled using pitfall traps, operated from May-September and emptied at 2-3 week intervals. I used NMDS ordination to compare the similarity of the carabid assemblages of different types of grassland, which showed a gradient of changing species composition from fresh grasslands on clay soils to dry grasslands on sandy soils. GLMM modelling of predicted species responses to level of urbanization and grassland type showed complex responses to three classes of urbanization and three habitat types. For instance, Amara nitida and Harpalus luteicornis were sensitive to urbanization, whereas Calathus erratus and Poecilus cupreus were more abundant in urban grasslands. Calathus melanocephalus was more abundant in dry grasslands, Ophonus rufibarbis favoured managed grasslands and Synunchus vivalis favoured fresh grasslands. The rarest species recorded were Amara equestris and Amara consularis, which are currently classified as LC, though until 2010 they were classified as VU.

Urban Effects on Diving Beetles (Coleoptera: Dytiscidae) and Implications for Wetland Management

Authors: Venn Stephen[1], Liao Wenfe[1] and Niemelä Jari[1], [1]University of Helsinki, Finland

Abstract: Urban blue infrastructure plays important roles in the ecology of cities, such as supporting aquatic biodiversity. Urban blue has received less attention than urban green. As consequences, it is unclear how urbanization has affected biodiversity in urban blue and what habitat features are essential for biodiversity to give management advice. We surveyed diving beetles in 26 urban ponds at 11 sites in Helsinki, Finland, with 1-litre activity traps. With generalized linear mixed models (GLMM) and non-metric multidimensional scaling (NMDS), we analyzed how dytiscid species richness and abundance were associated with the percentages of impermeable surfaces, pond margin slopes, and emergent plant coverage in ponds with and without fish. We found that the surrounding impermeable surfaces had negative effects on dytiscid species richness but not their abundance. Both species richness and abundance of dytiscids were lower in ponds with fish than in ponds without fish; both features decreased with increasing margin slopes and decreasing emergent plant coverage in ponds with fish, but not in ponds without fish. Urban wetlands can support a diversity of dytiscids at the regional level. Ponds free from predatory fish are ideal habitats for dytiscid diversity. In ponds with fish, emergent vegetation can be planted to create microhabitats for dytiscids to avoid predators. A diversity of wetland habitats are needed to maintain aquatic biodiversity in urban areas.

Comparison of leaf litter ant communities between core and buffer forests in the UNESCO Crocker Range Man and Biosphere Reserve, Sabah, Malaysia

Authors: Verble Robin[1] and Sumnicht Theodore[1], [1]Missouri University of Science and Technology, United States

Abstract: Borneo is home to the oldest and most diverse tropical forests in the world, but these forests are threatened by conversion, logging, agricultural clearing, and resource overexploitation. In an effort to preserve and conserve this biodiversity, the United Nations Educational, Scientific, and Cultural Organization (UNESCO) established a Man and Biosphere Reserve in the Crocker Range in 2014. The region is managed by the Sabah Biodiversity Centre and Sabah Parks. This reserve consists of three zones-- a highly protected interior core (144,492 ha), a buffer zone where development, tourism and agricultural activities are limited (60,313 ha), and a transition area where economic activities are less restricted (144,579 ha). We examined leaf litter ant biodiversity and community structure in the montane tropical forest of the core and buffer zones in Summer 2019 with the goal of evaluating the ant community structure between the two zones. Tropical leaf litter ant communities are spatially biodiverse and can vary on the 1-m scale. Leaf litter ants were collected via Berlese extraction of 0.25 m2 quadrats of leaf litter among core and buffer forest sites at Inobong Substation, Crocker Range. Ants were sorted to morphospecies using published keys. Total species richness, evenness, similarity, and relative abundance were compared among sampling quadrats, sites and forest zones. Results show predictably patchy ant communities, with differences among quadrats and sites, but limited differences between forest zones. Our results indicate that small place-based organisms are adequately protected by the core and buffer forests.

Pushed to the edge: dispersal syndromes and the eco-evolutionary dynamics of pushed vs. pulled range expansions in micro-wasps

Authors: Vercken Elodie[2], Guicharnaud Chloé[3] and Dahirel Maxime[1], [1]INRA, UMR 1355 Institut Sophia Agrobiotech, Sophia Antipolis, France, [2]National Institute for Agronomical Research (INRA), France, [3]Université Côte d'Azur, France

Abstract: While species ranges have always moved, the eco-evolutionary dynamics of range expansions have become especially relevant today, as human influence reshapes communities worldwide. Contrary to classical “pulled” dynamics, in which the low-density front populations provide most of the “fuel” for the advance, some expansions exhibit dynamics in which high-density rear populations actually “push” the expansion forward. Combining the pushed/pulled expansion concept with evolution at range edges highlights the importance of understanding how density-dependent dispersal or growth evolve during expansions. It has been suggested that not accounting for this may explain failures to predict colonization dynamics of e.g. invasive species or biocontrol agents. The comparative eco-evolutionary consequences of pushed vs. pulled dynamics remain to be studied however, especially in the context of preexisting life-history differences. To better understand these dynamics, we will create replicated range expansions using colonizations of experimental landscapes by Trichogramma micro-wasps, a biocontrol agent. We will compare the ecological and evolutionary dynamics of strains and species varying in dispersal ability, dispersal density-dependence, and in the association of these traits with life history traits. This will allow us to determine to what extent the evolution of density-dependent dispersal is predictable from initial trait architecture, and the consequences for the fate of pushed vs. pulled expansions. We will conclude by linking these experimental results to insights from individual-based models including more realistic trait architecture.

The open bar is closed: restructuration of native parasitoid communities following successful control of an invasive pest

Authors: Vercken Elodie[3], Muru David[3], Borowiec Nicolas[2], Thaon Marcel[1] and Ris Nicolas[3], [1]INRAE Sophia-Anitpolis, [2]INRAE Sophia-Antipolis, France, [3]National Institute for Agronomical Research (INRA), France

Abstract: When an invasive species establishes in a new area and reaches high densities, some antagonists may benefit from this bonanza situation. How such a native community may then evolve after the regulation of the invaders by external outputs – e.g. the deliberate introduction of specialized natural enemies – remains however poorly documented. To investigate this issue, we used the case study of the invasion of the Asian chestnut gall wasp Dryocosmus kuriphilus Yasumatsu in France and its subsequent control by the exotic parasitoid Torymus sinensis. From the survey of 26 locations during 5 years after the T. sinensis introduction, we more precisely analyze how the patterns of co-occurrence between the different native parasitoid species changed through time.

Our results demonstrate that native parasitoid communities show more competition as the D. kuriphilus levels of infestation decreased. During the last year of the survey, two alternative patterns were observed: either native parasitoid communities were almost inexistent, either the native parasitoid communities were dominated by one main parasitoid: Mesopolobus sericeus. We hypothesize that the scarceness of the newly-acquired resource forced the most generalist parasitoids to return to their original hosts, while only the most specialist native parasitoid remained. These results highlight how the “boom-and-bust” dynamics of an invasive pest followed by successful biological control can challenge the structure of native communities of natural enemies.

Optimizing the dose of biocontrol agents depending on local conditions: a mechanistic population growth model for soil-dwelling predatory mites

Authors: Vercken Elodie[4], Pasquier Antoine[2], Ferrero Maxime[3] and Andrieux Thibault[1], [1]Bioline agrosciences, France, [2]French National Institute for Agricultural Research / Bioline agrosciences, France, [3]Independant consultant, France, [4]National Institute for Agronomical Research (INRA), France

Abstract: Western Corn Rootworm (WCR), Diabrotica virgifera virgifera (LeConte) is an important pest of Maize, for which biological control options remain very limited. As WCR eggs and larvae inhabit the first centimeters of soil, soil-dwelling predatory mites are promising candidates as biocontrol agents against this pest. Recent work by our team led in controlled conditions revealed that the mite Gaeolaelaps aculeifer is able to feed on first and second instar larvae of WCR, and substantially reduce damage on maize plants when introduced at the timing of larvae emergence. These results open a promising perspective of biological control against this wildly spread pest.

However, the large-scale use of these mites to control WCR populations is currently facing two major constraints, as (i) the quantity of mites that would need to be spread to efficiently protect the maize is incompatible with economic viability, and (ii) the precise timing of WCR's larvae emergence in a given area is highly sensitive to environmental variations, which makes it difficult to predict. To address both these issues and improve the cost-efficiency balance of these candidate biocontrol agents, we propose an innovative strategy based on the deployment of a small quantity of mites early in the season, that will grow to reach a large-size population in time for WCR larvae emergence. The efficiency of such a strategy will strongly rely on the optimal correspondence between WCR population density, development time, and mites' population growth, all of which will depend directly on local parameters like soil temperature, precipitations, previous year's infestation, or the density of alternative preys.

In order to predict the optimal deployment strategy for soil-dwelling predatory mites, we built a 3-D spatial individual-based model accounting for mites' population growth and distribution in the soil. The model showed that variation in temperature and prey availability among regions directly impacts the initial dose of mites to introduce to reach optimal population size for WCR control at the time of larvae emergence. These results highlight the need for developing individually based advise methods that improve the cost-efficiency of biocontrol products in arable crops.

More bang for your knock(down): Methods and advancements for the cost-effective production of bacteria-derived double stranded RNA

Authors: Verdonckt Thomas-Wolf, KU Leuven, Belgium

Abstract: RNA interference is a highly conserved pathway for the post-transcriptional regulation of gene expression. It has become a crucial tool in life science research, with promising potential for pest-management applications. A major obstacle to applying this technique is the need to produce sufficiently large amounts of qualitative dsRNA in a cost-effective manner. To overcome this issue, much attention has been given to the development and optimization of biological production systems. One such system is the E. coli HT115 strain transformed with the L4440 vector. We recently demonstrated methods for the cost-effective extraction and purification of HT115 derived dsRNA, and its efficacy at inducing knockdowns in a lepidopteran cell line. In the presented study, we further elucidate the qualitative aspects of produced dsRNAs, their effect on the biological target system, and their impact on knockdown success. The insights and results from this poster will empower researchers to conduct otherwise prohibitively expensive knockdown studies, and greatly reduce the production times of routinely or large-scale utilized dsRNA substrates.

Co-occurrence models for global distribution of Robin’s pincushion (Diplolepis rosae) based on citizen science and open-source environmental data

Authors: Veres Robert[1] and László Zoltán[2], [1]Babeș-Bolyai University, Romania, [2]Hungarian Department of Biology and Ecology, Babeş-Bolyai University

Abstract: Species Distribution Models (SDMs) constitute an important tool to assist decision-making in environmental conservation and planning in the context of anthropogenic effects and climate change. Nevertheless, SDM projections are affected by a wide range of uncertainty factors (related to training data, climate projections and SDM techniques), which limit their potential value and credibility. Here we present a case study, where we used citizen science distribution data for Robin’s pincushion, a plant gall induced by Diplolepis rosae (Hymenoptera: Cynipidae) on Rosa spp. (Rosaceae), and explore multiple scenarios regarding the two species joint global distribution. For the generation of joint global distributions, we used pseudo-absence data generated with three different algorithms along with open-source global Bioclim climate, soil and land use data. For pseudo-absence generation, we used the “mopa” R package which provides multiple data generation algorithms and tools for designing JSDMs while combining multiple sources of uncertainty (e.g., baseline climate, pseudo-absence realizations, future projections). The aim of our study was to surpass challenges involving pseudo-absence data generation for presence only data and to develop a general pipeline for global JSDMs based on citizen science and open-source environmental data with the R package “sdm”.

Molecular basis and evolution of sexual dimorphism in Nasonia vitripennis

Authors: Verhulst Eveline[2], Guerra Filippo[1], Rougeot Julien[1], [1]Laboratory of Entomology, Plant Sciences Group, Wageningen University, Netherlands, [2]Wageningen University & Research, Netherlands

Abstract: Insects are well-known for their eye-catching colour differences or extreme size differences between the sexes. These sexually dimorphic traits are subjected to strong evolutionary forces and diversify rapidly within closely related genera or even within a genus, ultimately driving speciation. One essential transcription factor for sexual differentiation in insects is Doublesex (Dsx), which is involved in sex- and species-specific differences of e.g. pigmentation patterns, wing size, wing colour patterns and leg bristle number. The target genes on which Dsx acts, and the developmental and regulatory mechanisms underlying the rapid evolutionary changes are still poorly understood. However, a variety of studies show that most evolutionary novelties are caused by changes in the regulatory elements of pre-existing genes, so called cis-regulatory elements that contain binding sites for transcription factors to regulate gene expression.

The parasitoid wasp genus Nasonia (Hymenoptera) has a suite of sexually dimorphic traits that vary not only between sexes but also between species. One notable feature is wing size which is only sexually dimorphic in N. vitripennis. Males have short wings and cannot fly, while females have long wings and do fly. All three other male and female species in the genus have long wings and flight capabilities. In addition, leg pigmentation is a sexually dimorphic trait in all four Nasonia species; females have dark brown pigmented antennae and legs, while males lack pigmentation and have bright yellow antennae and legs. Lastly, all four Nasonia species have their own blend of sex pheromones that play a role in mate recognition and sexual communication which both evolve and diversify rapidly. This suite of traits makes Nasonia the perfect system to study the molecular basis of sexually dimorphic trait variation.

Here we present our results of Dsx developmental RNA interference experiments on the expression of the sexually dimorphic traits in N. vitripennis. Moreover, we present our identification of the Dsx binding site using the novel techniques, DNA Affinity Purification sequencing (DAP-seq), and our in-house developed DAP-qPCR. We found that N. vitripennis and Drosophila melanogaster Dsx homologs recognize the same extremely conserved sequence, suggesting that the rapid evolution of sexually dimorphic traits happens through gains or losses of regulatory regions of Dsx target genes, rather than in Dsx itself. Knowing the Dsx binding site sequence, we are able to study the Nasonia Dsx interactome and subsequently couple this with our study into the regulatory role of Dsx in the differentiation of the three sexually dimorphic traits: leg pigmentation, sex pheromone composition and wing size within the subfamily, on genus and species level. With this we aim to integrate our molecular understanding of sex determination and sexual differentiation with the rapid evolution of sexually dimorphic traits in insects.

Sex determination in the moth Ephestia kuehniella: Masc duplication and a candidate Fem piRNA

Authors: Verhulst Eveline[5], Marec František[2], Visser Sander[3], Voleníková Anna[1], Provazníková Irena[1], Dalíková Martina[5] and Nguyen Petr[4], [1]1 Institute of Entomology, Biology Centre CAS, Ceske Budejovice 2 Faculty of Science, University of South Bohemia, Ceske Budejovice, Czech Republic, [2]Institute of Entomology, Biology Centre CAS, České Budějovice, Czech Republic, [3]University of Groningen, Netherlands, [4]University of South Bohemia, České Budějovice, Czech Republic, [5]Wageningen University & Research, Netherlands

Abstract: Insect sex determination is a rapidly evolving developmental process with varying levels of gene conservation. Genes at the bottom of the sex determination cascade are highly conserved, while genes at the top of the cascade are mostly very diverse, with the exception of the recently discovered Maleness-on-the-Y (Moy) gene in tephritid fruit flies. Consistent with this evolutionary trend, the sex determination cascade identified in the silkworm, Bombyx mori (Lepidoptera), reveals low conservation with Diptera and Hymenoptera, i.e. only the bottom gene, doublesex, is conserved between these three orders. However, little is known about the molecular mechanism of sex determination in Lepidoptera other than B. mori.

Here we present data on the sex determination system in the Mediterranean flour moth, Ephestia kuehniella. We identified an ortholog of the Masculinizer (Masc) gene through comparison with closely related species, and we discovered a duplication of this gene on the Z chromosome. Knock-down experiments confirmed a conserved role of EkMasc in masculinization as reported in several other lepidopteran species. Subsequently, we did an extensive search of the W chromosome of E. kuehniella and identified multiple copies of Masc. In addition, we identified a short sequence with a high homology to Masc and designated this sequence as a candidate Feminizer piRNA (EkFem piRNA). Using molecular cytogenetic methods, we confirmed that the locus generating EkFem piRNA is located on the W chromosome as expected. Analysis of small RNA sequencing data showed that expression of the candidate EkFem piRNA is initiated during early embryogenesis. These findings indicate a sex determination system involving gene silencing through short RNAs. A comparison of the sex determination systems of B. mori and E. kuehniella thus suggests a similar primary feminizing signal in these species.

Assessment of the role of vectors for lumpy skin disease virus (LSDV) transmission

Authors: Veronesi Eva[2], Paslaru Anca[3], Vögtlin Andrea[1], Varga Jasmin[4], Maurer Lena[4], Renzullo Sandra[1] and Ruedin Yelena[1], [1]Institute of Virology and Immunology (IVI), Mittelhäusern, Switzerland, [2]University of Applied Sciences of Southern Switzerland - SUPSI Microbiology Dept, Switzerland, [3]Vector Entomology Unit, Institute of Parasitology, University of Zürich Institute of Virology and Immunology (IVI), Mittelhäusern, Switzerland, [4]Vector Entomology Unit, Institute of Parasitology, University of Zürich, Switzerland

Abstract: Lumpy skin disease (LSD) is an OIE listed viral disorder of cattle as a consequence of severe infections leading to high economic losses. Until 1989, the occurrence of LSD was restricted to the African continent. In 2015, the first European outbreak occurred in Greece, and in 2016 many countries of the Balkan region (Serbia, Kosovo, Bulgaria, Romania, Albania, Montenegro and FYR Macedonia) were affected resulting in a large economical loss. As a result of intensive vaccination campaigns, only Greece and FYR Macedonia were still reporting LSD cases in 2017 in Europe. In 2018 Turkey, Russia and Georgia still reported cases and in 2019 only Russia and Israel. The explosive spread of LSD in the Balkan countries, however, was reminiscent to the recent spread of the Culicoides-transmitted bluetongue virus in Europe. Although the role of arthropods in the transmission of LSDV is still unclear, it has been postulated Stomoxys calcitrans being the main incriminated vector based on circumstantial evidence and mathematical models.

This work is presenting data of a two-year project (2018-2020) funded by the Swiss Federal Food Safety and Veterinary Office (FSVO grant nr. 1.18. d) investigating the transmission efficiency (mechanically and biologically) for LSDV among field-collected and laboratory-reared mosquitoes (Aedes japonicus, Culex pipiens, and Aedes aegypti), Culicoides (Culicoides obsoletus, Culicoides pulicaris spp., and Culicoides nubeculosus) and flies (Stomoxys calcitrans). Arthropods were exposed to LSDV spiked blood, followed by their incubation under realistic fluctuating climatic conditions. Quantification of viral DNA was carried out from body parts (mouth part, head and abdomen) and faecal shedding at different time post oral infection.

Bluetongue virus reassortment and vector competence in Culicoides biting midges

Authors: Veronesi Eva[3], Carpenter Simon[2], Sanders Christopher[1], Flannery John[1], Darpel Karin[1], Guimera Marc[1] and Gubbins Simon[1], [1]The Pibright Institute, United Kingdom, [2]The Pirbright Institute, Woking, United Kingdom, [3]University of Applied Sciences of Southern Switzerland - SUPSI Microbiology Dept, Switzerland

Abstract: Bluetongue virus (BTV) is transmitted to its ruminant host almost exclusively during blood-feeding of Culicoides biting midges and causes haemorrhagic disease, bluetongue, especially in sheep. The complex interactions between mammalian hosts, insect vectors and viruses are very challenging to examine experimentally, and studies maybe compromised by needle-inoculation of the virus into the host. By allowing previously infected Culicoides vectors to blood-feed directly on the host, we use a more natural transmission model by feeding naïve insects on infected hosts to explore Culicoides-borne virus transmission dynamics and the impact of genetic drift and reassortment (the exchange of genome segments during coinfection) on the phenotype of virus strains.

The characteristics of three parental BTV strains of different serotypes (BTV-1, BTV-8 and BTV-4) and two field-isolated natural reassortment progeny strains (BTV4), that shared segment identity with either two or three of the parental strains, were examined in sheep. Infection of all sheep by feeding infected Culicoides was achieved, irrespective of BTV strain, even where only 1-3 individual infected Culicoides took a blood-meal. The reassortant strains displayed differential vector competence rate and pathogenicity phenotypes from the parental strains from which they derived. We demonstrate phenotypic differences in viremia and pathology in sheep and vector competence in Culicoides between the 2006 and 2015 re-emergent European strains of BTV-8 despite their genetic similarity.

Additionally, we use an immunofluorescence technique to visualise the infection and replication of BTV in whole organs of infected Culicoides and investigate potential barriers to infection, dissemination and virus transmission from individual insects. We aim to align molecular diagnostics by PCR and virus isolation with the probability of an individual carrying a transmissible BTV infection.

Irradiation as an effective phytosanitary treatment for Drosophila suzukii

Authors: Viana Gomes Inajara[1], Sanchez Jhonatan[1], Andrade Jennifer[1], Caceres Carlos[1], Vreysen Marc J. B.[1], Myers Scott W.[2] and Dias Vanessa S.[1], [1]International Atomic Energy Agency, [2]USDA, APHIS, PPQ, Science and Technology

Abstract: The spotted wing drosophila (SWD), Drosophila suzukii, is a pest native to Southeast Asia that has caused significant economic losses to soft fruit crops. Given that fumigation is the only postharvest treatment currently available for SWD, phytosanitary irradiation has been considered as a promising treatment option for the species. Yet, the validation of a phytosanitary irradiation dose is pending for SWD. We tested whether 80 Gy can provide quarantine security against SWD considering prevention of F1 generation as treatment endpoint. Naturally infested blueberries containing late pupae were either irradiated using gamma rays or left unirradiated as controls. Irradiated and non-irradiated pupae were then removed from the blueberries, counted, and transferred to emergence cages. Emerged females mated with siblings from the same treatments were provided with blueberries as oviposition substrates. Eggs laid in those blueberries were counted and held until the completion of the insects' development. The total number of late pupae irradiated at 80 Gy was 30,058. The females emerged from pupae that had been irradiated at 80 Gy laid a total of 49 eggs, none of which hatched. Our findings suggest that the radiation dose of 80 Gy can be effectively used as a phytosanitary treatment for D. suzukii.

Improving an attract & kill strategy targeting wireworms: influence of biotic and abiotic parameters

Authors: Vidal Stefan[2], Patel Anant[3], Beitzen-Heineke Elisa[1], Hermann Katharina[3], Przyklenk Michael[1], Laurenz Sebastian[2] and Beitzen-Heineke Wilhelm[1], [1]Biocare GmbH Biological Plant Protection, Dassel-Markoldendorf, Germany, [2]Georg-August-Universität Göttingen, Department of Crop Sciences, Agricultural Entomology, Germany, [3]WG Fermentation and Formulation of Biologicals and Chemicals Faculty of Engineering and Mathematics Bielefeld University of Applied Sciences, Germany

Abstract: Wireworms, the larvae of click beetles, are one of the most important insect pests of agricultural and horticultural crops worldwide. In recent decades, wireworm damage has continuously increased repeatedly reaching severe economic levels in particular in potatoes. Efficient and sustainable control measures are desperately needed, specifically in organic but as well as in conventional potato production.

The innovative capsule system ATTRACAP®, based on a biological attract-and-kill strategy against these soil dwelling insect pests takes advantage of the fact that larvae are attracted to CO2. The capsules produce and emit CO2, and an isolate of Metarhizium brunneum grows out of the capsules, with which the wireworms come into contact. Thus, a maximum probability of infection is achieved with a minimized application rate. Field applications on farmer fields and specific experiments have predominantly yielded efficacies up to 70%; however outliers downwards have been observed as well. In order to better understand the reasons for the variable efficiency ranges, we investigated the influence of either improved capsule formulations and production methods and abiotic parameters (soil moisture, humidity, and microorganism activity, respectively), wireworm species composition or application systems in experimental fields. Results identified soil condition during the first days and weeks after capsule application as a crucial factor influencing the efficiency of this Attract & Kill strategy. Technical solutions are available to take these different influencing factors into account. However, the very limited flexibility of the EU registrations conditions makes the implementation of site-adapted capsule types unlikely.

Defensive shimmering responses in the giant honeybee Apis dorsata are triggered by dark stimuli moving against a bright background

Authors: Vijayan Sajesh[2], Warrant Eric[1] and Somanathan Hema[2], [1]Department of Biology, Lund University, Sweden, [2]Indian Institute of Science Education and Research Thiruvananthapuram

Abstract: Due to the absence of physical barriers, the open-nesting giant honeybee Apis dorsata has evolved a spectacular collective defence behaviour – known as “shimmering” – against predators, which is characterised by travelling waves generated by individual bees flipping their abdomens in a coordinated and sequential manner across the bee curtain. We examined if shimmering is visually-mediated by presenting moving stimuli of varying sizes and contrasts to the background (dark or light) in bright and dim ambient light conditions. Shimmering was strongest under bright ambient light, and its strength declined in dim-light. A. dorsata shimmered only when presented with the darkest stimulus against a light background, but not when this condition was reversed (light stimulus against dark background). We suggest that this is an effective anti-predatory strategy in open-nesting A. dorsata colonies, exposed to high ambient light, as flying predators are more easily detected when they appear as dark moving objects against a bright sky. Moreover, the stimulus detection threshold (smallest visual angular size) is much smaller in this anti-predatory context (1.6° - 3.4°) than in the context of foraging (5.7°), indicating that ecological context affects visual detection threshold.

Combining new strains of predators, feeding strategies and hairless mutant cultivars to improve preventive control of pests on tomato

Authors: Vila Enric[2], Castañé Cristina[3], Alomar Oscar[3], Riudavets Jordi[3], Herzog David[5], Glas Joris[4], González Mónica[1] and Arévalo Ana Belén[1], [1]Agrobío S.L., [2]Agrobío S.L., Spain, [3]IRTA, [4]Rijk Zwaan Breeding B.V., [5]Rijk Zwaan Ibérica S.A.

Abstract: Aculops lycopersici is a key pest on tomato on a worldwide scale, causing severe damages in protected crops. The difficulty in controlling this pest with pesticides has enhanced the interest in biocontrol. Transeius montdorensis was reported as a promising predator. In this study preventive strategies have been evaluated by IRTA and Agrobío, based on introductions of this predator combined with releases of astigmatid mites as complementary food.

Rijk Zwaan Breeding BV has selected a tomato mutant that does not produce the type VI glandular trichomes. Utilizing these tomato cultivars gives new opportunities to apply biocontrol with natural enemies that otherwise would not survive on tomato plants. It has been stated that these varieties are less affected by A. lycopersici. However, preliminary trials have showed that these plants may be more vulnerable to other pests, such as thrips.

Two field trials by Rijk Zwaan and Agrobío have showed that a new strain of Orius laevigatus, performing better with suboptimal diets, can be established on tomato when combined with in-crop feeding strategies, improving the control of thrips. New designed mixed diets to favor a ‘standing army’ which improves the preventive control in the mutant varieties are discussed.

Beyond Arge, a phylogenetic hypothesis for argid sawflies (Hymenoptera: Tenthredinoidea) based on adult/larval morphology and genetic data

Authors: Vilhelmsen Lars[1], Malagon-Aldana Leonardo[2], [1]Associate professor Natural History Museum of Denmark University of Copenhagen, Denmark, [2]PhD student Natural History Museum of Denmark University of Copenhagen, Denmark

Abstract: Argidae belongs to the ancient phytophagous lineages (“Symphyta”) of the megadiverse order Hymenoptera; this is the second most diverse family of sawflies including more than 900 species and 60 genera distributed worldwide, with more than 300 species in the cosmopolitan genus Arge. However, the highest diversity of Argidae genera is found in South America. The Gondwanan family Pergidae has frequently been retrieved as the sister group of Argidae. To develop a phylogenetic hypothesis for Argidae and explore its relationship with Pergidae, we analyzed a data set of more than 220 adult morphological characters for adults, 65 larval characters, and six molecular markers (mitochondrial, ribosomal and nuclear). The most complete dataset was achieved for the adult morphological component, with a total of 110 terminals, representing all argid genera and 22 outgroup taxa from other tenthredinoid families, including 10 Pergidae. For morphological characters we use maximum parsimony criterion, while for the molecular markers different models of DNA evolution were used under Maximum likelihood and Bayesian inference estimations. In the analyses, Argidae was usually retrieved as monophyletic and sister to a monophyletic Pergidae, except for the Australian genus Zenarge, which is placed as sister to (Argidae s. str. + Pergidae). We propose a new subfamily classification for Argidae, analyze character evolution, historic biogeography and discuss taxonomic changes, including raising Zenarge (Zenarginae) to family status.

Bugdex – changing the way we learn about insects

Authors: Vilhelmsen Lars[1], K.-B. Cheung David[2] and Nørgaard-Kræmer Line[3], [1]Associate professor Natural History Museum of Denmark University of Copenhagen, Denmark, [2]DKB Digital Designs Ottawa, Canada, [3]Natural History Museum of Denmark SCIENCE University of Copenhagen, Denmark

Abstract: The world is filled with an overwhelming diversity of insects that is innately fascinating, but hard to get to grips with initially. Learning how to identify insects is very difficult and represents a threshold that might deter newcomers. Bugdex is an educational app that combines mobile technology, awe-inspiring animations and interactive design; it aims to both simplify insect identification and inspire future generations of entomology students. The app at its core is an identification key to common northern European and North American insect orders and families and is richly illustrated with interactive multimedia elements designed to inspire students to discover the wonders of entomology around them. Bugdex is being produced by DKB Digital Designs and the Natural History Museum of Denmark in collaboration; the app will be made freely available both for iOS and Android devices. The first planned output is a key to Insect orders of the world that will be published in multiple languages. Next, family level guides to common of northern European and North American Lepidoptera, Coleoptera, Diptera, Hemiptera and Hymenoptera will be released as updates. The complete set of guides is expected to be available before the end of 2023.

Molecular identification of Blowflies used in Maggot Debridement Therapy

Authors: Villet Martin[3], Williams Kirstin[2], Cronje Frans[4] and Tantawi Tarek[1], [1]Department of Zoology, Faculty of Science, Alexandria University, Egypt, [2]KwaZulu-Natal Museum Rhodes University, South Africa, [3]Rhodes University, South Africa, [4]Stellenbosch University, South Africa

Abstract: The use of maggots to clean necrotic wounds, known as maggot debridement therapy (MDT), has long been known to the scientific world. Various species of flies have been used for MDT, the most commonly used being Lucilia sericata, a greenbottle blowfly. This fly is closely related to another greenbottle, L. cuprina, but L. cuprina feeds on live as well as necrotic tissue, which is undesirable in MDT. L. cuprina is commonly named the ‘sheep blowfly’ because it is responsible for fly-strike in sheep, a form of myiasis that can kill sheep. L. sericata and L. cuprina are similar in morphology and it is extremely difficult to correctly identify them (especially females) using the literature as many characters in these works are subtle and subjective.

Flies were sampled from a laboratory colony of putative Lucilia cuprina at the Eugene Marais Hospital in Pretoria, South Africa and another of putative Lucilia sericata at Alexandria University in Egypt. DNA was extracted and polymerase chain reaction (PCR) amplification was performed. A total of 654 base pairs were sequenced for the 28S gene and a total of 601 base pairs were sequenced for the COI gene. Maximum Parsimony and Bayesian Inference analyses were used to analyse the data. The results indicated that L. sericata was being cultured at the Eugene Marais Hospital and L. cuprina was being cultured in Alexandria. This was unexpected and suggests that (1) these two flies are easily confused even in laboratory settings, and (2) L. cuprina can be safely used for maggot debridement therapy under controlled conditions.

The effects of larval density of Black Soldier Fly (L., 1758) (Diptera: Stratiumyidae) under scalable conditions

Authors: Villet Martin[3], Pryke James[4], Brits Devon[2] and Richards Cameron[1], [1]AgriProtein Technologies, South Africa, [2]Louisiana State University, United States, [3]Rhodes University, South Africa, [4]Stellenbosch University, South Africa

Abstract: Contemporary research has focussed on the mass rearing and up-scaling of Black soldier fly for feed production for livestock (i.e. poultry, swine and aquaculture) around the world due to H. illucens’ unique and sustainable characteristics. However, larval density is poorly known in terms of scale and the reliability of data that has been produced. Therefore, this study looks at optimizing larval feeding densities and attempts to show the effects of larval population scaling effects on survival and feeding efficiency of BSF. The first study examines what effects feeding/provisioning rations (mg/larva/day) have on varying larval densities and their feeding efficiencies using treatments between 75-150 and 200 mg/larva/day at set depths and feed particle sizes. The second study uses five treatments of population size in orders of magnitude between 5 and 50 000 individuals to test how this variable affects feeding efficiencies. Various dependent variables were investigated at set environmental conditions over a 15-day period on 6-day-old larvae for the 1st study while larvae were portioned and left to feed undisturbed for a full 21 days. In study 1, larvae fed on catering waste showed significant differences in most feeding efficiency variables at densities above 100 mg/larva/day, and positive trends in larval mass, prepupation rates and survival rates with increasing provisioning rations. Larvae could access feed within the first week and aggregations were at their hottest within the first three days of experimentation. Additionally, significant differences were noted between treatments in waste reduction, bioconversion, and crawl-off biomass. Study 2 showed, larval body mass reduces as population size increases but variation decreases above 500 larvae treatments. Bioconversion showed a promising linear increase with treatment but it is recommended that harvesting methods should be evaluated for future research. Recommendations and optimal conditions are suggested and discussed from the shown results and future considerations are mentioned.

Computational assisted development of novel insect control traits

Authors: Vinocur Basia[1], Emmanuel Eyal[1] and Rotem Or[1], [1]Evogene Ltd, Israel

Abstract: Genetically modified crops expressing Bt toxins have been a mainstay of insect control in the row crops industry since the late 1990s. However, with only a handful of resistance traits available to date in the market, these traits control merely a subset of the target pests and are being steadily broken due to their extensive use. Development of new resistance traits is, therefore, an urgent market need.

Over the past six years Evogene has been waging a computational discovery and optimization effort to deliver novel bacterial toxins applicable against major and emerging pests of Corn, Soybean and Cotton from the Lepidoptera, Coleoptera and Hemiptera insect orders. Dedicated big data composed of proprietary as well as publicly available genomes and metagenomes were mined using custom-made computational predictive tools, capable of associating insecticidal activity and complimentary attributes, required for trait functioning, with proteins having no prior insecticidal indication. Experimental validation in vitro and in planta led to establishment of novel toxins and toxin families that address different pests utilizing non-Bt mechanism of action. Rationale-based sequence optimization further drove toxin efficacy towards industrial grade.

In this talk the enabling technology and trait development advancements made with selected toxins and toxin families will be presented.

Wing shape variability and flight performance of invasive box tree moth

Authors: Viric Gasparic Helena[6], Bjelis Mario[4], Mikac Katarina M.[5], Novak Hrvoje[1], Dominguez Davila Jose H.[3], Pajac Zivkovic Ivana[7], Benitez Hugo A. [2] and Lemic Darija[7], [1]ICENT - Innovation Centre Nikola Tesla, [2]Laboratorio de Ecologia y Morfometria Evolutiva, [3]South Coast Structural Engineers, [4]University of Split, University Department of Marine Studies, [5]University of Wollongong, Faculty of Science, Medicine and Health, [6]University of Zagreb Faculty of Agriculture, Department of Agricultural Zoology, Croatia

Abstract: Box tree moth (Cydalima perspectalis, Walker) is an invasive species that has been present in Croatia since 2012, causing great damage to plants of the genus Buxus. The pest spreads rapidly, has high reproductive potential and good adaptability. The known natural dispersal velocity is up to 10 km per year. The objective of this study was to assess wing shape variability, flight propensity and of C. perspectalis and to evaluate its invasive character using geometric morphometric methods and the flight mill technique. An inter-site analysis was conducted, and the dataset was partitioned by geographic area, with intraspecific variation determined independently. Results indicate that wing shape is influenced by agroecological factors, with forewings being more plastic than hindwings. Regarding sexual differentiation, multivariate regression of wing shape revealed minimal differences between male and female forewings, with female wing shapes being more variable and covering a large percentage of the shape space. C. perspectalis flew a maximum distance of 15.6 km (virgin females) and spent a maximum flight time of 241 minutes (4 hours). The average speed of C. perspectalis ranged from 1.1 m/s to 1.6 m/s. Knowledge of the wing characteristics and flight performance of C. perspectalis is imortant in assessing dispersal and provides insights into migratory activities. Understanding the flight characteristics of insect pests is critical to developing effective strategies and programs for their management.

Is culture-based method effective for identification of insect gut mycobiome?

Authors: Višnovská Denisa[3], Drozd Pavel[5], Kolarík Miroslav[4], Šigutová Hana[2], Šigut Martin[2], Kostovcík Martin[1], Kotásková Nela[2], Dornák Ondrej[6] and Pyszko Petr[6], [1]Charles University; Institute of Microbiology of the Czech Academy of Sciences, Czech Republic, [2]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic, [3]Department of Biology and Ecology, Faculty of Science, University of Ostrava, Czech Republic; Microbiology Institute, Academy of Sciences, Czech Republic, [4]Microbiology Institute, Academy of Science of the Czech Republic, Department of Botany, Faculty of Science, Charles University, [5]University of Ostrava - Faculty of Science, Czech Republic, [6]University of Ostrava, Czech Republic

Abstract: Next-generation metabarcoding is becoming an indispensable tool in microbial community ecology and with the implementation of this is rapidly changing our understanding of the insect symbiosis by uncovering high fungal and bacterial diversity, which is often host specific. Due to the progress in molecular methods for the characterisation of the composition of the microbial community, NGS methods (DNA metabarcoding) have been used recently, while traditional cultivation followed by Sanger technology was used only for the isolation and more accurate identification of specific species. In fact, both approaches with their pros and cons are considered complementary. In particular, the availability of cultures allows species-level identification using the entire ITS barcode and alternative genes, whereas metabarcoding provides rather a genus or family-level identification.

Our study is a comparison of culture-dependent approaches (strain isolation plus molecular identification) and culture-independent approaches (metabarcoding) to characterize the diversity of the gut mycobiota of lepidopteran larvae. We sampled larvae from four tree species (Acer platanoides, Corylus avellana, Carpinus betulus, and Quercus robur). The guts of more than 60 individual larvae were subjected to ITS2 rDNA metabarcoding on the Miseq Illumina platform and simultaneously to Sanger based DNA barcoding of ITS rDNA of fungal strains.

Our results show that cultivation using a single medium did not allow us to characterize the mycobiome as accurately as metabarcoding. The diversity of genera in cultivations was 16 times lesser than those obtained by metabarcoding. In total metabarcoding covered 98.7% of genera found by cultivations, i.e., only 8 genera were unique for culture-based method. Other species identified by cultivation were evaluated as the most abundant fungal taxa obtained in metabarcoding. Our results clearly show that NGS methods are the most effective method for the identification of the insect gut microbiome with minor information losses. Information obtained from metabarcoding should be careful with respect to the possibility of contamination and identification of genetic material from dead organismal cells. On the other hand, culturing has allowed for more precise identification, which is invaluable when studying the ecology of individual components of the mycobiome.

The research was supported by the Czech Science Foundation (GA18-08803S, GA22-29971S) the Student Grant Competition projects of the University of Ostrava (SGS14/PrF/2022).

Close the circle: recycling by-products to develop standardized diets for edible insects

Authors: Vitale Maria Luisa[1], Verrastro Vincenzo[1], Avosani Sabina[1] and Lamaj Flutura[1], [1]CIHEAM Bari, Italy

Abstract: Tenebrio molitor was the first insect approved as a novel food by EFSA in 2021 and is currently one of the leading edible insects due to its nutritional value and food conversion rate. Within the European project CoRoSect, we aim at formulating a standardized diet for T. molitor based on agriculture and food industries by-products, to promote a more sustainable food production chain. Potato peels, tomato peels, brewer's spent grain and olive oil pomace were selected considering local availability, seasonality, and already-existing recovery paths. The by-products were dried, ground and chemically analyzed to define their physical and chemical composition. Wheat bran was used as control. Each by-product was provided ad libitum alone, although small pieces of pumpkin were used as water source. The diets' performance was evaluated considering larval mortality, larval weight gain and the amount of diet consumed. Ten replicas (n=20 larvae per replica) were performed and allowed the identification of the most promising by-products. The latter are going to be combined to formulate mixed diets that will be tested with a higher number of individuals, simulating intensive farming conditions, to provide a standardized and more sustainable food source for T. molitor. Results are presented and discussed at ICE22.

Investigating the black soldier fly's mycobiome composition "natural habitats" and it's metabolic effect on the larvae

Authors: Vitenberg Tzach[1] and Opatovsky Itai[1], [1]MIGAL, Israel

Abstract: In recent years, extensive information regarding the interactions between insects and bacteria was found, however, the interactions between the insects and fungi remain vague. Yeast and yeast-like fungi have significant metabolic complexity that can provide nutrients such as proteins, fatty acids and vitamins for insects. This study focuses on the interactions between fungi and the black solider fly (Hermetia illucens; BSF), which is efficient in the process of converting diverse organic wastes into nutritional valued biomass for animal feed. As BSF lives in environments of rotten organic material, which thrive with bacteria and fungi, we hypothesis that the coexistence of this insect and the fungi will lead to metabolic interactions that will benefit the BSF. In this study, BSF were collected from natural environment and the mycobiome composition, in the insect's gut and environment was analyzed using next generation sequencing. The main yeast species that was found in both the insect's gut and the insect environment was Candida spp.. In order to test whether this yeast like fungi affects the BSF life cycle and metabolic pathways, a metabolome analysis was conducted to BSF larvae that were fed with the fungi in laboratory experiments.

Microbial management and social immunity in burying beetles

Authors: Vogel Heiko[2], Heckel David[3], Vilcinskas Andreas[4] and Kaltenpoth Martin[1], [1]Department for Evolutionary Ecology, Institute for Organismic and Molecular Evolution, Johannes Gutenberg University Mainz, Hanns-Dieter-Hüsch-Weg 15, 55128 Mai, [2]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [3]Emeritus Group Entomology, MPI for Chemical Ecology, Germany, [4]Institute of Insect Biotechnology, Justus-Liebig University, Germany

Abstract: The tremendous evolutionary success of insects is at least in part owed to microbial symbionts which help them to explore novel ecological niches such as the ability to utilize unusual diets. Selective pressures from xenobiotics, nutrient limitations and natural pathogens may contribute to driving insects to adapt towards and enable exploitation of these diets.

An intriguing example of food preservation and controlling food-associated microbiomes are the burying beetles (Nicrophorus spp) that have evolved to occupy a unique ecological niche by reproducing on small vertebrate cadavers buried in the soil. Carrion-feeding insects that breed on decaying carcasses must overcome the challenges arising from competing microbes, which decrease its nutritional value and render it unpalatable or even toxic to animals. Adult burying beetles use effective counterstrategies to reduce detrimental microbial activity by treating the carcass with anal and oral secretions. We show that the burying beetle modifies the microbial communities of carrion, since beetle-tended carcasses showed no signs of degradation and supported the growth of the beetles' gut microbiota, including the yeast Yarrowia, in a biofilm-like matrix. In contrast, untended carcasses showed visual and olfactory signs of putrefaction and supported the growth of endogenous and soil-originating microbial decomposers. The beetles and their microbiome thus coordinate a specialized adaptive strategy of carrion management, enabling them to preserve carrion quality and support larval growth on a challenging resource.

Large-scale mitogenomics as a phylogenetic framework for insect biomonitoring across Earth's biomes

Authors: Vogler Alfried[1], Creedy Thomas[2], Liu Huaxi[2], Dawson Beth[1], Garner Beulah[3] and Zhou Zichen[1], [1]Imperial College London, [2]Natural History Museum

Abstract: Hyperdiverse insect groups such as Coleoptera are too poorly known for a global monitoring program. Mitochondrial genomes can be sequenced with relative ease and are a powerful marker to provide an increasingly complete phylogenetic tree of global lineage diversity and biogeographic distributions. We bulk sequence high-biodiversity samples from sites around the world (see www.site-100.org) and generate mitogenome sequences via a genome skimming technique to produce the phylogenetic framework of insect diversity composed of numerous regional samples. The resulting densely sampled tree is used to place any species encountered in (meta)barcoding using COI or other mitochondrial markers with high accuracy. Vice versa, the (meta)barcodes are added to the tree, for an ever more complete inventory at the species level, and themselves can help the placement of additional species not present in the tree. The approach thus goes beyond the standard biomonitoring schemes recording species presence/absence, and instead provides a phylogenetic fingerprint of local sites relative to a global sample of biodiversity, for measures of endemicity, phylogenetic diversity (PD), and functional diversity etc. of local communities, and their responses to global change.

The phylogenetic diversity of beetles in tropical forests

Authors: Vogler Alfried[3], Yeo Darren[4], Liu Huaxi[5], Nie RuiE[1], Ounjai Sarawut[2] and Creedy Thomas[5], [1]Chinese Academy of Sciences, China, [2]Imperial College London and Natural History Museum, United Kingdom, [3]Imperial College London, United Kingdom, [4]National University of Singapore and Imperial College London, Singapore, [5]Natural History Museum

Abstract: Tropical forests hold huge species diversity, but global patterns remain poorly known because of the greatly incomplete taxonomic inventories. We use 'genome skimming' from bulk samples of Coleoptera to generate mitochondrial genome sequences for a comprehensive set of species in several tropical forests around the world. Combining these data across sites provides a phylogenetic fingerprint of each local species assemblage. Sequencing from numerous such sites also provides a picture of the biogeographic distribution of the lineages present, and when combined with short DNA barcode and metabarcode sequences, these phylogenetic trees can produce an increasingly complete inventory of the biogeographically confined lineages of beetles on Earth. We demonstrate the power of this approach for characterising insect diversity in local forest sites in the context of the global phylogeny and, vice versa, how the inclusion of individual sampling sites improves the understanding global biodiversity patterns. The SITE-100 (www.site100.org) project implements this approach as a collaboration among researchers studying forest sites around the world.

Social environment and pathogen exposure influencing ant survival and gene expression

Authors: Vojvodic Svjetlana[2], Scavetta Joseph[1], Walsh Justin[3], Warner Michael[3] and Linksvayer Timothy[3], [1]Rowan University, United States, [2]Rowan University, United States, [3]University of Pennsylvania, United States

Abstract: Social structures that involve group living can induce a high rate of disease transmission and leave many individuals vulnerable to the infection. Eusocial insects are particularly under high disease pressure due to a close genetic relatedness and dense living conditions. To resist an epidemic, individuals perform behaviors that can reduce the disease outbreak among the infected members; broadly termed as social immunity. To observe the effects of social living and social immunity on the pathogen resistance, acorn ants Temnothorax curvispinosus were inoculated with the entomopathogenic fungus. After inoculation, ants were either kept in isolation or placed into groups and their survival was recorded. Subset of ants were dissected and tested for differently expressed genes one-day post pathogen or sham exposure. This study shows that the ant social environment plays a crucial role in the pathogen resistance, with differentially expressed genes in the head, mesosoma and gaster.

Diverge or converge: Differential trends in the macroevolution of defences among lowland and highland willow species

Authors: Volf Martin[1], Segar Simon T.[2], Souto-Vilaros Daniel[3], Salminen Juha-Pekka[4], Vojtech Novotny[5], [1]Biology Centre, Czech Academy of Sciences, Ceske Budejovice, Czech Republic, [2]Department of Crop and Environment Sciences, Harper Adams University, Newport, United Kingdom, [3]Faculty of Science, Charles University, Prague, Czech Republic, [4]Natural Chemistry Research Group, Department of Chemistry, University of Turku, Finland, [5]Biology Centre, Czech Academy of Sciences, Ceske Budejovice, CZ Faculty of Science, University of South Bohemia, Ceske Budejovice, Czech Republic

Abstract: Plants produce astonishing diversity of defensive metabolites in response to selection by the environment. To find the underlying mechanisms behind the variation in plant chemical defences, we need to understand how the prevailing environmental conditions contribute to their quantity, richness and variation between plant species. Species-rich plant genera with large elevational rages, such as willows (genus Salix L.), are ideal model systems for studying the macroevolution of defences in plants experiencing different selection pressures. Here we used willow species growing at different elevations to explore if macroevolution of defences follows different trajectories in plants exposed to different levels of abiotic and biotic stress. Our results show that lowland and highland plant species invest into different defensive traits as suggested by previous studies. However, we also show that the different macroevolution of traits among lowland and highland plants does not concern just the identity of the traits but also the trajectories by which they evolve. Lowland environment seems to promote variation in the type of defences employed and to generally promote divergence in defences among willow species. Contrastingly, highland environment selects willows for conservatism in their chemistry and supports directional trends towards escalation or de-escalation in individual traits, depending on their importance for the highland plants. These directional trends have pronounced effects on the macroevolution of chemical diversity in plant in terms of both richness and structural variation in metabolites employed by plants experiencing various environmental pressures.

Functional analysis of ichnovirus particles production

Authors: Volkoff Anne-Nathalie[1], Lorenzi Ange[2], Ravallec Marc[1], Jouan Véronique[1], Eychenne Magali[1] and Girard Pierre-Alain[1], [1]INRAE, [2]University of Georgia

Abstract: A crucial question considering endogenous viral elements (EVEs) found in parasitic wasps remains which viral functions have been retained during the virus domestication process. In ichneumonids, EVEs consist in tens of viral loci dispersed in th wasp genome. They include clusters of endogenized viral genes that compose the functional machinery allowing the wasp to produce virus-like particles. The other viral loci correspond to sequences that serve as templates to generate circular molecules encoding virulence genes and which are packaged into the particles to be delivered to the parasitoid’s host.

Ichneumonid EVEs derive from the integration of a non-determined virus and the genes composing the viral machinery have no similarity with known sequences. As a consequence, the function of such viral genes cannot be predicted. Our objective is to unravel their specific role in the different steps leading to the production of particles in the wasp ovaries. For that, we used RNA interference (RNAi) to silence a number of candidate viral genes. Using this approach combined with transmission electron microscopy observations, we were able to identify endogenized viral genes involved in particle assembly and particle trafficking.

A remarkable legion of guests: diversity and host specificity of army ant symbionts

Authors: von Beeren Christoph, TU Darmstadt, Ecological Networks, Germany

Abstract: Tropical rainforests are among the most diverse biomes on Earth. While species inventories are far from complete for any tropical rainforest, even less is known about the intricate species interactions that form the basis of these ecological communities. One fascinating but poorly studied example are the symbiotic associations between army ants and their rich assemblages of parasitic arthropod guests. Hundreds of these guests, or myrmecophiles, have been taxonomically described. However, because previous work has mainly been based on haphazard collections from disjunct populations, it remains challenging to define species boundaries. We therefore know little about the species richness, abundance and host specificity of most guests in any given population, which is crucial to understand co-evolutionary and ecological dynamics. Here, we report a quantitative community survey of myrmecophiles parasitizing the six sympatric Eciton army ant species in a Costa Rican rainforest. Combining DNA barcoding with morphological identification of over 2,000 specimens, we discovered 62 species, including 49 beetles, 11 flies, one millipede and one silverfish. At least 14 of these species were new to science. Ecological network analysis revealed a clear signal of host partitioning, and each Eciton species was host to both specialists and generalists. These varying degrees in host specificities translated into a moderate level of network specificity, highlighting the system's level of biotic pluralism in terms of biodiversity and interaction diversity. By providing vouchered DNA barcodes for army ant guest species, this study provides a baseline for future work on co-evolutionary and ecological dynamics in these species-rich host-symbiont networks across the Neotropical realm.

High-tech droplet digital PCR (ddPCR) diagnostics for pesticide resistance monitoring and management in major agricultural pests

Authors: Vontas John[2], Mavridis Konstantinos[1], Papapostolou Kyriaki Maria[6], Riga Maria[6], Michaelidou Kleita[7], Tsagkarakou Anastasia[5], Van Leeuwen Thomas[3], Bass Chris[8], Ilias Aris[4], [1]Agricultural University Athens, Greece, [2]Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology Hellas, Heraklion, Crete, Greece, [3]Department of Plants and Crops, Ghent University, Belgium, [4]Foundation for Research & Technology Hellas, Institute of Molecular Biology & Biotechnology, Heraklion Crete, Greece, [5]Hellenic Agricultural Organization "DIMITRA", Heraklion, Greece, [6]IMBB-FORTH, Heraklion, Greece, [7]School of Medicine, University of Crete, Heraklion, Greece, [8]University of Exeter, United Kingdom

Abstract: Decisions on which pesticide to use in agriculture are expected to become more difficult, as the number of available chemicals is decreasing. For major pests for which a number of candidate markers for pesticide resistance are available, molecular diagnostics could support decision-making for the rational use of pesticides. A suite of twenty TaqMan assays was developed to assay target site mutations in T. urticae mites, B. tabaci whiteflies and F. occidentalis thrips, validated against Sanger-sequencing, and adapted for use with ddPCR in bulk pooled samples. The achieved LoD was as low as 0.1% (detection of a 1 mutant in a background of 999 wild type pests). The assay panel was assessed in terms of agreement with phenotypic resistance, through a pilot application in field populations, with strong correlation and thus diagnostic value of the molecular assays in some cases. It was also able to capture incipient resistance that was missed by phenotypic bioassays in other cases. DdPCR diagnostics could prove a valuable tool for pesticide resistance management. This work was supported by the European Union's Horizon 2020 research and innovation program (Grant: 773902-SuperPests) and the project 'SmartPP', funded by the Crete Operational Program 2014-2020 and ERDF (Action 1.b.1, RIS3Crete).

Molecular characterization of insecticide resistance in malaria and arbovirus vectors and access to advanced diagnostic tools (INFRAVEC2)

Authors: Vontas John[2], Chaskopoulou Alex[7], Mavridis Konstantinos[1], Grigoraki Linda[8], Kefi Mary[4], Fotakis Max[5], Bellini Romeo[3] and Balabanidou Vasileia[6], [1]Agricultural University Athens, Greece, [2]Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology Hellas, Heraklion, Crete, Greece, [3]Centro Agricoltura Ambiente, Department of Sanitary Entomology and Zoology (EZS), Italy, [4]Department of Biology, University of Crete, Heraklion, Greece, [5]Department of Crop Science, Laboratory of Pesticide Science, Agricultural University of Athens, Athens, Greece, [6]Institute of Molecular Biology and Biotechnology, Foundation of Research and Technology, Heraklion, Greece, [7]USDA-ARS European Biological Control Laboratory, Thessaloniki, Greece, [8]Vector Biology, Liverpool School of Tropical Medicine, Liverpool, United Kingdom

Abstract: Abstract The intense use of insecticides in vector and agricultural pest control programs has resulted in a dramatic selection of resistance in mosquito populations to such an extent that their control becomes exceedingly challenging. We investigate the mechanisms of insecticide resistance, by using a variety of classical and modern approaches, including bioassays, transcriptomic studies, functional expression and characterization of recombinant proteins, immunohistochemical stainings and genome-editing CRISPR/Cas9 approaches, aiming to understand the role of specific genes and mutations in the resistance phenotype. Examples from our most recent studies include: (1) the elucidation of leg-based pyrethroid resistance mechanisms in the major malaria vector Anopheles gambiae, (2) the characterization of temephos and pyrethroid resistance in Aedes albopictus, (3) the characterization of target site diflubenzuron resistance in Culex pipiens and (4) the development of sample-to-answer multiplex molecular diagnostics for malaria and arbovirus vectors. FORTH-IMBB is a partner in the INFRAVEC2 Horizon2020 EU project and provides access to infrastructures for insecticide resistance research at no cost to the end-user, such as: (a) the genotyping of mosquito vectors of malaria and arbovirus for species ID, insecticide resistance traits (metabolic resistance and target site mutations) and detection of pathogens (plasmodium, arboviruses etc) and (b) the analysis of the mosquito cuticle thickness and composition, as a marker of cuticular resistance.

The emergence of multiple insecticide resistance in Tuta absoluta and the implications in the management of the most important tomato pest

Authors: Vontas John[1], Roditakis Emmanouil[3], Tsagkarakou Anastasia[3], Ilias Aris[2], Vasakis Emmanouil[3] and Stavrakaki Marianna[3], [1]Institute of Molecular Biology and Biotechnology, Foundation for Research and Technology Hellas, Crete, Greece, [2]Foundation for Research & Technology Hellas, Institute of Molecular Biology & Biotechnology, Heraklion, Crete, Greece, [3]Hellenic Agricultural Organization "DEMETER", Institute of Olive Tree, Subtropical Crops and Viticulture, Department of Viticulture, Vegetable Crops and Plants, Greece

Abstract: The tomato borer Tuta absoluta Meyrick (Lepidoptera: Gelechiidae) is the most important pest of tomato. It is mainly controlled by chemical insecticides, which resulted in the development of resistance. The first and most striking resistance case at a global scale was that of diamide insecticides. Significant pest control problems were associated with the rise of diamide resistance thus it was thoroughly investigated. Indoxacarb resistance is now widespread and high levels of resistance were detected in both Greece and Cyprus associated with known target site mutations. To date, moderate to no resistance levels have been documented to insecticides spinosad and emamectin benzoate, allowing the use of these chemicals as the last resorts of effective control agents for T. absoluta infestations. Studies were performed on laboratory selected strains and novel resistance mechanisms were detected for both insecticides. However, in 2019 populations from Tympaki area exhibiting multiple resistance levels against all tested insecticides were identified for the first time. More specifically, strain GR-TYMP-19-2 exhibited 1777-, >1000-, 250- and 157-Resistance Ratio to the insecticides chlorantraniliprole, indoxacarb, spinosad and emamectin benzoate respectively. The control failure likelihood was significant (p<0.05) in all cases, suggesting that the particular multi-resistant strain could not be controlled by any of the register insecticides, thus the current pest management schemes have to be drastically revised with minimal reliance to chemicals. Currently, novel insecticides, microbials and plant extracts are tested in search of novel pest management tools. Still most of these novel candidates are several years away from the market and their incorporation in agricultural practices. Also, it is admitted that greenhouse tomato production is still largely based on chemical insecticide applications and a shift to IPM schemes that don't predict use of insecticides is technically impossible for the majority of the farms at this stage. Therefore, we intend to aid the rational and sustainable revision of pest management tactics for T. absoluta in tomato crops with the contribution of academia and the support of the policy makers.

Parasitoid pre-adaptation improves biological control of symbiont-protected aphids

Authors: Vorburger Christoph[1] and Rossbacher Silvan[1], [1]Eawag & ETH Zürich, Switzerland

Abstract: Aphids are commonly infected by the heritable bacterial endosymbiont Hamiltonella defensa, which increases aphid resistance to parasitoid wasps. Laboratory cage experiments have shown that the release of parasitoids rapidly selects for symbiont-protected aphids, resulting in failed biological control, while other experiments have shown rapid counter-adaptation of parasitoids to the presence of H. defensa in their hosts. Taken together, these findings suggest that parasitoid pre-adaptation could be a viable strategy to improve biological control of symbiont-protected aphids. We tested this prediction in laboratory cage populations of black bean aphids (Aphis fabae) and their main parasitoid Lysiphlebus fabarum. Aphid populations comprised a mixture of H. defensa-free aphids, aphids infected with a moderately protective strain of H. defensa, and aphids with a strongly protective strain. These populations were exposed to five different treatments: (i) no parasitoids, (ii) parasitoids experimentally evolved on H. defensa-free aphids, (iii) parasitoids evolved on aphids protected by the less protective strain of H. defensa, (iv) parasitoids evolved on aphids protected by the more protective strain, and (v) a mixture of iii and iv. As expected, all treatments with parasitoids resulted in strong selection for H. defensa-protected aphids, but parasitoids adapted to H. defensa-free aphids and parasitoids adapted to the less protective strain of H. defensa failed to reduce aphid infestations relative to the parasitoid-free control. Parasitoids adapted to the more protective strain and the mixed parasitoid treatment, on the other hand, strongly reduced aphid densities, resulting in significantly improved host plant condition. This study thus showed, for the first time, that parasitoid pre-adaptation can improve the control of partly resistant aphid populations harbouring a protective endosymbiont.

The evolutionary ecology of defensive symbioses in aphids

Authors: Vorburger Christoph, Eawag & ETH Zürich, Switzerland

Abstract: Aphids engage in symbioses with a diverse menagerie of maternally transmitted bacterial endosymbionts. Maternal transmission couples host and symbiont fitness. This has facilitated the evolution of host protection: Several endosymbionts are known to increase aphid resistance to parasitoids or pathogens. A well-studied case is the gamma-proteobacterium Hamiltonella defensa, which occurs in many aphid species and provides protection against parasitoid wasps. Using the example of the black bean aphid (Aphis fabae) and its main parasitoid Lysiphlebus fabarum, I demonstrate that Hamiltonella plays an important role in mediating host-parasitoid coevolution. Hamiltonella increases the heritable variation available to selection, it alters the specificity of the host-parasitoid interaction as a consequence of genotype-by-genotype interactions between symbionts and parasitoids, and it modifies the trade-off between aphid resistance to parasitoids and other components of fitness. A better understanding of these complex interactions will be important to address the challenge endosymbionts pose for aphid pest control with parasitoids.

Endophytically colonized plants influence on thrips foraging behaviour

Authors: Vu Anh[1], Meyhoefer Rainer[2], [1]Leibniz Universität Hannover, Zoological Biodiversity, Applied Entomology, [2]Leibniz Universität Hannover, Zoological Biodiversity, Applied Entomology, Germany

Abstract: As a major pest in onions foraging behaviour of onion thrips, Thrips tabaci, has been investigated in detail. Many studies show that host plant selection by onion thrips is affected by visual as well as chemical host plant cues. Moreover, recently symbiotic interactions between host plant and fungal endophytes, with capacity to increase host plant resistance, has come into focus. Nevertheless, how endophytes influence onion thrips foraging behaviour still remains unexplored. In order to address this question, foraging behaviour of female T. tabaci was investigated in the laboratory with onion plants colonised by endophytic fungi, i.e. Trichoderma harzianum or Beauveria bassiana. Especially orientation towards the host plant was investigated by choice tests and feeding activity on the host plant by electrical penetration graph (EPG). Results show, that onions colonised by endophytic fungi were strongly avoided by onion thrips, and in consequence feeding damage and egg laying activity was largely reduced. Endophytic colonization also clearly showed an influence on thrips feeding behaviour, since the number of probes and probing duration of T. tabaci were significantly reduced on inoculated plants. Results will be discussed in the context of thrips foraging behaviour and possible advances in biological control.

Beetles LIFE: Positive effects of restoration burning on saproxylic insects in Finland (LIFE17 NAT/FI/000181)

Authors: Vuorio Ville, Finland

Abstract: Protected beetles that play an important role in Finland's boreal forests and bog woodlands are under threat due to loss of habitat and fragmentation, and due to a reduction in wildfires as a result of human intervention. To improve the conservation status of eight insect species across 26 project sites in Finland, degraded forest habitats are being restored and new habitats created through controlled burning and simulations of storm damage to increase the amount of decaying wood. Bog woodlands are also being restored through blocking of ditches and removing trees to improve water retention. Project monitoring has revealed that restoration measures have been successful: project target species were recorded in Kakonsalo (Stephanopachys linearis) and UK National Park (Stephanopachys substriatus and Aradus angularis) project sites as well as several fire-dependant Coleoptera and Hemiptera species including Aradus laeviusculus, a species classified as vulnerable in the 2019 Red list of Finnish species.

GOS Traps, NS1 kit and climatic factors for early surveillance of dengue in multi storey dwellings in Malaysia

Authors: Vythilingam Indra[1], Wee Kent Liew Jonathan[1] and Selvarajoo Sivaneswari[1], [1]Department of Parasitology, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia

Abstract: Dengue is a serious public health problem in Southeast Asia and has increased 37- fold in Malaysia compared to decades ago. New strategies are urgently needed especially with the current change in climatic conditions. A two-year study was conducted in a high human density dengue-endemic urban area in Selangor, where Gravid Ovipositing Sticky (GOS) traps were set up to capture adult Aedes spp. mosquitoes. All Aedes mosquitoes were tested using the NS1 dengue antigen test kit. All dengue cases from the study site notified to the State Health Department were recorded. Weekly microclimatic temperature, relative humidity (RH) and rainfall were monitored. 95.6% of the mosquitoes trapped were Ae. aegypti of which 23% was found to be positive for dengue using the NS1 antigen kit. Confirmed cases of dengue were observed lag of one week after positive mosquitoes were obtained. It was also observed that Ae. aegypti increased by lag of 2-3 weeks when temperature increased from 28oC to 30oC, and lag of 3 weeks with increase in rainfall. Currently a randomised-control trial is ongoing. Surveillance using the GOS traps should be able to efficiently provide adequate coverage for multi-storey dwellings where population per unit area is likely to be higher. Furthermore, trapping dengue-infected mosquitoes using the GOS trap, helps to halt the dengue transmission carried by the mosquito. It is envisaged that the results of this randomized controlled trial will provide a new proactive, cheap and targeted surveillance tool for the prevention and control of dengue outbreaks.

How a minute mite promises to make big waves in biocontrol

Authors: Wackers Felix[2], Pijnakker Juliette[1], Moerkens Rob[1], Duarte Marcus[1], Benaventa Alfredo[1] and Vangansbeke Dominiek[1], [1]Biobest Group, [2]Biobest Group NV, Belgium

Abstract: Eriophyid pests and powdery mildew are two main problems in crop cultivation for which no effective biocontrol solutions exist to date. In greenhouse trials we investigated the potential of a new group of miniscule mites (Iolinidae) to control these problem pests and key pathogens. Using Typha pollen, the Iolinid Pronematus ubiquitus established well on all tested crop plants. On tomatoes the established population was capable of controlling subsequent infestations with both russet mites and powdery mildew. This represents the first case, where an omnivorous arthropod has been shown to control a pest- and pathogen problem concurrently. The additional experiments in other crops also showed strong mildew suppression potential.

Preventatively establishing P. ubiquitus could be a real game-changer in biological crop protection as it eliminates the need for repeated pesticide use or sulphur applications. The finding that arthropods can effectively control diseases opens up entire new opportunities for biological crop protection.

Manipulating the behavior of the African weaver ant, Oecophylla longinoda, to promote biological control of mango fruit flies

Authors: Wackers Felix[1], Chailleux Anaïs[3], Correa Philippe[2], Detrain Claire[4] and Brévault Thierry, [1]Biobest Group NV, Belgium, [2]-CIRAD, UPR HortSys, Centre Commun ISRA-IRD, Senegal -Biopass, Cirad-IRD-ISRA-UCAD, Dakar, Senegal -UCAD-FST, ED SEV, Dakar, Senegal, [3]Senegal, [4]Unity of Social Ecology, University of Brussels, Belgium

Abstract: Damage to mangoes caused by tephritid fruit flies, particularly the Oriental fruit fly, Bactrocera dorsalis (Hendel) (Diptera: Tephritidae), leads to significant crop losses in Senegal. Though African weaver ants, Oecophylla longinoda (Latreille) (Hymenoptera: Formicidae), are effective predators of fruit flies, they are often considered as pests by farmers due to indirect damage caused by mealybug tending to collect honeydew. Moreover, growers blame ants for other nuisances such as biting and nesting on trees. It is thus essential to reduce the negative effects of ants to improve their adoption as a biocontrol agent in fruit tree orchards. Providing sugar to weaver ants could be a way to manipulate ant behavior and interspecific interactions with mealybugs and fruit flies. Here, we hypothesize that provision of sugar sources to ants will (i) reduce both mealybug tending, abundance of nests and ant aggressiveness, and (ii) increase their predation of fruit flies. To that end, a long-term study was launched in an organic orchard in Senegal. Three treatments have been compared: (1) mango trees with both ants and sugar feeders, (2) mango trees with ants but no feeders, and (3) mango trees without ants nor feeders. The population dynamics of mealybugs and weaver ants has been monitored over one year. Ant abundance decreased during the dry season following mango harvest and increased in the early rainy season in connection with fruit production and increase of food resources. The effect of sugar feeders on ant foraging, predation, nesting, aggressiveness, and mealybug tending was lower than expected and varied across time. Results will be key for the development of strategies for the biological control of fruit flies in African mango orchards.

Precipitation Changes as Drivers of Insect Decline

Authors: Wagner David, University of Connecticut, United States

Abstract: Changes in historical patterns of rain and snowfall have many consequences for the flora and fauna of terrestrial ecosystems. Insects, with their enormous surface body-to-volume ratios and dependence on spiracular ventilation, are particularly vulnerable to drying. In addition to the immediate threat of desiccation, decreases in precipitation have weighty knock-on effects for affected regions: they result in lowered surface waters, water tables, and soil-moisture levels; diminish snow cover, which can insulate in-ground faunas, and provide water over summer months via snow melt; elevate fire risks; lower hostplant fitness and affect plant defense systems; diminish nectar availability; and ultimately lead to hostplant death (and range contractions). Given that nearly one-half of all described insects are specialist herbivores, the reshaping of global plant communities, due to changed patterns of precipitation, will have enormous consequences for global food webs, that will cascade across the tree of life. The talk will anchor to data from the Southwestern USA but explore other regions where changes in rain and snowfall may be driving declines.

Estimating the contribution of beekeeping to household wellbeing and conservation motivations in the Tanzanian Miombo

Authors: Wagner Kata[1], Meilby Henrik[2] and Cross Pau[1], [1]Bangor University University of Copenhagen, United Kingdom [2]University of Copenhagen, Denmark

Abstract: Beekeeping is used by numerous development agencies in their efforts to promote livelihood activities that constitute alternatives to slash-and-burn agriculture in order to reduce poverty and provide incentives for forest conservation. Besides short-term monetary focused project evaluation reports, there is little evidence on the effectiveness of beekeeping to achieve these goals. We examine the contribution of beekeeping to household wellbeing and conservation motivations in four rural communities in Central Tanzania using a mixed methods approach. First, we identified predictors of beekeeping adoption, dependence and success. We found that beekeepers were often also livestock keepers and wild honey hunters. The results also indicate that beekeeping uptake was mainly motivated by the prospect of cash income, but the lack of suitable land, means to acquire hives and technical knowledge were significant inhibitors. We also found that beekeeping training provided by governmental organisations did not lead to improved beekeeping success when compared to local training provided by neighbours and family members. Lastly, elite capture of project benefits was a frequent occurrence when project participation was linked to the requirement to form associations. We then assessed whether beekeepers were better-off in ten crucial life domains than their non-beekeeping peers and whether beekeeping was effective in filling an income gap during the agricultural year. We observed that while beekeepers were slightly more food secure, positive effects on other life domains were limited to beekeepers marketing more than just honey. Beekeepers were slightly more resilient and had marginally more farm-and non-farm assets, but the differences to non-beekeepers were relatively negligible. We found that beekeeping income was not sufficient to effectively bridge income gaps throughout the year. Finally, we analysed the associations between beekeeping and conservation by assessing a range of factors contributing to forest-friendly behaviour. While we found beekeeping to be linked to slightly more intensive forest use, more positive attitudes towards the forest and a stronger appreciation of conservation benefits, the observed differences between beekeepers and non-beekeepers were again relatively small. Beekeepers also engaged in forest destructive behaviours or did not have sufficient influence within their communities to protect forest resources. These findings are of importance, as considerable efforts are being paid to the promotion of beekeeping in developing countries, including in the context of REDD+. The results of this study can inform better-targeted investment in beekeeping as an alternative livelihood option by improving the selection of beneficiaries and the design of project delivery mechanisms, by creating realistic expectations of potential beekeeping benefits and identifying further measures potentially needed to achieve livelihood and conservation goals.

A modeling approach to improve the efficiency of augmentative biological control with arthropod natural enemies

Authors: Wajnberg Eric, I.N.R.A. Sophia Antipolis Cedex, France

Abstract: Identifying key life-history traits of biocontrol agents and their effect on population dynamics is important to obtaining more efficient pest control and generating higher economic returns for biocontrol practitioners. An optimality simulation model was built to identify the most important life-history traits of natural enemies to improve their efficacy as biocontrol agent, taking into account the costs and benefits for biocontrol practitioners. Two different optimized life-history strategies for the agents were found with higher potential economic returns. These strategies differ in the plant-leaving decision and host handling time of the biocontrol agents, but also in their respective fecundity, longevity and dispersal ability. The preferred strategy depends on the number of agents released and the growth rate of the plant.

What shapes leaf miner abundance on oak trees in a forest: leaf quality or movements?

Authors: Walczak Urszula[1], Melosik Iwona[1], Prinzing Andreas[2] and Molleman Freerk[1], [1]Adam Mickiewicz University in Poznań, Poland, [2]Université de Rennes 1

Abstract: The abundance of leaf miners on a tree may be affected by leaf quality and the rate of movements among trees. Factors affecting leaf quality include genetic traits, responses to herbivory, and interactions with neighbouring trees. Insect movements may be limited by distantly related neighbours. We recorded leaf mines in the crowns of mature oaks (Quercus petraea) in a forest in western Poland in July and October of three years. We evaluated the effects of budburst phenology, microsatellite traits, genome size, physical and chemical traits of leaves, leaf damage by other insect herbivores, and the phylogenetic distance to neighbours as predictors of leaf miner density and community structure. We found that leaf miner abundance was higher on trees that appeared less nutritious (low nitrogen content) and more defended (high polyphenol content). The phylogenetic neighbourhood of the tree did not appear to affect leaf miner abundance. Our results suggest that leaf miner abundance is mainly affected by oviposition behaviours and establishment success. In addition, leaf miners may avoid competition with other herbivores by selecting trees with low leaf quality, while they suffer little costs because they may be able to locally alter leaf chemistry.

Grant No. 2018/29/B/NZ8/00112 National Science Centre (Poland).

Native and non-native egg parasitoids of Halyomorpha halys: variation among regions and habitat types in the U.S.A.

Authors: Walgenbach James[3], Bergh Chris[13], Beers Elizabeth[2], Krawczyk Greg[6], Shrewsbury Paula M.[1], Hoelmer Kim A. [7], Welty Celeste[5], Holthouse Cody[12], Lowenstein David[4], Alston Diane[12], Ogburn Emily[3], Galindo Gracie[10], Andrews Heather[4], Lee Jana[10], van Zoeren Janet[9], Tatman Kathy[11], Fox Vik Kristina[5], Fann Lauren[8], Quinn Nicole[13], Wiman Nik[4], A. Waterworth Rebeccah[1] and Bessin Ricardo[8], [1]Department of Entomology, University of Marland, United States, [2]Department of Entomology, Washington State University, United States, [3]North Carolina State University, United States, [4]Oregon State University, United States, [5]The Ohio State University, United States, [6]The Pennsylvania State University, Department of Entomology, Fruit Research and Extension Center, Biglerville, PA, United States, [7]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States, [8]University of Kentucky, United States, [9]University of Wisconsin, United States, [10]USDA ARS Horticultural Crops Research Unit, Corvallis, OR, United States, [11]USDA-ARS, Beneficial Insects Research Laboratory, Newark, DE, United States, [12]Utah State University, United States, [13]Virginia Tech, ASAREC Winchester, VA, United States

Abstract: Halyomorpha halys is an invasive insect found throughout many regions of the U.S. and in a diversity of managed (orchard, vegetable and field crops) and natural (wooded edges) habitats. Its abundance and pest status varies by region and habitat type. To determine the identity of natural enemies associated with H. halys and their impact on H. halys eggs, a large collaborative survey was conducted over two years in five U.S. regions, involving 13 states and 26 scientists. Surveys using sentinel and naturally laid H. halys eggs elucidated differences in native and non-native egg parasitoid identity and their impact on H. halys eggs among regions and habitat type. As expected Trissolcus japonicus was the only non-native egg parasitoid emerging from H. halys eggs and native parasitoids included Trissolcus spp., Anastatus spp., Telenomus spp., and an Ooencyrtus sp. The native and non-native parasitoids associated with H. halys varied by region and habitat type, and between the first and second year of the study. For example, non-native T. japonicus was found in only one region in 2017 and in 3 regions in 2018 (of 5 regions), while native Anastatus spp. was found mainly in the mid-Atlantic and Southeast regions, with very low numbers on the Pacific Northwest region both years. Parasitoid diversity was greatest in the mid-Atlantic region, which was predicted since this is where H. halys was detected and became an outbreak pest first. While overall parasitism (emerged parasitoids) was low (4%), it was greatest in semi-natural, forests and ornamental habitats. Parasitoid species varied in their relative abundance among habitat types. For example, Anastatus and Trissolcus are arboreal and Telenomus and Ooencyrtus were found only in vegetable / field crop habitats. Knowledge of differences in parasitoid species identity and their impacts on H. halys among diverse habitats and regions will assist in identifying measures to maximize biological control programs in the U.S. and other invaded countries.

Problems Created by the brown marmorated stink bug invasion, and the scientific and industry response.

Authors: Walgenbach James, North Carolina State University, United States

Abstract: In North America, the brown marmorated stink bug (BMSB), Halyomorpha halys Stål, first appeared as a major pest in 2010 in the mid-Atlantic states of the USA, approximately 15 years after it was first detected in that region. With the agricultural community largely unprepared for this abrupt population explosion, BMSB caused near catastrophic damage to a wide range of tree fruit and vegetable crops, especially apples, peaches and fruiting vegetables. This was followed by large invasions of homes in residential areas when adults dispersed to overwintering areas in the fall of 2010. The pest subsequently spread to other regions of the country, and now has been detected in 46 states with established populations in 38 states. The response of the scientific community, grower organizations, and crop protection industry was swift. A BMSB working group was formed to identify research and outreach priorities, and a large Federal grant that included over 50 PI's from nine states was successfully obtained to guide research. Initially, tree fruit IPM programs that took decades to develop, and which relied on soft chemistry, mating disruption, and biological control, were replaced by frequent applications of broad spectrum pyrethroid insecticides. This predictably led to secondary pest outbreaks and additional pesticide use. However, multidisciplinary research teams have made considerable progress in understanding the biology and ecology of BMSB, developing monitoring programs, semiochemical based management tactics, and expanding biological control of BMSB with Asian parasitoids. This symposium will highlight progress that has been made in rebuilding IPM programs following the invasion of BMSB.

Insect venoms: Biochemical weapons used to facilitate and defend against predation

Authors: Walker Andrew[3], Sombke Andy[4], G. Fry Bryan[5], J. Merritt David[5], A. B. Undheim Eivind[1], F. King Glenn[2], Vetter Irina[2], Dobson James[5], Jin Jiayi[2], Mayhew Mark[5], D. Robinson Samuel[2] and Herzig Volker[2], [1]Centre for Advanced Imaging, The University of Queensland, Australia, [2]Institute for Molecular Bioscience, The University of Queensland, Australia, [3]Institute for Molecular Bioscience, The University of Queensland, Australia, [4]Integrative Zoology, University of Vienna, Austria, [5]School of Biological Sciences, The University of Queensland, Australia

Abstract: Venom use to facilitate or defend against predation has evolved independently at least 13 times among the insects. However, almost nothing is known about the venom systems or toxins of most venomous insect groups excepting the Hymenoptera (wasps, ants, and bees). To address this gap in knowledge, we have investigated the venom systems of three diverse but neglected insect groups, specifically the assassin bugs and allies (Heteroptera: Reduviidae), robber flies (Diptera: Asilidae) and nettle caterpillars (Lepidoptera: Limacodidae) using proteomics, transcriptomics, imaging technologies, and toxicity assays.

Assassin bugs and giant water bugs have morphologically complex venom glands that produce two different venoms that they can inject independently. Venom from the posterior main gland rapidly paralyses and kills prey insects when injected, and activates mammalian peripheral neurons that sense pain. Although assassin bug venom contains peptide toxins with similar structural folds to spider venom 'knottin' toxins, much of its bioactivity depends on currently uncharacterised protein toxins with higher molecular mass.

Robber fly venom displays similar insecticidal and pain-causing bioactivities as assassin bug venom, but contains a more diverse range of peptide toxins. We have solved the structure of two heterologously expressed robber fly venom peptides that cause rapid paralysis when injected into insects. One of these, Dg3b, is a member of the cystine-stabilised a/ß defensin family and is closely related to insect innate immunity peptides, but shows greater similarity to scorpion venom peptides both structurally and in its ability to modulate neuronal potassium channels.

In contrast to the orally produced venoms of assassin bugs and robber flies that are used primarily for predation, venoms of nettle caterpillars (Limacodidae) are produced in cuticular spines and used only for predator deterrence. Their venoms contain more peptides and fewer enzymes, and do not kill but cause pain and aversion, and include both 'knottin' peptides and modified insect neurohormones.

Currently, we are seeking to identify the individual venom toxins from each of these three families that underlie the biological effects of venom, and to characterise them structurally and functionally. We believe this will provide new insights into the molecular weaponry used by insects, both to facilitate predation and defend against it.

Codling moth sterile insect releases: A supplementary phytosanitary measure for New Zealand apple exports

Authors: Walker Jim[1], Rogers Dave[1], Suckling Max[1], Lo Peter[1], Horner Rachael[1] and Sullivan Thomas[1], [1]The New Zealand Institute for Plant and Food Research Limited, New Zealand

Abstract: The New Zealand apple industry ships almost 50% of its export production to Asian markets that require strict phytosanitary measures to eliminate the risk of codling moth (CM) larval infestation in fruit. Apple growers follow Integrated Fruit Production (IFP) principles and the industry adheres to the New Zealand Ministry of Primary Industries' 'systems-based' programme, for additional CM risk mitigation in crops destined for Asia. Despite the high phytosanitary performance of this regulatory programme, some Asian countries have a zero tolerance for CM and require mandatory postharvest disinfestation with the fumigant methyl bromide. New Zealand aims to eliminate the last remaining uses of this greenhouse gas so the apple industry is investigating localised eradication of CM as a potential supplementary phytosanitary measure for apple exports to markets with a zero tolerance.

The sterile insect technique (SIT) is being attempted on six IFP orchards (total 350 ha), and one 38 ha organic orchard, in Central Hawke's Bay (CHB). The orchards are isolated by farmland from each other and other orchards which greatly reduces the risk of CM immigration. IFP programme measures include threshold-based insecticide applications and use of pheromone mating disruption. We are supplementing these measures with weekly releases of sterile CM (~250 per ha) delivered by a fixed-wing, unmanned aerial vehicle (UAV) flying at a height of 40–50 m. Three orchards are currently in the fifth year of releases and catches of wild CM on these orchards in 2018–19 were 93–96% lower than in 2013–14, the year before releases began. Three orchards have had 3 years of moth releases and average annual catches have decreased 84–92% since 2015–16. The BioGro™ New Zealand certified organic orchard has had 2 years of SIT releases and catches are down by 79%, but initial populations were much higher than other orchards.

Catches of wild CM on the IFP orchards are now extremely rare (range 0.03–0.22 moths/ha/season in 2018–19) and packhouse records show no codling moth damaged or infested fruit have been detected since SIT moth releases commenced in 2014. There are relatively few wild apple host trees within a >5 km radius of the SIT-treated orchards. Pheromone trapping found mixed densities in these host trees; season-long moth catches in 30 traps were: 0 moths (7 traps), 1–5 moths (11 traps), 9–13 moths (6 traps) and 22–53 months (6 traps). Recent expansion of the SIT programme (+80 ha) onto the Heretaunga Plains (New Zealand's major apple growing region) using a DJI M600 Pro hexacopter has enabled more manoeuvrable flight at lower altitudes (25 m) and recapture of sterile moths averaged 10 times and three times higher, respectively, than that of moths released via the fixed-wing UAV. Special measures to reduce pest prevalence, such as additional sterile insect releases or alternate host tree removal, would be needed to reduce the risk of immigration and achieve local eradication.

An atypical moth pheromone receptor in the genus Spodoptera

Authors: Walker William[9], Caballero Vidal Gabriela[5], Jacquin-Joly Emmanuelle[3], Montagné Nicolas[2], Koutroumpa Fotini[4], Maria Annick[7], de Fouchier Arthur[3], Meslin Camille[5], Monsempès Christelle[4], Wang Guirong[6], Bastin-Heline Lucie[7], François Marie-Christine[1], Cao Song[8] and Chertemps Thomas[7], [1]iEES-Paris Institute, Paris, France, [2]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [3]INRA, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [4]INRAE, iEES-Paris Institute, Versailles, France, [5]INRAE, Sorbonne Université, Institute of Ecology & Environmental Sciences of Paris, Versailles and Paris, France, [6]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [7]Sorbonne University, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [8]State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing, China, [9]USDA-ARS, United States

Abstract: In the highly diversified insect order Lepidoptera, male pheromone receptors (PRs) tuned to female-emitted type I pheromones (which make up the vast majority of pheromones identified) form a dedicated subfamily of odorant receptors. Using a combination of heterologous expression and in vivo genome editing via CRISPR-Cas9, we identified in males of the cotton leafworm Spodoptera littoralis one PR that does not belong to this subfamily but to a distantly related lineage. It suggests two independent apparitions of PR for type I pheromones in moths. This PR is specifically tuned to the major sex pheromone component emitted by females and mutant males for this receptor are not able to mate. Using available genomic and transcriptomic data, we also identified orthologues and paralogues of this receptor in other Spodoptera species and compared their response spectra, in order to rebuild the evolutionary history of this receptor and to understand how it became specifically tuned to the major pheromone component in S. littoralis and its sister species S. litura.

Virus discovery and dynamics in a wild Drosophila community

Authors: Wallace Megan, University of Exeter, United Kingdom

Abstract: The fruit fly Drosophila melanogaster remains a key model system for the study of insect-virus interactions, and recent metagenomic sequencing studies have identified over 140 naturally-occurring viruses of the Drosophilidae. This could enable the study of study of 'typical' wild co-evolutionary dynamics between insects and their viruses, which might help us to understand the evolution of insect-vectored viruses with economic and public health impacts.

In this study, we make the first attempt to quantify the dynamics of wild drosophilid virus communities. We used metagenomic sequencing to describe the 41 new and previously described viruses present in populations of Drosophila in South-east Scotland, along with their host range, finding that over 90% of these viruses infect multiple host species. We also examined how ten of these viruses vary in prevalence in the wild using repeated, spatially and temporally structured sampling of a total of 2227 flies of 15 species, over three years. We describe prevalence variation across host species, and season, along with the frequency of co-infection. We then investigate what predicts patterns of host range and prevalence in insect viruses using phylogenetic mixed models. Together, these data capture a rare snapshot of multi-host, multi-virus community dynamics in wild insects.

Attraction of pollinator Eupeodes corollae is mediated by odorant receptor 25 narrowly tuned to aromatic floral compounds

Authors: Wang Bing[1] and Wang Guirong[1], [1]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: Flowering plants have evolved strategies to attract pollinators with volatile compounds that are accurately perceived by the sensitive olfactory system of insects. Syrphid flies are the largest flower visiting Diptera, but little is known on how they detect floral scents at the molecular level. In this study, fourteen aromatic compounds were used in Electroantennogram (EAG) recordings, and all of them elicited responses from the antennae of Eupeodes corollae. In order to identify ORs of E. corollae tuned to aromatic volatiles, we analyzed functional profiles of Drosophila melanogaster odorant receptors (ORs), DmelOR46a and DmelOR71a, which are narrowly tuned to phenolic compounds and represent the orthologues of E. corollae OR25 and OR28, respectively. The full-length genes encoding EcorOR25 and EcorOR28 are expressed in the antennae of both sexes and were functionally characterized. EcorOR25 is narrowly tuned to several structurally-related floral scent volatiles, including eugenol, p-cresol and methyl eugenol. Finally, choice behavior assays showed that eugenol and methyl eugenol were strong attractants for both sexes of E. corollae adults. In summary, our study indicates that EcorOR25 of E. corollae may be involved in flower foraging and pollination.

Prevalence of Three Common Urban Pests in Low Income Housing

Authors: Wang Changlu, Department Entomology, Rutgers University, United States

Abstract: Urban pests infestations commonly occur in residential buildings. The prevalence of different urban pests infestation is affected by both building occupant behavior and efficacy of pest management service. To address the infestations, residents often take matters into their own hands, which can result in the misuse of insecticide applications, and pose potential health risks to residents. In this study, community-wide pest surveys were carried out. More than 4000 apartments from twenty low-income apartment buildings, occupied by senior citizens in New Jersey, United States, were included. The objective of this study was to analyze the presence, prevalence, and spatial distribution of German cockroaches, house mice, and common bed bugs in relation to the environmental conditions, resident demographics, and pest control history of each apartment. We conducted resident interviews and visual inspections and assessed apartment conditions. To detect the presence of most common urban pests, sticky traps for German cockroaches, baited-mouse stations for house mouse, and interceptors for common bed bugs were employed. The inspection found the top three urban pests to be as follows: German cockroaches (Blattella germanica L. [Dictyoptera: Blattellidae]), rodents, and bed bugs (Cimex lectularius L. [Hemiptera: Cimicidae]). The results will help pest management professionals, public housing authorities, and residents in selecting for optimum strategies in managing indoor pest infestations.

Spatial distribution of German cockroaches in a high-rise apartment building before and after implemetation of an IPM program

Authors: Wang Changlu[2] and Zha Chen[1], [1]Apex Bait Technologies, Inc., United States, [2]Department Entomology, Rutgers University, United States

Abstract: The German cockroach, Blattella germanica (L.) (Blattodea, Ectobiidae), is one of the most common indoor pests in multifamily housing communities. Our objectives were to investigate the spatial distribution patterns of German cockroach infestations in a multiunit dwelling before and after building-wide integrated pest management (IPM) implementation. The study was conducted in a high-rise apartment building with 188 residential units in Paterson, New Jersey, USA. At 0 month, 49% of the apartments were infested with German cockroaches. All the identified infestations were treated by researchers using IPM implementation, and monitoring was repeated at 6 and 12 months after the initial survey. The building-wide infestation rate decreased from 49% to 24% and 12%, at the 6- and 12-month inspections, respectively . We examined cockroach spatial distribution patterns within and between apartments. Traps placed by the stove and refrigerator caught significantly more cockroaches than traps placed in the kitchen cabinet under the sink or in the bathroom. At month 0, cockroach infestations within the building were spatially correlated. At 12 months after implementation of IPM, only infestations cross the floors remained to be correlated. Therefore, IPM not only eliminates cockroach infestations in individual units, but also reduces cockroach dispersal between units.

Olfactory coding of sex pheromone blends with reverse ratios in two Helicoverpa moth species: so similar, yet so different

Authors: Wang Chen-Zhu, State Key Laboratory of Integrated Management of Pest Insects and Rodents, Institute of Zoology, Chinese Academy of Sciences, China

Abstract: Sex pheromones released by female moths are detected by the olfactory sensilla with high specificity and sensitivity in antennae of conspecific males. The two sympatric closely related species, Helicoverpa armigera and Helicoverpa assulta share two major sex pheromone components, cis-11-hexadecenal and cis-9-hexadecenal, but in reversed relative concentrations, 97:3 and 7:93, respectively. We combined molecular biology, electrophysiology, optical imaging and behavior to investigate the olfactory coding mechanisms in males to their sex pheromone blends. Five pheromone receptors from the two species were identified functionally in the Xenopus laevis oocyte expression system. Specific olfactory sensory neurons (OSNs) in three types (including some subtypes) of antennal sensilla were proved to be involved in the pheromone coding. The projection of the axons of OSNs to the male specific macroglomerular complex in the antennal lobe was also compared between the two species. I will report how we assign different PRs to OSNs and types of sensilla responding to the pheromone components and the related compounds. We find that the PR orthologs in the two species do not necessarily have the same selectivity, and their species-specific changes in the tuning selectivity in male moths could be achieved with just a few amino acid mutations. We conclude that evolution of the olfactory coding mechanisms for pheromones of the two species satisfies the need of specific-species pheromone detection, which shed new light onto the reproductive isolation between these species.

The functional correlation between pheromone binding proteins and pheromone receptors in Helicoverpa armigera

Authors: Wang Chen-Zhu[1], Guo Hao[2], Huang Ling-Qiao[2] and Guo Ping-Ping[2], [1]Institute of Zoology, Chinese Academy of Sciences, Beijing, China, [2]Institute of Zoology, Chinese Academy of Sciences, China

Abstract: Three pheromone-binding proteins (PBPs) are abundantly expressed in antennae of moth species. Despite they have widely been studied by the competitive fluorescence binding assay, the roles of the PBPs in olfactory peripheral events remain contradictory. Helicoverpa armigera, wreaking havoc on agriculture and horticulture worldwide, utilizes (Z)-11-hexadecenal (Z11-16:Ald) and (Z)-9-hexadecenal (Z9-16:Ald) as its principal sex pheromone components. A pheromone receptor (PR), HarmOR13 when co-expressed with HarmORco in Xenopus oocytes is strongly activated by Z11-16:Ald, albeit with mediocre but appreciated sensitivities to other structural analogs. Here, by devising the olfactory system in Drosophila T1 sensilla, we studied the functional correlations of HarmPBPs with HarmOR13. First, RNA in-situ hybridization together with in-depth immuno-fluorescence staining revealed the three PBPs were colocalized in the supporting cells underneath trichoid sensilla, implying a specific role for pheromone detection. HarmOR13 olfactory receptor neurons (ORNs). Next, we expressed each PBP into the supporting cells of Drosophila T1 trochoid sensilla by LUSH-GAL4 drivers and investigated whether the presence of PBP could modulate the sensitivity and selectivity of HarmOR13 that is concomitantly expressed in OR67d ORNs using ORCO-LexA driver line. We found that the three PBPs were ineffective to change the selectivity of HarmOR13. Moreover, the presence of each PBP increased the sensitivity of HarmOR13 to Z11-16:Ald and other analogs in similar manners. Taken together, our results suggest that PBPs are essential to maintain the full peripheral sensitivity but play a negligible role to modulate the specificity.

A taxonomic study on the genus Odonterpyris Kieffer (Hymenoptera, Bethylidae) from China

Authors: Wang Chunhong, Institute of Insect Sciences, Zhejiang University, China

Abstract: The genus Odontepyris Kieffer 1904 belongs to the subfamily Bethylinae and it’s one of the most recognizable genera of Bethylinae for the large size and the present of median longitudinal as well as transverse carinae in the propodeal disc.
Currently, 42 species of this genus have been recorded in the world. Among this genus, 8 species are known from China . After carefully examined the specimens of this genus collected from China, we provided descriptions of 14 new species as well as a key to Chinese species.

Mechanisms underlying whitefly manipulation of plant defence response by a salivary protein

Authors: Wang Fang, Institute of Insect Sciences, Zhejiang University, Hangzhou, China

Abstract: Many phloem-feeding insects are able to manipulate host plant defence using salivary effectors. We demonstrated previously that expression of the whitefly Bemisia tabaci salivary protein BtQ0F1 enhanced whitefly performance on its host tobacco, and we hypothesized that this enhancement effect may be associated with leveraging crosstalk between jasmonic acid (JA) and salicylic acid- (SA-) signaling pathway in the plant. In this study, we show that the whitefly salivary protein BtQ0F1 increases the susceptibility of host plant by suppressing SA signaling pathway as well as JA signaling pathway. Overexpression of BtQ0F1 gene in planta promotes the susceptibility of tobacco to whitefly and suppresses SA signaling pathway as well as JA signaling pathway. In contrast, silencing whitefly BtQ0F1 gene significantly decreases whitefly performance on host plants. Our results indicate that the whitefly salivary protein BtQ0F1 suppresses plant defence by interfering the crosstalk between JA-SA signaling pathways in host plants.

Study on the Resurgence and Steam Treatment of Bed bugs in Mainland China

Authors: Wang Desen[1], He Yurong[1], [1]Department of Entomology, College of Agriculture, South China Agricultural University, China

Abstract: BACKGROUND: Bed bugs (Cimex lectularius L. and Cimex hemipterus (F.)) are obligate blood-sucking insects that feed upon humans and other animals. Recent two decades, the reports of bed bugs infestation have increased gradually in Mainland of China, especially for the Pearl River Delta Region. However, the species of bed bugs in this area is less reported. Based on our previous lab studies, steam treatment can be applied as an effective method to kill bed bugs on bed or sofa surface and under a cloth fabric, as well as in crack; and can temporarily reduced bed bug mobility and blood-feeding ability. However, less report was concerned on the field control of bed bugs through steam treatment. In this study, firstly, morphological identification and molecular technique that based on the differential of genetic distances of mitochondrial Cytochrome C oxidase subunit I gene (COI), were conducted for identifying the species of bed bugs collected from Guangzhou and Foshan City. Secondly, the efficacy of one affordable consumer-grade commercial steamer for killing bed bugs was evaluated in field study. The results of our studies may have important implications on the use of steam treatment for bed bug management in China.

RESULTS: There was no significant difference in the width to height ratio of Guangzhou (2.6) and Foshan (2.4) samples' pronotum, but both of them were significantly lower than those of Cimex lecturlarius (Ft. Dix strain, 3.1) which was used as a reference substance. The genetic distances of test samples with Cimex hemipterus were 0-0.2%, and 22.2-22.6% with Cimex lecturlarius. In the Maximum likelihood phylogeny tree, the tested samples were clustered into a same branch with C. hemipterus, and the support rate was 100%. In field study, the consumer-grade steamer at an affordable price can achieve a high control efficacy of bed bugs that exposed on mattresses, as well as hided in cracks.

CONCLUSION: Bed bugs collected from Guangzhou and Foshan belong to C. hemipterus. Proper use of steamers can kill all life stages of bed bugs. Even the affordable consumer-grade steamer can also be effective for eliminating bed bugs resting on mattresses, or hiding in cracks.

Multi-Omics Integration and CRISPR-based Genome Editing to Improve Poplar for Bioenergy and Stress Response

Authors: Wang Jack[1], Sederoff Ron[2] and Chiang Vincent[2], [1]Forest Biotech Group, NC State University, United States, [2]NC State University, United States

Abstract: Multi-Omics integrative analysis of lignin biosynthesis can advance the strategic engineering of forest trees for adaptation and utilization. Lignin is a heterogeneous phenolic polymer deposited in secondary cell walls of vascular plants. It provides mechanical support to plant cell walls, hydrophobicity for water transport, and augments defenses against biotic and abiotic stresses. Lignin is polymerized from three monomers (monolignols) produced by a grid-like pathway. The pathway in wood formation of Populus trichocarpa has at least 21 genes, encoding enzymes that mediate 37 reactions on 24 metabolites, leading to lignin and affecting wood properties. We perturb these 21 pathway genes and integrate transcriptomic, proteomic, fluxomic and phenomic data from 221 lines selected from ~2,000 transgenics. Stem-differentiating xylem of the transgenics and wildtype were analyzed by 239 full transcriptomes and 239 proteomes to regress the abundances of transcripts and proteins. Using recombinant proteins from the 21 monolignol pathway genes, we determined 207 reaction and inhibition enzyme kinetic parameters to predict the effects of protein abundances on pathway metabolic-fluxes and metabolite concentrations. To determine the effects of metabolic-fluxes and metabolite concentrations on lignin and wood properties, we quantified the chemical composition of 220 wood samples, and 76 lignin samples using 2D HSQC NMR for lignin composition and structures. We measured the growth of 221 lines, the modulus of elasticity of 416 wood samples, and the density of 213 wood samples. All these data were then systematically integrated to describe the transduction of biological information from the 21 monolignol genes through transcripts, proteins, metabolic-fluxes, and metabolite concentrations, leading to 25 wood traits, including lignin content, composition, and interunit linkages. The analysis then predicts improvements in any of these 25 traits individually or in combinations, through engineering expression of specific monolignol genes. The analysis informs CRISPR-based editing strategies to improve wood utilization and may lead to a greater understanding of plant adaptation to biotic and abiotic stresses.

Neuropeptide signaling in the male reproductive system of Drosophila

Authors: Wang Jinjun[2] and Xu Li[1], [1]1Key Laboratory of Entomology and Pest Control Engineering, College of Plant Protection, Southwest University, Chongqing 400715, China 2Academy of Agricultural , [2]Key Laboratory of Entomology and Pest Control Engineering, College of Plant Protection, Southwest University, Chongqing, China; State Cultivation Base of Crop S

Abstract: Myosuppressin peptides (Ms) are well-conserved insect brain-gut peptides with a -FLRFamide C-terminus and have roles in regulating muscle activity of the gut, heart and female reproductive tissues. The Drosophila genome has two GPCR type receptor genes (MsR1 and MsR2) that bind Drosophila Ms peptide. The pharmacology of these two receptors appear to very similar, when heterologously expressed in cell lines. We have been investigating a role for Ms signaling in the male reproductive tract of D. melanogaster and possible involvement in regulating ejaculation. Both sperm and non-sperm components (seminal fluid) of the male ejaculate are important for reproductive success in insects. In Drosophila, mature sperm is released from the seminal vesicles (SV) and mixed with seminal fluid prior to ejaculation. Copulation takes around 20 min and seminal fluid and sperm transfer (SFST) is complete by 12 min. The paired male accessory glands (MAG), the ejaculatory duct (ED) and the ejaculatory bulb (EB) all contribute to the seminal fluid with the MAG providing the bulk of the material. Initiation and termination of ejaculation will rely on the coordinated activity of the muscle layers surrounding these male structures. Four corazonin/cholinergic interneurons of the male abdominal ganglion promote SFST by activating 5-HT neurons that project directly to the MAG, ED and SV. We find distinctive Ms neurons from the abdominal ganglion, two rectal cells and a single cell positioned close to the ED innervating the male reproductive tract, suggesting a role for Ms in muscle inhibition. We show that the MAGs display bursts (~25 s) of strong muscular contractions that are asynchronous with the sustained peristaltic contractions of the ED. The MAG contractions are strongly inhibited by exogenous Ms, with full inhibiton at 10 µM. Null mutant alleles of both Ms receptors (MsR11 and MsR21) were generated by targeted gene-editing using CRISPR/Cas9 technology. Ms inhibited MsR11 MAG contractions, but no Ms induced suppression was observed with MsR21 glands, demonstrating a specific role for the latter receptor in transduction of the Ms signal. Strong expression of MsR2-GAL4, but not of MsR1-GAL4, in the MAG muscle is consistent with this conclusion. Direct evidence of the importance of male Ms signaling in reproduction was obtained by silencing male Ms-neurons and by phenotypic analysis of the performance of MsR21 males. We conclude that Ms plays an important role in male reproductive physiology and that this is dependent on MsR2.

Discovery of culturable bacteria and fungi in mosquito saliva: potential players in mosquito-borne virus infection?

Authors: Wang Lanjiao[1], Delang Leen[2], Remue Laure[2], [1]Rega Institute for Medical Research, Belgium, [2]Rega Institute of KU Leuven

Abstract: Pathogens transmitted by mosquitoes result in the death of almost 1 million people every year. As mosquito saliva plays a key role in virus transmission and pathogenesis in human skin, here we explore if salivary microbes are potential contributors to this effect.

The saliva of Aedes aegypti and Culex pipiens was harvested and plated on agar plates to detect actively growing fungal and bacterial colonies. We identified the fungal species Penicillium crustosum for the first time in mosquitoes. Culturable bacteria we detected include Serratia marcescens, Serratia nematodiphila, Enterobacter spp. and Klebsiella spp. which were identified previously as mosquito or insect endosymbionts. Blood-feeding positively affected the bacterial but not fungal load in Aedes aegypti saliva. Our in vitro study showed that pre-incubation with mosquito saliva significantly reduced Semliki Forest virus replication in skin fibroblasts compared to cells without saliva. Interestingly, the removal of all salivary microbiota resulted in a significant reduction of virus replication compared to saliva with microbiota.

This study concluded for the first time that the saliva of Aedes aegypti and Culex pipiens contains bacteria and fungi. Furthermore, saliva and salivary microbes may play a negative role on viral replication in human skin cells.

First report of kdr L1014F and ace-1 G119S insecticide resistance in Belgian Culex (Diptera: Culicidae) mosquitoes

Authors: Wang Lanjiao[1], Soto Alina[2], Delang Leen[2], [1]Rega Institute for Medical Research, Belgium, [2]Rega Institute of KU Leuven

Abstract: The emergence of West Nile virus and Usutu virus in Europe is a significant risk to public health. In the absence of efficient antiviral therapy or vaccine candidates, the only strategy to control these arboviruses is to target the Culex mosquito vector. However, the selection pressure caused by exposure to insecticides in vector control or agricultural pest control can lead to the development of insecticide resistance reducing the efficacy of insecticide-based vector control interventions. In Culex mosquitoes, two of the most common amino acid substitutions associated with insecticide resistance are the kdr L1014F in the voltage gated sodium channel and G119S in the acetylcholinesterase.

In this study, Culex pipiens biotype pipiens, Culex torrentium, and Culex modestus were sampled from 2019 to 2021 in three distinct environmental habitats (urban, peri-urban, and agricultural) in and around the city of Leuven in Belgium. Two mutations resulting in L1014F and G119S amino acid substitutions were screened for in individual mosquitoes. Both mutations were observed in Culex pipiens and Culex modestus mosquitoes across the four collection sites, but not in Culex torrentium. Furthermore, multi-resistance or cross-resistance could be a developing threat, since both mutations were observed at low frequencies (resistant allele frequency <30%) and always in heterozygosity.

These results provide the first report of kdr L1014F and ace-1 G119S resistance in Culex pipiens and Culex modestus mosquitoes from Belgium, highlighting the importance of mosquito surveillance for the development of effective arbovirus control strategies in the event of an outbreak in Belgium.

The toxicity of triflumezopyrim and its sublethal effect on red imported fire ant Solenopsis invicta Buren

Authors: Wang Lei[3], Lu Yongyue[3], Zhao Fei[4], Li Jiayi[2], Tao Qiuhong[3], Xu Yijuan[1] and Li Zhiqiang[4], [1]770269271@qq.com, China, [2]937818440@qq.com, China, [3]Red Imported Fire Ant Research Center, South China Agricultural University, China, [4]Shenzhen Agricultural Science and Technology Promotion Center, Shenzhen Administration for Market Regulation, China

Abstract: The red imported fire ant, Solenopsis invicta Buren, is a serious invasive pest in its invaded range. The use of insecticide remains the frontline method in controlling red imported fire ant (Solenopsis invicta Buren), which is one of the top 100 worst invasive organisms worldwide. Neonicotinoids are effective ingredients found in toxic baits that are used to suppress S. invicta population. To search for new and effective insecticides, we evaluated the toxicity of the novel neonicotinoid analog triflumezopyrim against S. invicta, and examine its sublethal effect in S. invicta food consumption (sugar water and locusts) and aggressiveness. Triflumezopyrim exposure to S. invicta did not cause high mortality, even at 120 μg/mL dosage for 72h treatment. Long-term exposure showed that 10 μg/mL triflumezopyrim caused 100% mortality after 2 weeks, but 1 μg/mL did not cause any significant effect on colony growth within the 56-day treatment period. Triflumezopyrim at 10 μg/mL did not inhibit S. invicta food consumption including sugar water and locust within the 7-day treatment period. Similarly, the addition of 1 μg/mL of triflumezopyrim did not inhibit the food consumption of S. invicta during the whole trial period. S. invicta treated with 10 μg/mL triflumezopyrim displayed a significant reduction of aggressiveness during interspeci?c confrontations and showed higher mortality than the control group after aggressive encounters. However, S. invicta treated with 1 μg/mL did not show any significant impact both on aggressiveness and mortality after aggressive encounters. Overall, our results showed that triflumezopyrim has a significant negative effect on fire ant population fitness. These findings imply that triflumezopyrim could be used as a bait toxicant against S. invicta.

Multiple responses of Diadegma semiclausum and its host Plutella xylsotella to elevated temperatures are asymmetrical and more detrimental to the parasitoid.

Authors: Wang Leyun[1], Walter Gimme[3], Etebari Kayvan[3] and Furlong Michael[2], [1]Australia, [2]School of Biological Sciences, The University of Queensland, Australia, [3]The University of Queensland, Australia

Abstract: Understanding how temperature affects host-parasitoid interactions is crucial for predicting the likely effects of climate change. The solitary, endo-larval, koinobiont parasitoid Diadegma semiclausum is a specialist attacking Plutella xylostella and it is an important biological control agent of the pest. The development, pupal weight and fecundity of non-parasitized P. xylostella and D. semiclausum developing in P. xylostella hosts were investigated at constant temperatures of 10, 15, 20, 25, 30°C. Parasitoids reared at 30°C had the shortest adult life span, lowest egg load, lowest pupation rate, smallest pupal weight and incurred the largest costs arresting host development. Investigations of the outcome of parasitism, the effects of parasitism on host development, intergenerational population growth between the parasitoid and the non-parasitized hosts showed that higher temperatures were more detrimental to the parasitoid than its host. A higher proportion of parasitoid larvae could not complete development when reared at 30°C, the temperature at which host biomass was smallest and the metabolic demands of the parasitoid even greater than at lower temperatures. These responses might have contributed to previous failures of the parasitoid to establish in lowland tropical regions. Elevated temperatures affect host and parasitoid growth and development in multiple ways. These effects are consistently more detrimental to parasitoids than their hosts, explaining why parasitoids are more susceptible to elevated temperatures, a consistent response that might affect their impact on pest populations under conditions of predicted climate change.

Worldwide historical biogeography of termites (Blattodea: Isoptera)

Authors: Wang Menglin[1] and Bourguignon Thomas[2], [1]OIST, Japan, [2]Okinawa Institute of Science & Technology Graduate University, Japan

Abstract: Termites are well-known for their importance in organic matter decomposition and soil fertilization in tropical and subtropical ecosystems. Termites diverged from other cockroaches ~170 Ma, and all modern termite species share a common ancestor dated at 149 Ma. Given the antiquity of termites, both vicariance, through plate tectonics, or dispersal, through oceanic rafting or across land bridges, can explain the current distribution of termites. The phylogenetic relationships among termite families and subfamilies are well-studied. However, the relationships among lineages that diverged more recently have been unknown until recently. In our project, we used complete mitochondrial genomes to build time-calibrated phylogeny of termites, with the final aim of resolving the global historical biogeography of termites. We selected a representative set of samples, including species from all lineages, and from across the geographic locations where termites are known to occur. This dataset allowed us to reconstruct the precise origins and dispersal patterns of termites. Finally, we will sequence mitochondrial genomes of around 2000 samples including almost all termite species of the Neotropical regions.

RNA interference strategy triggered the abnormal reproductive development through silencing the crucial genes of the Sphingolipid pathway in the Brown Planthopper (Nilaparvata lugens)

Authors: Wang Ni, ZheJiang University, China

Abstract: Insect fecundity is defined as the number of offspring produced by an individual female during a set time period. Their robust fecundity not only ranks insects as the most diverse class of animals on earth but also makes insect pests a tremendous threat to human health and agricultural production. Sphingolipids are major structural components of endomembranes, which plays a crucial role in differentiation senescence, proliferation, apoptosis, programmed cell death and stress responses. In past studies in our laboratory on Sphingolipid pathway, the fecundity-related mechanisms have been studied at the levels of pathways and genes. Serine palmitoyltransferase (SPT) and Sphingomyelin phosphodiesterase (SMPD) are the key enzymes of sphingolipids, silencing the SPT and SMPD via RNA interference showed abnormal development and low fecundity.MicroRNAs(miRNAs)are a group of small non-coding RNAs involved in various development and biological processes through negative regulation of mRNAs at both transcriptional and post-transcriptional levels. It's also act in insect development and reproduction by regulating genes involved in these physiological processes. Although hundreds of insect miRNAs have been identified, the biological roles of most remain poorly understood.The brown planthopper (BPH), ilaparvata lugens (sta(o)l), which belongs to Homopteran, Delphacidae, is one of the most serious and destructive insect pests of rice. BPH have two wing phenotypes, long-winged (LW) and short-winged (SW) morphologies. LW morphs are capable of long-distance migration,while SW morphs have high reproduction capabilities. In the present study, small RNA libraries from (dsGFP, dsSPT, dsSMPD) short-winged morphologies female adults were constructed and sequenced. Subsequently, we examined the expression patterns of these miRNAs at three libraries. We used a multi-algorithm approach for miRNA target prediction in 3'UTRs of fecundity-related genes in the brown planthopper (BPH) Nilaparvata lugens and identified 43 putative miRNAs targeting SPT, 70 miRNAs targeting SMPD. High-ranked miRNAs were selected for target validation. Though QRT-PCR from different development phases and tissues, we experimentally verified N. lugens SPT may as an target of microRNA-1a. SMPD may targeting miR-71 and miR-184. In the females, SPT relative expression was down-regulated after injection of a miR-1a-3p agomir but up-regulated after injection of a miR-1a antagomir. In addition, overexpression of miR-1a disrupted ovary development in N. lugens. These findings showed that miR-1a is involved in regulating N. lugens fecundity by targeting SPT. Moreover, this study may lead to better understanding of the fecundity of this important agricultural insect pest.

Density-dependent aging plasticity in the migratory locust, Locusta migratoria

Authors: Wang Xianhui, Institute of Zoology, Chinese Academy of Sciences, China

Abstract: Locusts are one of the world's most destructive agricultural pests. At 2020, the locust swarms in East Africa and Middle Asia made more than 19 million people at risk of severe food insecurity. The lifespan and aging of locusts is one of the most important factors that determine the extent of locust plague. Thus study of the aging characteristics of gregarious locusts will help predict the hazard area and duration of locust plague. Here we systemically study the aging signatures of gregarious locusts at the physiological, cellular, and molecular levels. We first characterized the lifespan of adult locust males and found the locust has a short lifespan with median 22 days after exclusion. Then we assessed the changes of two key physiological traits, flight ability and sperm states which is important to locust plague. Our results revealed a remarkable and fast declines in flight ability and relative slight declines in sperm states upon aging. The cross-species comparisons of aging-related transcriptomes revealed the common signatures of aging-related genes between locusts and other model species, suggesting the overall conserved aging mechanisms between locusts and other species. Furthermore, we assessed the tissue-specific transcriptional changes in locusts, characterized by fast and intense alterations in flight muscle and fat body but stable testis and brain. Aging of flight muscle is accompanied by dramatic decline in the expression of genes involved in energy metabolism and aged fat body displayed intense upregulation of genes related to detoxification and immunity, revealing the intense homeostatic disruptions of metabolism and stress responses in aged locusts. The histological experiments also revealed remarkable aging deterioration in flight muscle and fat body but not brain. Lastly, we identified 4 representative locust aging genes (LIPT1, JUN, IAP1, and PGRP-SA) through screening locust transcriptomes, the knockdown of these 4 genes and 3 well-known aging genes (SOD1, LAMIN, and PINK1) in locusts all lead to short lifespan and aging phenotypes. Our results revealed although locusts have a large extent of conservation of aging characteristics with other species, they also displayed specific aging signatures such as fast deterioration of fat body and insensitivity to aging of brain, activation of detoxification, and several locust-specific aging genes. These findings will help us understand the aging process of gregarious locusts and contributed to accurately predict the extent of locust plague by considering the aging-related deteriorations.

Yeast-dependent population differentiation in Drosophila melanogaster

Authors: Wang Xiaocui[1], G Kiran[1] and Maan Martine[1], [1]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [2]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands

Abstract: Adaptation to different ecological environments through divergent natural selection could result in reproductive isolation between populations and drive the formation of new species. Reproductive isolation will be accelerated when heterogeneous food resources not only promote divergent adaptation but also provide the substrate for reproduction. In many taxa, semiochemicals play a crucial role in food localization. Therefore, semiochemicals derived from food sources may attract different individuals to different food sources and hence reduce mating opportunities with one another. Over the course of many generations of selective pressure from heterogenous food resources, populations may evolve different behaviours including feeding and mating preferences. We test this hypothesis using Drosophila melanogaster and its main food source, yeast, which is essential for almost all stages of fly life cycle. Given the enormous diversity of yeast species and the global distribution of Drosophila melanogaster, different Drosophila populations may have adapted to different local yeast species. To explore the relevance of Drosophila-yeast interactions, we examined the influence of yeast and its semiochemicals on major Drosophila life history traits including: attraction, feeding, mating, oviposition and offspring development. We quantified these traits in a Drosophila-yeast matrix of 7 globally distributed fly populations and 4 yeast species. Our results reveal that different Drosophila populations respond differently to different yeast species in mating rate, fecundity and offspring development. There is thus an interaction between Drosophila populations and yeast species, suggesting that yeast and its semiochemicals may drive fly population differentiation and hence may have impacted Drosophila evolution.

Suppression of period and timeless arrest the photoperiodic induction of summer diapause in a cabbage beetle

Authors: Wang Xiao-Ping[2], Zhu Li[1], Liu Wen[2], [1]College of Plant Science and Technology, Huazhong Agricultural University, China, [2]Huazhong Agricultural University, China

Abstract: In insects, facultative diapause is a state of developmental arrest mainly induced by photoperiod or temperature that allows insects to survive adverse environmental conditions. Understanding how insect initiates facultative diapause and prepares diapause can provide us new insights to study developmental and evolutionary biology. It has been shown that the circadian clock genes can participate in photoperiodic measurement and regulate reproductive diapause initiation through JH signaling in short-day-induced winter diapause. However, how circadian clock genes translate photoperiodic information into downstream JH signaling for diapause destiny and then affect diapause preparation remains largely unknown. In the present study, we investigate this in the cabbage beetle Colaphellus bowringi which undergoes reproductive diapause under long-day condition. We respectively knocked down two circadian clock negative regulators, period (per) and timeless (tim), in the 3-day-old larvae (most sensitive to photoperiod), and dsgfp treatment was served as a control. Under the diapause-inducing photoperiod (16L:8D), knocking down per and tim significantly decreased the rate of burrowing behavior. And many female beetles of the per and tim RNAi showed developed ovary, decreased lipid accumulation and downregulated expression of stress resistance genes. The JH-induced genes, Kr-h1, JHE1, Vg1, and Vg2, significantly increased in the females with suppression of per and tim. It implied that suppression of per and tim during diapause initiation phase (DIP) could activate the JH signaling in the female adults. Before the beetles enter into diapause preparation phase (DPP), we used RNA sequencing to analyze gene expression profiles after per and tim RNAi. It showed that many differentially expressed genes were enriched in environmental information processing, such as mTOR and TGF-beta signaling pathway. To ask whether per and tim also regulate diapause preparation, we knocked down these two genes in the female adults during DPP. It showed that the diapause destiny was not affected, but the lipid storage in diapause-destined females was significantly reduced after per and tim RNAi. Interestingly, per- and tim-regulated lipid storage during DPP was independent on JH signaling. We further found that per and tim promoted lipid storage by regulating the expression of genes that control lipogenesis and lipolysis. In summary, these results suggest that per and tim participate in photoperiodic measurement and initiate reproductive diapause through JH signaling during DIP in long-day-induced summer diapause. The mTOR and TGF-beta signaling pathways may be involved in the regulation of JH signaling by circadian clock genes. Meanwhile, per and tim transduce photoperiodic signal and promote lipid storage during DPP in a JH-independent manner. These results provide us new clues to study the molecular mechanism of photoperiod-regulated diapause induction in insects.

Begomovirus ßC1 attenuates plant defense responses via interacting with NtSKP1 to promote vector performance

Authors: Wang Xiao-Wei[2], Zou Chi[1], Yang Jing-Jing[1], Chen Na[1] and Shu Yan-Ni[1], [1]Ministry of Agriculture Key Laboratory of Molecular Biology of Crop Pathogens and Insects, Institute of Insect Sciences, Zhejiang University, China, [2]Zhejiang University, China

Abstract: Virus-plant-insect tripartite interaction is one of the important determinants of the population dynamics of both types of organisms in the field. The relevant literatures have identified patterns about plant-mediated interaction between whitefly MEAM 1 and Tomato yellow leaf curl China virus (TYLCCNV). Thereinto, the virulence factor ßC1 encoded by TYLCCNV betasatellite played a key role in this indirect mutualism. Here, we found ßC1 interacted with the tobacco protein SKP1 (S-phase kinase associated protein 1), and NtSKP1 regulated the survival rate and fecundity of whitefly on plants. NtSKP1 and ßC1 could impact the gene transcript level in jasmonic related pathway through degrading the JAZ1 protein. These results suggested that ßC1 inhibited the plant defense responses through interacting with NtSKP1, and enhance the performance of vectors on plants.

Biology and ecology of Lycorma delicatula in its home range in China

Authors: Wang Xiaoyi, The Key Laboratory of Forest Protection, State Forestry and Grassland Administration, Research Institute of Forest Ecology, Environment and Protection, Chinese

Abstract: The spotted lanternfly, Lycorma delicatula, is a plant hopper that is invasive in the USA and South Korea but is native to China. Lycorma delicatula is not a serious pest in China, and its biology and host range are not well studied. The host dependence, oviposition substrates, and population differentiation were studied in the home range in China. From 2017-2019, eight species of host trees were caged to determine whether L. delicatula could complete its life history or not. The results showed that the tree-of-heaven (Ailanthus altissima), Chinese toon (Toona sinensis) and chinaberry (Melia azedarach) were the preferred hosts of the pest. The spotted lanternfly can develop into adults and produce egg masses feeding solely on each of these trees. The pest feeding on grapes developed into adults but never laid eggs. The nymphs feeding on kiwifruit and Sophora japonica died before the third instar. The oviposition behavior of L. delicatula is not aligned with what would be expected based on optimal oviposition theory; the pest can oviposit on host plants, non-host plants, and even some inorganic substrates such as stones, textile, etc. The pest probably prefers to oviposit on the substrates that are stable, sheltered from rain and wind, and with lower pressure from natural enemies. As we found both the morphology and population density among different regions were varying, the differentiation of geographical populations of spotted lanternfly was also analyzed by using molecular methods based on samples collected from all locations where the pest occurred naturally in China

Development of a biological control program against spotted lanternfly: preparing for the future

Authors: Wang Xiao-Yi[2], Hoelmer Kim A.[4], Wang Xiaoyi[3] and Broadley Hannah[1], [1]Department of Environmental Conservation, University of Massachusetts, Amherst MA 01003 & USDA APHIS Plant Protection and Quarantine, Science and Technology, Bu, [2]Research Institute of Forest Ecology, Environmental and Protection, Chinese Academy of Forestry, China, [3]The Key Laboratory of Forest Protection, State Forestry and Grassland Administration, Research Institute of Forest Ecology, Environment and Protection, Chinese , [4]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States

Abstract: The spotted lanternfly (Lycorma delicatula) is an exotic invasive plant-hopper that was discovered in Berks County Pennsylvania in 2014 and has since spread to five additional counties, as well as to Virginia, Delaware, and New Jersey, indicating that populations of spotted lanternfly are on the move. It threatens the grape, tree fruit, plant nursery and timber industries, which in Pennsylvania are valued at over $12 billion. This insect causes direct damage by removing sap, but indirect damage also occurs because black sooty mold grows on the copious honeydew excreted by nymphs and adults. Quarantines have been put in place to restrict the movement of plant, wood and stone products, but unfortunately the spotted lanternfly is not finicky about oviposition sites. Egg masses are cryptic and it is difficult to regulate the movement of all items potentially harboring them. Recent research on host plant utilization indicates that spotted lanternfly may be able develop to the adult stage on plant species other than tree-of-heaven (Ailanthus altissima), which could confound the eradication effort based on using tree-of-heaven as trap trees. We propose that given the eradication challenges, we should be proactive and develop a biocontrol program against the spotted lanternfly. As pest densities decrease, natural enemies with good searching behavior can be used as a tool in the ongoing eradication effort, and if eradication becomes untenable, the groundwork will have been laid for a classical biological control program.

The goal of our research is to discover parasitoids attacking spotted lanternfly in China where these pests are not in outbreak and are not considered economic pests, with the hypothesis that these natural enemies are partly responsible for reducing pest population density. To date we have discovered two potential biocontrol agents: Anastatus orientalis (an egg parasitoid) and Dryinus sp., which attacks lanternfly nymphs. Anastatus orientalis is found throughout the range of spotted lanternfly in China and depending on the circumstances (host plant, lack of pesticide use, etc.) parasitism rates can be high. We have conducted quarantine studies on the biology and life-cycle of A. orientalis, and we have initiated host specificity testing against plant-hoppers native to the U.S. In 2018 we collected Dryinus individuals and brought them to quarantine in the U.S. to start a rearing colony. Research on the biology, rearing, and host specificity testing of Dryinus species is ongoing.

Recent advances in biological control of important native and invasive forest pests in China

Authors: Wang Xiao-Yi[1], Zhang Yanglong[1], Yang Zhongqi[1], Wang Xiaoyi[2], [1]Research Institute of Forest Ecology, Environmental and Protection, Chinese Academy of Forestry, China, [2]The Key Laboratory of Forest Protection, State Forestry and Grassland Administration, Research Institute of Forest Ecology, Environment and Protection, China

Abstract: In recent decades, China has suffered severe attacks by both native and invasive forest pests. We have carried out a series of research projects on biological control of these pests. The fall webworm, Hyphantria cunea (Drury) (Lepidoptera: Arctiidae) has been sustainably controlled by an effective gregarious pupal endoparasitoid, Chouioia cunea Yang (Chalcidoidea: Eulophidae), which is native to China, and spraying HcNPV virus against the pest's larval stage. Pine wilt disease, caused by the pine wood nematode (Bursaphelenchus xylophilus (Steiner et Buhrer) Nickle) (Aphelenchida: Aphelenchidae), is currently the number one pest in China. The strategy for controlling the disease is to manipulate the nematode's vector, Monochamus alternatus Hope (Coleoptera: Cerambycidae). We discovered that Dastarcus helophoroides (Fairmaire) (Coleoptera: Bothrideridae) is the most important natural enemy in China pine forests. Mass rearing and release techniques were studied and developed. By releasing the parasitoid, 92.6% of the M. alternatus were parasitized in the first year. Meanwhile, three elaterid beetle species were found to prey on the larva of M. alternatus. The red turpentine beetle, Dendroctonus valens (LeConte) (Coleoptera:Scolytidae) was suppressed by a predator, Rhizophagus grandis Gyllenhal (Coleoptera: Rhizophagidae) introduced from Belgium and a total 3334 ha. of pine forests were protected. The oak longhorned beetle, Massicus raddei (Blessig) (Coleoptera: Cerambycidae) is the number one pest in the northeast forests of China, where it damages trunk of oaks, mainly Quercus liaotungensis and Q. mongolicus. An integrated management technique was developed for controlling the longhorned beetle: a special black light was invented for trapping the adults; the parasitoid Sclerodermus pupariae Yang et Yao (Hymenoptera: Bethylidae) was released against young larvae; and the parasitoid Dastarcus helophoroides eggs and/or adults were released when the hosts were mature larvae and/or pupae. By applying the technique for five years in northeastern China oak forests, the oak longhorned beetle has been controlled to a large extent. The emerald ash borer, Agrilus planipennis Fairmaire (Coleoptera: Buprestidae), is native to eastern Asia, including China, and feeding by larvae damages ash trees. Natural enemies of the emerald ash borer were investigated and seven species were found in China, of which Spathius agrili Yang (Hymenoptera:Braconidae), Tetrastichus planipennisi Yang (Hymenoptera: Eulophiae), Sclerodermus pupariae Yang et Yao and Oobius agrili Zhang et Huang (Hymenoptera: Encyrtidae) are predominant and have high potential for biocontrol of the pest. The biology, behavior, ecology and mass rearing techniques of the parasitoids were studied.

Effects of rearing on the host specificity and performance of a potential biological control agent of the olive fruit fly

Authors: Wang Xingeng[2], Tannières Mélanie[1], Desurmont Gaylord[1], [1]European Biological Control Laboratory (EBCL USDA ARS), France, [2]USDA-ARS, United States

Abstract: Psyttalia ponerophaga is a parasitoid of the olive fruit fly Bactrocera oleae that shows potential as a possible biological control agent against this invasive pest. This parasitoid has been reared for 9 years (75 generations) at EBCL USDA ARS on an alternative host, Ceratitis capitata. The present study was designed to test the hypothesis that rearing on an alternative host affected the performance and specificity of P. ponerophaga. To test this hypothesis, two populations of P. ponerophaga (rearing and wild) were compared in host specificity and performance trials under non-choice and choice conditions with two non-target Tephritidae species. Results showed that parasitoids of the two populations tested were able to successfully parasitize the two non-target species. The hypothesis that >75 generations of rearing on an alternative host decreased the specificity of the parasitoid was not supported by the data, which showed the opposite pattern: the wild population was more effective at successfully attacking non-target hosts than the rearing population under no-choice conditions. Parasitism of non-target hosts was significantly lower in choice-test settings, but was not totally absent. Genetic analyses of dead pupae of the two non-target species revealed several occurences of failed parasitism attempts on both species, particularly in trials involving the rearing population of P. ponerophaga. The wild P. ponerophaga population was more efficient than the rearing population at parasitizing B. oleae larvae: overall parasitism rate and progeny produced per female were higher, and sex ratio was more female-biased in the wild population. These results show that long-lasting rearing on an alternative host decreased the efficacy of P. ponerophaga at attacking its main host, which could have negative consequences for its foraging efficiency under realistic field conditions.

Post release monitoring of genetic diversity and Wolbachia infection of recovered Psyttalia lounsburyi, a biocontrol agent of the olive fruit fly in California

Authors: Wang Xingeng[4], Tannières Mélanie[5], Pickett Charles, H[1], Hoelmer Kim A.[2], Blanchet Arnaud[5], Guermache Fatiha[5], Daane Kent[3] and Manaargadoo-Catin Ludovic[5], [1]California Department of Food and Agriculture, Meadowview, California, United States, [2]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States, [3]University of California, Berkeley, California,, United States, [4]USDA-ARS, United States, [5]USDA-ARS-European Biological Control Laboratory, France

Abstract: Introduced biocontrol agents are expected to experience a loss in genetic diversity as the result of severe bottlenecks at different stages of biocontrol programs. Moreover, released biocontrol agents have to face and adapt to new abiotic or biotic conditions. Hybridization between individuals from different origins may favour the adaptability of the released biocontrol agents by increasing the available genetic variability. However, hybridization can be prevented when the two parents are harbouring different reproductive manipulators, such as the cytoplasmic incompatibility-inducing Wolbachia symbiont. It is thus important to get a better understanding of genetic processes and host-microbe interactions that can affect the establishment of a biocontrol agent.

Bactrocera oleae (Diptera: Tephritidae), is the most serious pest of cultivated olives worldwide. The parasitoid wasp Psyttalia lounsburyi (Hymenoptera: Braconidae) collected in Kenya and South Africa, were evaluated in quarantine. At the onset of the biological control program, the two populations of P. lounsburyi mass reared in the quarantine were genetically characterized and it indicated that they belonged to two different mitochondrial lineages. In addition, Wolbachia infection statuses were assessed for both populations and revealed the presence of two genetically different Wolbachia variants, a double infection in 96% of Kenya population, and a single infection in 50% of the South Africa population. A preliminary study on the effects of Wolbachia on its host suggested that the two variants are able to induce cytoplasmic incompatibility and that they are incompatible one with another. It also indicated that Wolbachia infection was associated with a decrease of available mature eggs.

From 2005 to 2015, more than 60 000 individuals of P. lounsburyi have been released in different counties of California. P. lounsburyi was recovered from field samples and is now established in coastal regions. The goals of this study were to assess the genetic diversity of the recovered parasitoids to identify which populations of P. lounsburyi established and spread and to study the Wolbachia population dynamics in the released populations in term of prevalence, and spatial and temporal variation of Wolbachia variants. Questions about the role of Wolbachia in the success of population establishment and hybridization were also addressed by this study.

Whereas P. lounsburyi of Kenya origin represented more than 99% of the parasitoids released, genetic studies of specimens recovered in 2015 revealed that the predominant haplotype is of SA origin. In addition, almost all the tested individuals of SA origin harbor the Wolbachia variant II indicating the spread of this Wolbachia variant in SA population. P. lounsburyi of Kenya origin mostly harbors both Wolbachia variants. The fitness cost of Wolbachia coinfection might be considered as a factor limiting the establishment of Kenya population although other fact

Evolution of active tandem repeat arrays in the nuclear and mitochondrial genomes of the jewel wasp

Authors: Wang Xu[5], Zhang Dapeng[2], Lin Jerry[3], Wang Jinbin[1], Werren John[4], Wang Xiaozhu[5], Tang Xueming[1] and Tan Yongjun[2], [1]Biotechnology Research Institute, Shanghai Academy of Agricultural Sciences, Shanghai, China, [2]Department of Biology, College of Arts & Sciences, Saint Louis University, MO, United States, [3]Department of Biology, Columbus State University, Columbus, GA, United States, [4]Department of Biology, University of Rochester, Rochester, NY, United States, [5]Department of Pathobiology, Auburn University, Auburn, AL, United States

Abstract: In this study, we sequenced, assembled and annotated the genomes in four jewel wasp species in the Nasonia genus and an outgroup species Trichomalopsis sarcophagae. The mitochondrial (MT) genome ranges from 14 to 16 Kbp in four species, with length variations due to the AT-rich control region (CR). Strikingly, we identified an 8,876 bp repetitive region in the CR of Nasonia vitripennis (Nv) MT genome immediately after the Cyb gene, containing thirty-seven 217-bp tandem repeat units organized in a palindromic structure. Unlike the typical tandem repeats found in known MT genomes, these repeats are significantly longer and extremely GC-rich (51%). The Nv-specific repeats were confirmed in all strains with Nv MT background, including three laboratory Nv strains collected in the US, one lab strain in Europe, an European population reference panel, as well as an Nv-mitochondrial replacement strain, suggesting that they were acquired after the split from other Nasonia species. Furthermore, these tandem repeats are actively jumping into the protein-coding regions in a subset of Nv MT genes, resulting in heteroplasmy that likely disrupts function of a subset of mitochondria within individuals, perhaps contributing to mitochondrial mutational load. Extensive search in public databases only identified repeat arrays with >70% sequence similarity in Nv nuclear genome and its B-group Wolbachia wVitB. A total of 19 repeat regions were identified in the Nv nuclear genome, 14 of which have more than 10 repeat units. The largest repeat array consists of 147 repeat units. At least 5 of these repeat arrays are insertions from the MT genome, as they are located in the NuMTs (nuclear mitochondrial DNA) and encompass partial MT-Cyb pseudogene sequences. These sequences are molecular fossils of the ancient MT repeats. After inserted into the nuclear genome, they undergo significant expansion through an unknow mechanism. We also discovered four types of repeat units in the Nv Wolbachia strain wVitB genome, suggesting the MT copies could be derived from the Wolbachia genome. This 9Kb parasitic repeats can be highly deleterious in the Nv MT genome, and we hypothesize that it may serve as the replication origin in the MT and reached fixation in Nv. This type of repeat was not observed in any other insect. They have similar characteristics of alpha-satellite sequences in vertebrates but with no sequence homology. This tandem repeat family behaves like a mobile element within the mitochondrion and between nuclear and cytoplasmic genomes.

Circadian light entrainment in a hymenopteran insect (Nasonia vitripennis)

Authors: Wang Yifan, University of Groningen, Netherlands

Abstract: Earth experiences daily and seasonal variations in light intensity and temperature due to its rotation. As a consequence of this, organisms under selection pressure have evolved an endogenous system to optimally capitalize environmental resources and to adapt to frequent fluctuations in light and temperature (Allada and Chung, 2010). This endogenous circadian rhythm persists in constant conditions but is also entrained by external signals, with light being the most important stimuli (Ben-Shlomo and Kyriacou, 2002). The molecular mechanisms of how the daily and seasonal changes of day length are detected, measured, interpreted, and translated into physiological signals are under intensive investigation. Cryptochromes, sensitive to UV and blue light, are important photoreceptors involved in the circadian light entrainment in Drosophila and plants by inducing protein degradation (Katz and Minke, 2009). However, a non-light sensitive mammalian-like CRY is found in other insect orders forms part of the biological clock as the core transcriptional inhibitor (Chauhan et al., 2017). It remains unclear what mechanisms are used in circadian light entrainment in insects with only the non-photosensitive mammalian-like CRY (Lam and Chiu, 2017). The Hymenoptera is a major insect order, comprising of bees, wasps, and ants, that carries mammalian CRY only. Therefore, the aim of this project will be to elucidate the mechanism by which the circadian clock of Hymenopteran insects (using Nasonia vitripennis as a model) is used to synchronise to light and to find the molecular substrate for latitudinal selection pressures on variation in light sensitivity. The results expected include the qPCR measurements of light induction of circadian clock genes, an action spectrum for circadian light resetting, and CRISPR-CAS manipulation of candidate circadian light induction pathway genes. While the experiments are still ongoing, I will present current data on the effects of different light intensity on circadian phase shifts and future experiment designs.

Circadian photoreception in a hymenopteran insect Nasonia vitripennis

Authors: Wang Yifan, University of Groningen, Netherlands

Abstract: Hymenopteran insects are crucial species of our ecosystems and fulfill valuable ecological roles in nature, as well as in agricultural and industrial sectors. With the global declines in their population sizes, it is necessary to understand their circadian system, since it is essential for orientation, foraging, and anticipation of the environment (Eban-Rothschild and Bloch, 2011).

A key component in circadian system regulation is light. Cryptochromes (CRY) is an important photoreceptor involved in the circadian light entrainment in Drosophila by inducing protein degradation (Katz and Minke, 2009). However, many other insects such as Nasonia vitripennis, are lacking such light-sensitive CRY and thus, the circadian photoreceptors and the mechanisms underlying circadian light entrainment remain unclear (Lam and Chiu, 2017).

By constructing a circadian action spectrum, the current results indicate that opsins are the major circadian photoreceptors in Nasonia, and more than one opsin is involved in the regulation of circadian responses. There are potential color contrast mechanisms between different opsins. These results provide insight into reducing the harmful effect of artificial light at night (ALAN), by using artificial light with a narrower bandwidth and specific wavelengths.

Genetic mechanisms underlying desiccation resistance across Drosophila species

Authors: Wang Zinan[1], Chung Henry[1], [1]Michigan State University, United States

Abstract: One of the largest challenges for organisms living in terrestrial environments is water loss. Insects use cuticular hydrocarbons (CHCs), a lipid layer on the body surface, to prevent water from escaping from their body. Previous studies have shown that the presence of a subset of these CHCs, the methyl-branched CHCs (mbCHCs), contribute to desiccation resistance in some Drosophila species. Among Drosophila species possessing mbCHCs, a length variation of mbCHCs ranging from 24 to 32 carbons has been observed. The longer chain mbCHCs physically correlate with higher efficiency in preventing water evaporation. However, whether the length variation of mbCHCs accounts for different levels of desiccation resistance is unknown, along with the molecular mechanisms. In our study, we conducted a meta-analysis which showed Drosophila species with longer chain mbCHCs have higher desiccation resistance. Using a candidate gene approach, we identified a fatty acyl-CoA elongase gene in D. melanogaster, which we named mElo, responsible for elongating mbCHCs from 24 to 28 carbons. Drosophila mojavensis is a desert fly species with the highest desiccation resistance and the longest mbCHCs (28 – 32 carbons). In D. mojavensis, we identified its mElo ortholog (Dmoj/mElo) and showed that the transgenic overexpression of Dmoj/mElo in D. melanogaster led to longer chain mbCHCs and significantly higher desiccation resistance than the control flies. Phylogenetic analysis suggested that mElo is conserved across Drosophila species. Future studies will focus on understanding whether this fatty acyl-CoA elongase gene underlies the length variation of mbCHCs and different levels of desiccation resistance in Drosophila species.

Geographical variability of Messor arenarius ants from different regions in Northern and Central Israel

Authors: Warburg Ittai, Haifa, Israel

Abstract: In this work it was found, that lengths of Messor arenarius ants from southern parts of the Coastal Plain of Israel between Tel-Aviv and Ashkelon (12.32mm ± 1.68mm; N=37), are significantly bigger than lengths of those ants from northern and central parts of this Coastal Plain between Tel-Aviv and Rosh-Haniqra (11.46mm ± 1.83mm; N=63) (t=2.3463; S.E.=0.368; D.F.=98; P=0.0210 in a bilateral t-test). It was also found, that mandible widths of M. arenarius ants from southern parts of the Coastal Plain of Israel between Tel-Aviv and Ashkelon (2.216mm ± 0.630mm; N=37), are mostly significantly bigger than mandible widths of those ants from northern and central parts of this Coastal Plain between Tel-Aviv and Rosh-Haniqra (1.746mm ± 0.530mm; N=63) (t=3.9910; S.E.=0.118; D.F.=98; P=0.0001 in a bilateral t-test). These differences in sizes of M. arenarius ants between these northern and central regions and these southern regions are related to climatic differences between these areas. The southern parts of the Coastal Plain of Israel are hotter and have more arid conditions than the northern and central parts of this Coastal Plain.

A long and perilous crossing: the migratory trajectories and journey times of the Australian Bogong moth

Authors: Warrant Eric[1], R. Taylor John[4], Alistair Drake V.[3] and Hao Zhenhua[2], [1]Department of Biology, Lund University, Sweden, [2]School of Sciences, UNSW, Canberra, Australia Department of Biology; Lund University, Sweden, Australia, [3]School of Sciences, UNSW, Canberra, Australia; Institute for Applied Ecology, University of Canberra, Australia, [4]School of Sciences, UNSW, Canberra, Australia

Abstract: Studies of the large-scale population dynamics and pathways of migratory insects are few due to the difficulty of observing and tracking such small animals. Entomological radars provide observations of high-altitude insect migration activity and have revealed many fascinating aspects of migration ecology and flight behavior. However, this technique can only provide information on migrations at particular locations. We report here a study of springtime migratory movements of Australian Bogong moths (Agrotis infusa; Lepidoptera: Noctuidae) from their breeding grounds on the inland plains of New South Wales to their aestivation sites in the Snowy Mountains, a journey of up to 1000 km towards the south or east. The study draws on long-term data from an entomological radar at Bourke, NSW, observations from weather surveillance radars at Namoi, NSW and Yarrawonga, VIC, and a modified trajectory simulation model, to assess the moths' migratory paths. We extracted events and seasonal patterns of migration activity across the 14-year study period and correlated these events with meteorological variables. We then assess the likelihood of a take-off (initiation of migration), based on the weather conditions at the time, and predict the trajectories the migrants would then have followed. We predict that migration will be most strongly influenced by synoptic-scale pressure patterns that bring higher temperatures and stronger winds in a favorable migratory direction, but that these conditions only occur intermittently (i.e. on a minority of nights), with the moths hiding, feeding or resting at other times. Consequently, trips from northwest NSW to the Snowy Mountains may take many weeks depending on how frequently favorable conditions occur in a particular season.

Spatial configuration and landscape context of wildflower areas determine their benefits to pollinator α- and β-diversity

Authors: Warzecha Daniela[3], Diekötter Tim[1], Wolters Volkmar[2] and Jauker Frank[2], [1]Christian-Albrechts-Universität zu Kiel, [2]Justus-Liebig-Universität Gießen, [3]Senckenberg Research Institute and Natural History Museum , Germany

Abstract: Wildflower areas have become a staple tool within agro-environmental schemes (AES) to counteract pollinator declines. While their role in providing food resources to resident flower-visiting insects is unambiguous, the conservation effectiveness in a landscape context is less clear. Particularly, how multiple vs. single wildflower area utilization differs between simple and complex landscapes is understudied. We examined colonisation and community dynamics of wild bees and hoverflies in 33 newly established wildflower areas across a gradient of landscape complexity and connectivity during three consecutive years. We recorded more than 25% of the wild bee and hoverfly species of Hesse in an area of approx. 10 ha, substantiating the general benefit of wildflower areas to pollinators. While alpha-diversity increased with landscape complexity in isolated wildflower areas, the opposite pattern was observed for connected ones. The low alpha-diversity in complex landscapes indicated a dilution effect between connected sites. The inverse relationship between alpha and beta diversity among wildflower areas within landscapes suggests interspecific trade-offs between local resource conditions and landscape context. Accordingly, the establishment of multiple wildflower areas is advisable to increase connectivity of suitable habitats in simple landscapes. Moreover, adjusting local conditions to landscape context likely optimizes conservation effectiveness in modern agroecosystems.

Arthropod genomics for our planet: the i5k, Darwin Tree of Life, and Earth BioGenome projects

Authors: Waterhouse Robert[1], Hackett Kevin[3], Lawniczak Mara[5], Richards Stephen[4] and Brown Susan[2], [1]Department of Ecology and Evolution, University of Lausanne, and Swiss Institute of Bioinformatics, Switzerland, [2]Kansas State University, United States, [3]United States Department of Agriculture, Agricultural Research Service, United States, [4]University of California, Davis, United States, [5]Wellcome Sanger Institute, United Kingdom

Abstract: Arthropod genomes are critical for performing cutting-edge entomological research, from gaining key insights into basic animal biology, to finding new ways to limit the effects of damaging species or protect threatened ones, and to understand the evolution of arthropod diversity on Earth. The recent successes of the pilot phase of the 5’000 arthropod genome sequencing initiative (i5k, http://i5k.github.io), and the launching of the Darwin Tree of Life (www.darwintreeoflife.org) and Earth BioGenome (www.earthbiogenome.org) projects highlight the importance of insect genome biology as a tool to improve our knowledge of the millions of species with which we share our planet. The i5k initiative has been growing as a community of researchers focused on arthropod genomics that works towards improved sequencing, assembly, annotation, and data management standards, with the goal of facilitating the sequencing and analyses of the genomes of 5’000 arthropod species. The Darwin Tree of Life project, led by the Wellcome Sanger Institute, plans to sequence and assemble high-quality genomes of all known species of animals, plants, fungi and protists in the British Isles. These projects, along with other global partners including the Global Invertebrate Genomics Alliance and the Global Ant Genomics Alliance, form part of the larger Earth BioGenome project, which aims to sequence, catalogue and characterise the genomes of all of Earth’s eukaryotic biodiversity. Rapidly advancing technologies are making such ambitious projects possible, but scientific and organisational challenges will still need to be overcome in order to maximise the benefits to humanity. Here we present a brief overview and up-to-date progress report with contributions from leaders of each of these major arthropod genomics initiatives.

Effects of ground temperatures on survival and energy usage of overwintering queen bumblebees

Authors: Waybright Sarah A.[1], Dillon Michael E.[1], [1]University of Wyoming, United States

Abstract: Bumblebees are critical pollinators in serious decline, in part due to changing climate. Studies have primarily focused on effects of rising temperatures during the growing season, but most of a temperate bumble bee’s life cycle is spent overwintering underground. Queen bumble bees burrow underground in the fall and rely on energy stores to survive harsh conditions until the following spring. Fall and winter ground temperatures therefore determine energy use, overwintering survival, and potentially the spring nesting success of queens. However, little is known about ground temperatures experienced by overwintering bumble bees or how those temperatures determine success during this critical period. We combined measurements of lower lethal temperatures and the temperature dependence of metabolic rates for overwintering and active bumble bee queens with ground temperature data to estimate geographic variation in survival and energy use at different soil depths. Ground temperatures from throughout North America provided estimates of range-wide differences in optimal overwintering soil depth. This approach not only reveals optimal overwintering depths for bumble bees now, but also allows for predictions of how a warming climate might influence bumble bee overwintering survival in the future.

Can thermal plasticity improve insects’ resilience to climate change?

Authors: Weaving Hester[3], Terblanche John[1], Pottier Patrice[2], English Sinead[3], [1]Department of Conservation Ecology & Entomology, Stellenbosch University, [2]The University of New South Wales, Sydney, [3]University of Bristol, United Kingdom

Abstract: Extreme temperature events are increasing in frequency and intensity due to climate change. Insects are particularly vulnerable as, predominately, species are ectothermic. Insects can enhance their thermal limits through acclimation, yet evidence that plasticity is sufficient to aid survival under temperature extremes is limited. Here, using meta-analyses across 1,374 effect sizes, 72 studies and 94 species, we show that thermal limit plasticity is pervasive but generally weak: per 1°C rise in acclimation temperature, critical thermal maximum increased by 0.09°C and per 1°C decline, critical thermal minimum decreased by 0.15°C. Moreover, small but significant publication bias suggests that the magnitude of plasticity is marginally overestimated. Juvenile insects were more plastic than adults: thus, indicating a developmental window which elicits a larger response. Overall, critical thermal limit plasticity is likely of limited benefit to insects during extreme climatic events, yet we need more studies in under-represented taxa and geographic regions.

Biodiversity and evolution in fossil insects from the Eocene

Authors: Wedmann Sonja, Senckenberg Research Station Grube Messel, Germany

Abstract: Eocene climates around 50 Mio years ago provide possibly the best analogs for the world's near-future climates (Burke, Williams, Chandler et al. 2018). In the Early Eocene no ice was present even at the poles, and warm-adapted organisms had a wide diversity and unexpected biogeography. The high biodiversity and evolution of Eocene insects can be exemplified from the fossil Lagerstätten Messel and Green River. The Messel Pit Fossil site is a UNESCO world natural heritage site in Germany and its maar lake sediments preserve a highly diverse flora and fauna (e. g. Smith, Schaal & Habersetzer 2018). The Green River Formation was deposited in a large lake system located in Utah, Wyoming and Colorado (USA) (e.g. Smith, Carroll & Singer 2008, Grande 2013). Recently studied ichneumonid wasps (Hymenoptera) from Messel provide evidence that the extant genera Rhyssella and Xanthopimpla date as far back as the Early/Middle Eocene. Xanthopimpla is considered to indicate a warm climate. Five out of seven new species from Messel can be placed unequivocally in extant subfamilies and genera. A new species belonging to the subfamily Labeninae is the only record from Eurasia and suggests a formerly wide distribution of this group (Spasojevic, Wedmann, Klopfstein 2018). From Green River, two new, probably extinct genera and five new species have been described, and ten formerly described species were revised (Spasojewic, Broad, Bennett et al. 2018). Bugs (Heteroptera) have also been studied from both sites, and studies are still ongoing. For example, tingid bugs are present in both sites. Their diversity in Messel with more than four species is high, while from Green River only one species of tingid bugs has been described. The species from Green River displays strongly enlarged antennae, which are completely unknown in tingid bugs today. These distinctive modifications of the antennae got lost in the extant relatives (Wappler, Guilbert, Labandeira et al. 2015). Another peculiar, extinct genus of bugs belongs to Pentatomidae, and is present in both fossil sites. These bugs possess prominent humeral angles of the pronotum and a spinose pronotum and abdomen. A possible function of this extreme morphology might be defense against predators (Wedmann, Kment, Campos et al. 2021). Extinct giant ants belonging to the genus Titanomyrma (Formicidae, Hymenoptera) are present in Messel with two species and in Green River with one species. Giant ants were shown to be thermophilic and the distribution in North America and Europe implies that migration took place during a hyperthermal episode in the beginning of the Cenozoic (Archibald, Johnson, Mathewes et al. 2011).

Effectivenesses of the various exposure patterns of insecticides against the brown planthopper, Nilaparvata lugens (Stål)

Authors: Wei Qi[1], Wan Pin-Jun[2] and Fu Qiang[2], [1]China National Rice Research Institute, China, [2]State Key Laboratory of Rice Biology, China National Rice Research Institute, Hangzhou, Zhejiang, China

Abstract: Chemical pest control was still the dominant strategy in Asian rice production through the last decades, and therefore the precision-sprays of pesticides technologies for integrated high-tech crop protection were required, such as the use of drones. However, the cases of less than ideal insecticidal efficacies always appeared depending only on the drone-based system in the rice fields, especially for the brown planthopper (BPH), Nilaparvata lugens, a notorious pest damaging on the rice stems.

We supposed that the cause of failure might be related to the position differences between the BPH damage parts (rice stem base) and the distribution of pesticide deposition (rice canopy) after the drone sprayer operation. This present study focused on pesticide utilization rates under the conditions of the various exposure patterns of insecticides and their effectiveness against BPH at tillering growth stage of rice. For these three insecticides, dinotefuran, nitenpyram and pymetrozine, they had optimum controls (70.0 % - 87.5% against BPH) on day seven by the normal insecticide spraying (NIP) application (whole plant exposed to individual insecticide mentioned above), the range of corresponding pesticide residue (CPR) was 0.231 mg/kg - 0.693 mg/kg on day four; the second one was the spraying application covering the rice stem (56.7% - 75.0% against BPH), their CPR were accounting for 59.7% - 88.2% of the NIS application levels; the worst ones were the applications of directly adding the chemicals into water (depth: approximately 3.3 cm) and leave-only exposed to insecticide (25.5% - 55.4% against BPH), their CPR were accounting for 29.6% -57.6% of the NIS application levels. Taken together, under the conditions of the same amount of pesticide use, there were remarkable differences in utilization rates of insecticides among the various exposure patterns, which also could have immediate impacts for BPH control. This research provided the empirical evidences of normal BPH management decision-making, also could contribute to improve the operations of pesticides precision-sprays against the pests and diseases by innovative technology in the future.

Knockdown of the chromatin remodeling ATPase gene Brahma impairs the reproductive potential of the brown planthopper, Nilaparvata lugens

Authors: Wei Qi, China National Rice Research Institute, China

Abstract:

1. The full-length cDNA of the chromatin remodeling ATPase gene Brahma was cloned in N. lugens.
2. NlBRM transcripts was abundantly expressed in the egg and ovary.
3. Knockdown of NlBRM by RNAi could impair the ovarian development and fecundity of females.

Functional analysis of non-ATPase regulatory subunit genes in a rice pest, Nilaparvata lugens

Authors: Wei Wang, State Key Laboratory of Rice Biology and Ministry of Agriculture Key Lab of Molecular Biology of Crop Pathogens and Insect Pests, Institute of Insect Sciences, China

Abstract: The 26S proteasome is involved in the regulation of the process of degradation of ubiquitinated proteins in organisms. The 26S proteasome consists of the 20S core particle (CP) complex and the 19S regulatory particle (RP) complex. The composition of the 19S complex divided into ATPase regulatory subunit (Rpt) and non-ATPase regulatory subunit (Rpn). Here, we identified 14 Rpns through searching the transcriptome data of the brown planthopper, Nilaparvata lugens, a monophagous rice pest. The developmental stage-expression showed that Rpn transcripts were detected at high levels in egg and/or female adult, but at low levels in male adult. RNA interference via microinjection with double-stranded Rpns resulted in the abnormal ovary development in N. lugens female adults and inhibited oviposition or egg hatching from the rice seedlings (except dsRpn5), implying that Rpns were necessary for oocyte maturation in female adult. These findings improve our understanding of the reproductive and developmental strategies in insects and provides potential targets for the future management of rice pests.

Fast polypedal locomotion: Experiments and modelling approaches to explain the occurrence or absence of gait changes

Authors: Weihmann Tom, Dept. of Animal Physiology Institute of Zoology University of Cologne, Germany

Abstract: Legged locomotion is a main concern of integrative physiological research. Traditionally it is examined on various levels from a range of different perspectives including behaviour, control and biomechanics. For arthropods, much of this research is based on very few established laboratory species largely ignoring major anatomical differences while wider ranges of body size, running speed and behavioural adaptations are often available only for vertebrates. In legged terrestrial locomotion, different gaits and energetic economy are largely determined by the biomechanical characteristics of a locomotor apparatus defining the dynamics of the centre of mass (COM). However, COM dynamics are determined by the degree of leg synchronization, the single leg duty factors and the resulting overall vertical ground reaction forces. While slow locomotion in arthropods seems to lack much COM oscillation many insects employ alternating sets of diagonally adjacent legs when moving quickly, which can result in pronounced COM bouncing and might indicate elastic energy recovery within the legs. Apart from synchronized sets of legs, storage and recovery of movement energy also requires cyclical movements which are mostly restricted to relatively smooth, firm and reliable substrates. For small scale creatures like terrestrial arthropods, natural substrates rarely fulfil all three of these conditions, which might compromise the exploitation of COM oscillations in order to economize locomotion energetics. Accordingly, it has been shown recently, that some insect and arachnid species switch back to lower degrees of leg synchronization when running close to their top speed. By using simple model approaches, I will explain the impact of running speed, anatomy, leg coordination and temporal disturbances of the legs' touch-down and take-off on the gait choice at high running speeds in multilegged animals.

Microbiota of solitary pollinators - A moving target for priority effects

Authors: Weinhold Arne, Ludwig-Maximilians-Universität München, Germany

Abstract: Unlike social insects, solitary pollinators acquire their microbiota entirely from the environment, which makes them highly vulnerable to environmental influences. The timepoint of acquisition can be important for the microbial community assembly, known as priority effect, but depends largely on stochastic effects and random influences. Here, the influence of local habitat (e.g. local flower diversity or fragmentation of the habitat) can play a major role, as well as the movement pattern and foraging distance which definiens the microbial acquisition range. Host movement has contrasting effects on the gut-microbiota as it can either reduce or enlarge spatial scale (aggregating vs dispersing host). While aggregation could enhance inter-host transmissions and increase the uniformity among conspecifics or social groups, an increased dispersal movement could dissolve effects of the local environment and extends microbial dispersal limitations across plant-pollinator networks (comparing local foraging of mason bees vs. semi-migratory butterflies). Though host movement and migration distance and can directly influence major drivers of the host microbiota it has been little regarded within host-microbiota frameworks.

Evolution of oviposition strategies in Heteroptera

Authors: Weirauch Christiane[2], Johnson Kevin[1], Standring Samantha[2] and Allen Julie[3], [1]Illinois Natural History Survey, University of Illinois, United States, [2]University of California, Riverside, United States, [3]University of Nevada, Reno, United States

Abstract: Ovipositor morphology has been shown to be associated with life history strategy in several groups of insects. Heteroptera include lineages with plate-like and laciniate ovipositors and oviposition sites range from leaf litter, soil, and surfaces of plants to eggs being inserted into plant tissue. The literature on both ovipositor morphology and oviposition sites of Heteroptera is dispersed. We here use a phylogenomic dataset covering ~80% of true bug families (Hemiptera: Heteroptera) and comprehensive literature searches to trace the evolution of ovipositor types and oviposition strategies across the suborder.

Evolution of raptorial legs in the assassin bugs (Hemiptera: Heteroptera: Reduvioidea)

Authors: Weirauch Christiane[2], Knyshov Alexander[1], [1]United States, [2]University of California, Riverside, United States

Abstract: Reduvioidea (Hemiptera: Heteroptera), or the assassin bugs, are one of the morphologically and ecologically most diverse lineages of hemimetabolous insects, with around 7000 described species, 2 families and 26 subfamilies. As predators, they have evolved a great variety of leg modifications to handle the prey. However, detailed assessment of the raptorial features has been done only for few specific groups within Reduvioidea, while broader analyses lacked comprehensive taxon sampling. Additionally, the investigation of evolutionary history of raptorial leg modifications has been hindered by a lack of comprehensive phylogenetic hypothesis of the group. Here we will show a recent progress on reevaluating morphological characters pertaining to raptorial behavior. A phylogenetic dataset with significantly improved taxon sampling and comprised of various data types will be used to provide a framework for reconstructing evolutionary history of raptorial characters.

Bacterial inhibition of trypanosome infection establishment in the tsetse fly midgut and its potential to enhance the efficacy of sterile insect technique-mediated population suppression

Authors: Weiss Brian[1], Vigneron Aurelien[1], Maltz Michele[1] and Aksoy Serap[2], [1]Yale School of Public Health, Department of Epidemiology of Microbial Diseases, New Haven, CT., United States, [2]Yale School of Public Health, United States

Abstract: Tsetse flies (Glossina spp.) vector pathogenic trypanosomes in sub-Saharan Africa. These parasites cause human and animal African trypanosomiases, which are debilitating diseases that inflict an enormous socio-economic burden on inhabitants of endemic regions. Disease control currently relies largely on reducing tsetse population densities through the use of pesticides, traps and sterile insect technique (SIT). While these programs are effective, their high cost and intensive labor investment make them difficult to sustain. Additionally, SIT presents epidemiological risks because released (sterilized) male flies can transmit disease (male and female tsetse are obligate blood feeders). With respect to enhancing the efficacy of tsetse SIT programs, novel strategies aimed at reducing the vector competency of released males require development. With this goal in mind, we discovered that stable colonization of tsetse's midgut with the exogenous bacterium Kosakonia cowanii Zambiae (Kco_Z) inhibits the ability of trypanosomes to colonize the fly. This parasite refractory phenotype results from the fact that Kco_Z acidifies tsetse's midgut environment, which inhibits trypanosome growth and thus infection establishment. Importantly, Kco_Z infection does not impact the fecundity of male or female tsetse, nor the ability of male flies to compete with their wild-type counterparts for mates. We thus propose that Kco_Z could be used as one component of an integrated strategy aimed at improving tsetse SIT programs via the release of trypanosome-refractory flies.

Climate oscillations and nutrient dilution underlie insect herbivore cycles and declines

Authors: Welti Ellen[5], Joern Anthony[2], Roeder Karl[1], de Beurs Kirsten[4] and Kaspari Michael[3], [1]Department of Entomology University of Illinois Urbana-Champaign, United States, [2]Division of Biology Kansas State University, United States, [3]Geographical Ecology Group University of Oklahoma, United States, [4]Geography and Environmental Sustainability University of Oklahoma, United States, [5]Smithsonian Institution, United States

Abstract: Parsing variation in animal abundances at multiple time scales, and assigning mechanism, is a fundamental challenge in an era of global change. Key drivers of insect herbivore abundances include climate, plants communities, and their interactions. Disentangling these signals sheds light on underlying drivers of abundance patterns and recent widespread reports of insect decline. We tested two time series (16 and 22 years) of annual grasshopper abundances for cyclicity using spectral analysis and then decomposed time series to disentangle cycle and trend. We asked if large-scale climate oscillations of El Niño Southern Oscillation (ENSO), North Atlantic Oscillation (NAO), and Pacific Decadal Oscillation (PDO) drive grasshopper abundances. We then examined changes in plant biomass and nutrient content as drivers of long-term trends in grasshopper abundances. Abundances exhibited a significant 5-year cycle and the presence of abundance cycles caused overestimation of grasshopper declines in the shorter time series. Climate cycle indices of spring ENSO, summer NAO, and winter PDO predicted grasshopper abundances in the 22-year time series, while summer NAO and spring PDO predicted grasshopper abundances in the 16-year time series. In addition to cycling, grasshopper abundances declined 2.2-2.7% annually resulting in a cumulative 37% decline in the 22-year time series. Local plant biomass in this system increased over time, diluting nutrient concentrations in plant tissues. Grasshopper abundances track plant nutrient concentrations, suggesting decreasing food quality in response to CO2 fertilization drives grasshopper abundance declines.

Mapping the distribution of coccinellids in Argentina through Citizen Science: goals and challenges

Authors: Werenkraut Victoria, Ecotono Laboratory, INIBIOMA/National University of Comahue, CONICET, Argentina

Abstract: Native ladybird biodiversity is declining in many regions of the world mainly due to the effect of invasive species, habitat loss, and climate change. Argentina presents a very diverse landscape with about 160 reported ladybird species, from which 21% are endemic. However, because of the lack of researchers studying their biodiversity, the knowledge about ladybird abundance and distribution shows big gaps, making it impossible to evaluate their trends and to develop conservation strategies. In addition, deforestation, changes in land use, and the extended invasion of the harlequin ladybird (Harmonia axyridis) threatens native ladybird species and call for urgent national initiatives in the conservation of this group and other beneficial insects. The use of traditional techniques for biodiversity surveys in large countries like Argentina would be extremely expensive and time-consuming. Citizen Science is a powerful alternative to gather biodiversity data for wide geographical scales, and it is also a way of engaging people with science, increasing their awareness of environmental issues. Here, I will present preliminary data of a new long term Citizen Science Project aimed to map the distribution of conspicuous ladybirds across the country and to analyse their trends which will be the base for the development of conservation programs. I will also discuss the limitations and challenges of this kind of approach in South America.

Modality-specific circuits for skylight orientation in the fly visual system

Authors: Wernet Mathias, Free University Berlin Institute of Biology, Germany

Abstract: Different visual cues like celestial bodies, skylight polarization, and colour gradients are used by navigating insects. How the brain processes and integrates this information for navigational decisions (like a given flight heading), remains incompletely understood. On a cellular and synaptic level, little data exists on either (i) the specific differences between those circuits mediating polarization vision versus color discrimination, or (ii) at which level they are integrated. We use Drosophila as a model system for dissecting the pathways which connects the eye with the central brain, using a combination of molecular-genetic, ultrastructural, behavioral, and physiological techniques.

Like in other insects, the ommatidia of the fly compound eye fall into three subtypes, as defined by Rhodopsin expression in their long visual fiber photoreceptors (R7 and R8), connecting to an equal number of repetitive microcircuits within the optic lobes. While two stochastically distributed subtypes mediate color vision, morphologically and molecularly distinct ommatidia in the ‘dorsal rim area (DRA)’ detect skylight polarization and are necessary for mediating orientation responses. Using the Drosophila neuroanatomical toolkit, we have shown how DRA-specific differences in neural circuit architecture (cellular composition, morphology, synaptic distribution and connectivity) adapt DRA microcircuits to their modality-specific function, i.e. polarization instead of color vision.

We are now characterizing the circuits for skylight orientation using a combination of light-microscopic neuroanatomy tools and 3D reconstruction of electron microscopic data spanning the entire fly brain. The importance of modality-specific circuit elements are being characterized using different behavioral assays, like virtual flight arenas for tethered flies, as well as GCamp activity imaging. The circuit motifs we describe will add much-needed details to the connectivity diagram of the compass pathway of insects. More generally, our model system serves as a platform for understanding how a locally-restricted part of the visual system is adapted to a specific function.

Evaluating the impact of commonly used herbicides on African honey bee gut microbiota in Kenya

Authors: Wesonga Zamira[3], Bargul Joel[2], Paredes Juan[1], Lattorff Michael[4], [1]research scientist, Kenya, [2]Senior Scientist, Jomo Kenyatta University of Agriculture and Technology, Kenya, [3]Student, Jomo Kenyatta University of Agriculture and Technology molecular biology and bioinformatics, Kenya, [4]University of Nairobi; Martin-Luther-University Halle-Wittenberg

Abstract: Honey bees play a crucial role in natural ecosystems and agricultural production. The honey bee harbors specific yet simple gut microbiota composed of about nine bacterial clusters. The gut microbiome are being implicated in food digestion, detoxification of harmful molecules, protection from opportunistic pathogens and parasites, providing essential nutrients, among other key roles. In the last decades, the honey bee population worldwide has drastically decreased and the causes are not yet fully understood. Aspects such as environmental stressors, low genetic diversity or invasive pests and pathogens might all be implicated. Another potential course is herbicide use which is known to have side effects in crops and/or beneficial insects that visit such crops. This detrimental effect could be sometimes direct (e.g. affecting the insect's natural system) or indirect (e.g. by affecting the beneficial microbes associated to the insect). We hypothesize that honey bees' health is compromised by usage of herbicides via their gut microbiota. Therefore, this study aims to evaluate the effects of paraquat and glyphosate herbicides on the adult honey bee gut microbiota. The study will also aim to determine if the gut microbiome, in short time scale, might develop resistance to such chemicals. Glyphosate and paraquat are herbicides are commonly used in Murang'a County, Kenya, where large scale of fruit farming e.g. avocado and cucurbits is practiced.

To achieve our goals, the toxicity level of glyphosate and paraquat on honey bees will be determined before evaluating their effects on the bee gut microbiota. We will also examine whether these compounds induce oxidative stress in the honey bee gut tissue. Lastly, a serial gut microbiota passages from bee to bee, chronically fed with the herbicide will be conducted until a potential resistance is observed.

We expect that the data and possible bacterial strains generated in this study will outline the impacts of pesticides in honey bee health and set up the basies for policy development in safe pesticide use/doses. In addition, if we find a resistance development against the herbicides, we will analyze this further with the aim of spreading such beneficial effect in the field.

Non-insecticidal Mosquito Bite-resistant Garments

Authors: West Andre[5], McCord Marian[2], S. Apperson Charles[3], DenHartog Emiel[4], Luan Kun[2] and Michael Roe R[1], [1]Department of Entomology and Plant Pathology, North Carolina State University, United States, [2]Department of Forest Biomaterials, College of Natural Resources, North Carolina State University., United States, [3]NC State University, United States, [4]Wilson College of Textiles, North Carolina State University, United States, [5]Wilson College of Textiles, North Carolina State University, United States

Abstract: Vector-borne diseases have had a devastating impact on human health through arthropods, especially mosquitoes. Garments may be used as a barrier to biting insects, and thereby are useful in preventing disease transmission. Commercially available insect protective clothing is either untreated or is treated with permethrin, an insecticide that kills or repels insects through contact with the treated surface. Widespread use of permethrin in both long-lasting insecticidal nets (LLINs) and as an agriculture insecticide has resulted in high levels of resistance, especially in Africa. Resistant mosquitoes may land on permethrin treated surfaces without experiencing adverse effects, and therefore, clothing treated with permethrin may not be effective at preventing bites in areas where resistant strains are dominant. Other concerns about insecticide treated textiles include a limited active period, potential adverse effects on human health and poor compatibility with synthetic fibers. Given the rise in insect-transmitted disease and the prevalence of resistance, there is a need to develop alternative safe and effective bite-resistant garments that are active against resistant mosquitoes and other arthropods and pose no possible hazard for human health. Prototype bite-resistant textiles were designed to provide a physical barrier to penetration while also maximizing thermal comfort and durability. A predictive model was developed based solely on mosquito morphometric analysis and describes combinations of textile structures that effectively prevent mosquitoes from biting. The bite-resistant capacities of the prototype fabrics were evaluated by an arm-in-cage bioassay and were used to validate the predictive model. Protective garments constructed from prototype fabrics were evaluated for bite resistance in walk-in cage experiments. thermal comfort was evaluated in tests using a sweating manikin under controlled conditions. The prototype garments provided 98% or higher protection from mosquito bites with air/moisture vapor permeability that was superior to chemically treated uniforms. Based on these results, this unique textile technology has enormous potential for mitigating the incidence of vector-borne diseases by preventing human-vector contact.

Landscape heterogeneity shapes functional community composition and can mitigate adverse effects of local land use intensification

Authors: Westphal Catrin, Functional Agrobiodiversity Department of Crop Sciences University of Goettingen, Göttingen, Germany

Abstract: Landscape composition (e.g. diversity of habitat types) and landscape configuration (e.g. number, size and arrangement of habitat patches) represent two components of landscape heterogeneity and can have different ecological implications for species diversity, community composition and provisioning of ecosystem services. Moreover, local habitat characteristics, such as the intensity of agricultural management, can interact with the two components of landscape heterogeneity and can also modify functional community composition. I will focus on the general research question how effects of local land use intensity and landscape heterogeneity interact in shaping the composition of arthropod communities in grasslands. First, I will examine how independent gradients of compositional and configurational landscape heterogeneity, across eight spatial scales, shape taxonomic and functional diversity of butterfly communities in 91 managed grasslands across Germany. Second, I will disentangle the effects of independent gradients of landscape composition (diversity of land cover types: measured using the Shannon diversity index) and configuration (average patch size within the surrounding landscape) and local land use intensity on the functional composition of grassland arthropod communities comprising six orders (i.e. Araneae, Coleoptera, Diptera, Hemiptera, Hymenoptera and Lepidoptera) and 599 species.

Instead of using land cover maps, functional maps were derived based on habitat preferences of individual butterfly species during different life stages. Landscape heterogeneity metrics were then calculated from these functional maps. While functional landscapes with high compositional heterogeneity promote butterfly communities with greater taxonomic diversity, high configurational heterogeneity enhances functional diversity of butterfly communities with increasing numbers of vulnerable species (e.g. feeding specialists).

A RLQ analysis was used to investigate the co-correlations between in-field management intensity and landscape-scale heterogeneity (R table) and species trait attributes (Q table), constrained by the relative abundance of each species (L table). The grassland arthropod communities showed a unified response to both landscape-scale heterogeneity and local land use intensity. Adults and larvae with specialized feeding habits, species with shorter activity periods and relatively small body sizes are selected against in simplified landscapes with intense in-field management.

The studies demonstrate that landscape-level effects determine functional community composition and can even buffer negative effects of in-field management. A decline in functional community composition can lead to functional homogenization, affecting the viability of the ecosystems by decreasing the variability in their responses to disturbance and altering their functioning and the provisioning of ecosystem services.

The role CABI plays in building trust for sustainable access and benefit-sharing of biological control genetic resources

Authors: Weyl Philip[2], Hinz Hariet[2] and Smith David[1], [1]CABI, Egham, United Kingdom, [2]CABI, Switzerland

Abstract: CABI is a not-for-profit international organization with the mission of improving people's lives worldwide by solving problems in agriculture and the environment, while engendering trust, facilitating science and ensuring that benefits are shared. CABI is in a unique position in that it is both a provider and a user of biological control agents and often acts as an intermediary between provider and user countries. As a way of building trust between both sides, CABI has developed a publicly available access and benefit sharing (ABS) policy and ABS best practices built around the principles of the Nagoya protocol. CABI's ABS best practices aim to facilitate compliance with national legislation on ABS in the countries in which it works and in those that provide genetic resources for CABI's use. As an initial step CABI started to align its ABS best practices to comply with its host country requirements. In Switzerland for example, CABI is in discussion with the Swiss Competent National Authority to get CABI's ABS Best Practice officially recognized in a public register. The benefit of having a best practice recognized is that it is an accepted procedure that reduces the risk of non-compliance while at the same time building trust with the provider and user countries. In addition to this, CABI is working openly to negotiate agreements in provider countries such as China. Ultimately, CABI as an international, intergovernmental organization is committed to the Convention on Biological Diversity and the Nagoya protocol and its staff will ensure the compliant access and utilization of biological control agents in the countries where CABI works.

Understanding ladybirds – the "extinction of experience"

Authors: Weyman Gill[1], Butler Fidelma[3], Whelan Padraig[4] and McKeown Sean[2], [1]Fota Wildlife Park and University College Cork, Ireland, Ireland, [2]Fota Wildlife Park, Ireland, [3]University College Cork, School of Biological, Earth and Environmental Sciences, Ireland, [4]University College of Cork, School of Biological, Earth and Environmental Science, Ireland

Abstract: Ladybirds are often considered to be charismatic insects. Yet, what do people really know about them? Threats of urbanisation, habitat availability and disconnection of people from nature add up to what is termed the "extinction of experience". This lack of understanding of nature has been frequently highlighted and a loss of first-hand experience being during childhood is likely to have contributed to a decline in values of biodiversity held by humans. Research in the United Kingdom found that children often lack the ability to identify common species. The complexity of natural systems also makes it difficult for people to understand conservation issues. Life experiences can be very important and outdoor recreation, education, fieldwork, museum, and laboratory studies have the potential to provide young people with necessary close experiences of life. A questionnaire survey in 2018 found that 96% of participants recognised the shape of a ladybird when compared to other invertebrates and 60% agreed that ladybirds were important. A follow-up survey in 2019 investigated the origin of public attitudes and understanding of ladybird conservation, taking into account a range of factors including early childhood experience, gender, and age.

Mating Disruption as an integral part of the Integrative Pest Management of Row Crops

Authors: Wheeler Christopher[1], Srigiriraju Lakshmipathi[1], Serrano Miguel[1] and Galvan Tederson[1], [1]Provivi Inc.

Abstract: The Lepidopteran chemical communication system involved in mate finding was first manipulated in the 1970's with the area-wide application of synthetic female sex pheromones to control the economic infestations of P. gossypiella in cotton. Since the success of this novel pest control method, mating disruption technology has been developed and commercialized for some of the most economically important moth pests of the world. Mating disruption has been most popularly adopted in pome fruit & nut tree agricultural systems but has also had commercial success in the control of C. suppressalis in Spanish rice, and now S. frugiperda in Mexican corn. Mating disruption is a species-specific, non-lethal form of pest control that can reduce crop damage and pest populations to levels comparable with conventional insecticide approaches. The traditionally high cost of synthesizing lepidoptera sex pheromones have likely been a barrier to the adoption of this technology in low-cost, large hectarage row crops. Recent advancements in the syntheses of these pheromones, and the arrival of invasive species like the fall armyworm create a potential for more widespread adoption of mating disruption as a viable and economically-feasible pest control method in row crop agricultural systems like the corn and rice systems therein described.

Machine Learning Classification for Lidar-based Insect Detection

Authors: Whitaker Bradley[1], Vannoy Trevor[1] and Shaw Joseph[1], [1]Montana State University, United States

Abstract: Lidar-based insect detection is of growing interest to the entomological community due to the noninvasive and nondestructive nature of lidar measurements. Unfortunately, the vast quantity of data collected by pulsed lidar systems makes it time consuming to identify data samples corresponding to insect data. This problem is compounded when lidar measurements are taken in the field, rather than in a controlled laboratory environment. In field measurements, it is quite common that less than 1% of the raw data includes information about flying insects. In this abstract, we show how machine learning algorithms can support manual inspection by quickly identifying possible insect-containing lidar field measurements, allowing scientists to avoid the tedious process of manually sifting through the collected data. Using supervised algorithms with modifications to account for high class imbalances, we automatically identify approximately 1% of the raw data as containing insects; this portion of the data contains over 50% of human-identified insects In addition, we propose advancements in algorithm development and hardware implementation that will lead to real-time insect detection. In addition to accelerating entomological decision-making processes, real-time insect detection may allow for higher quality data collection in field measurements. While still in its early stages, machine learning has the potential to accelerate lidar-based entomological research.

Probing molecular interactions between orthotospoviruses and thrips vectors for discovery of new targets for disrupting transmission.

Authors: Whitfield Anna[1], Rotenberg Dorith[1], Han Jinlong[1], Mulot Michaël[1] and Chen Yuting[1], [1]North Carolina State University, United States

Abstract: Tomato spotted wilt virus (TSWV) and other thrips-transmitted orthotospoviruses are significant threats to production of food, fiber, and ornamental crops. There are limited effective control strategies for this virus due to the difficulty of controlling the thrips vector. We study the basic transmission biology of TSWV with the goal of developing new ways to disrupt the disease cycle. We have documented that the TSWV Gn protein is a viral attachment protein and capable of inhibiting virus acquisition and subsequent inoculation by thrips. We have also characterized thrips proteins that respond to and interact directly with virus during the transmission process. With this new knowledge, we aim to determine if TSWV-interacting proteins are determinants of vector competence and possible targets for reducing thrips vector transmission efficiency.

Ancient Enemies: Phylogenomics of the Culicidae Reveals Ancient Radiations

Authors: Wiegmann Brian[1], Soghigian John[1], Sither Charles[1] and Reiskind Michael[1], [1]North Carolina State University, United States

Abstract: The Culicidae are among the deadliest animals on Earth, responsible for immense human suffering due to the numerous vector-borne diseases they transmit. Although there are more than 3500 described species of mosquitoes, the vast majority of research has focused on a handful of species responsible for epidemics of disease, such as Aedes aegypti and Anopheles gambiae. As such, our evolutionary understanding of mosquitoes lags behind many other important insect groups. This lack of knowledge prohibits analyses of key vector phenotypes, such as host association and vector competence, and complicates taxonomy and broader systematics. To date, there have been only limited studies utilizing molecular data in this family, and morphology has at times provided conflicting information on deeper relationships among genera in the Culicidae. Here, we present the results of the most comprehensive phylogenetic analysis of the Culicidae to date, based on genomic data. We leverage existing genomic resources and new sequence capture data from 200 species to reconstruct the evolutionary relationships of major genera in the family. Then, we use this phylogenomic dataset to date the key divergence times in this group, and evaluate those divergence in context with major vertebrate lineages to provide insight into the evolution of the world's deadliest animals.

Chemical and behavioural adaptations of Maculinea butterfly larvae to their Myrmica host ants on the example of the reintroduced and source population of Maculinea teleius

Authors: Witek Magdalena[2], Sánchez Garcia Daniel[2], Wynhoff Irma[1] and Pietro Casacci Luca[2], [1]De Vlinderstichting / Dutch Butterfly Conservation, Netherlands, [2]Museum and Institute of Zoology, Polish Academy of Sciences, Poland

Abstract: Ants of genus Myrmica hosts diverse myrmecophilous community including social parasites such as Maculinea butterflies, which larvae live inside host nests. The most crucial moments in the parasite life cycle are the infiltration of the butterfly larvae in the host ant nest and integration with host colony. Both steps are mediated mostly by chemical deception; Maculinea larvae synthesize a mixture of cuticular hydrocarbons (CHC) that mimic those of Myrmica ant species. Also Myrmica host ant populations can change their cuticular hydrocarbons in response to parasite pressure and become stricter in recognizing nest-mates. Chemical mimicry match of Maculinea larvae to their host ants can be reflected by ant behavior towards parasite larvae during adoption process as well as by larval survival inside host colony.

We study this co-evolution system on the population of Maculinea teleius that was reintroduced in the Netherlands in 1990 and the source butterfly population from Poland. Such difference of almost 30 butterfly generations between the source Polish and the reintroduced Dutch population offers unique opportunity to study the local adaptations of M. teleius butterflies to their host ants and to detect ongoing co-evolution processes between parasite and host populations. We will present results of CHC profiles of pre adoption M. teleius larvae as well as CHC profiles of Myrmica ants coming from the source and reintroduced populations. Moreover, we will also show results of cross-adoption experiment between Dutch and Polish M. teleius larvae and their main host ant, Myrmica scabrinodis coming from source and reintroduced population.

The distribution of viral natural enemies in fall armyworm (Spodoptera frugiperda) in Africa

Authors: Withers Amy[2], Pearson Aislinn[5], M. Jones Chris[4], Kachigamba Donald[1], De Boer Jolanda[6], Smith Judith[6], Wilson Kenneth[3] and Donkersley Philip[3], [1]Bvumbwe Research Station, Malawi, [2]Lancaster University, Rothamsted Research, United Kingdom, [3]Lancaster University, United Kingdom, [4]Liverpool School of Tropical Medicine, United Kingdom, [5]Rothamsted Research, United Kingdom, [6]University of Central Lancashire, United Kingdom

Abstract: The fall armyworm (FAW, Spodoptera frugiperda) is a highly invasive crop pest. Native to America, it was first reported in Africa in 2016 and rapidly spread throughout the continent causing devastation to crops, particularly maize (Zea mays) and rice (Oryza sativa). It has since spread to Asia, with countries including India, China and Japan all reporting that FAW is present. One mechanism for the control of fall armyworm is biocontrol using the virus Spodoptera frugiperda nucleopolyhedrovirus (SfMNPV). As well as being sprayed artificially, SfMNPV is also present naturally within FAW populations in the Americas. African armyworm (Spodotpera exempta) populations in Africa also have a nucleopolyhedrovirus present naturally, Spodoptera exempta nucleopolyhedrovirus (SpexNPV), which also has the potential to be used as biocontrol against the African armyworm. These viruses are ideal as biocontrol agents as they are highly species-specific meaning the risk to non-target species is minimal, are safer for farmers to use than chemicals and have relatively high success rates when sprayed in fields. It is not yet known whether either of these viruses are present within FAW populations in Africa. However, increasing our understanding of these viruses within FAW in Africa could provide insights into natural population control, and highlight the potential for biocontrol in Africa. To address this gap in our understanding, this study investigated the distribution and abundance of SfMNPV and SpexNPV within Africa. This study found that throughout Africa, both SfMNPV and SpexNPV were found to be present within FAW populations. Interestingly, the prevalence of both viruses varied between different African countries. Furthermore, virus distribution also varied between different sites within countries. Overall, this study provides a useful insight into the distribution of viral natural enemies within FAW in Africa, and how this varies between different countries and regions.

Developing and testing annual flowering seed mixes for wild pollinators in gardens and urban green spaces

Authors: Witter Lucy[2], Lowe Abigail[3], Ford Col[4], Beatty Gemma[1], Jones Laura[3], de Vere Natasha[2], Dennis Peter[1] and Ritchie Will[4], [1]Institute of Biological, Environmental and Rural Sciences, Aberystwyth University, Aberystwyth, United Kingdom, [2]1.National Botanic Garden of Wales, Llanarthne, UK 2. Institute of Biological, Environmental and Rural Sciences, Aberystwyth University, Aberystwyth, United Kingdom, [3]1.National Botanic Garden of Wales, Llanarthne, UK 2. School of Natural Sciences, Bangor University, Bangor, United Kingdom, [4]National Botanic Garden of Wales, Llanarthne, United Kingdom

Abstract: The decline of pollen and nectar feeding insects is a cause for concern, given their vital contribution to pollination services. Multiple factors are attributed to their decline, with fragmentation and loss of floral resources considered one of the most important. As the wider landscape becomes more fragmented, gardens and urban green spaces can provide an important network of resources for wild pollinators. Public awareness of the plight of pollinators has led to an increase in wildlife friendly gardening, including the use of pollinator friendly seed mixes and recommendation lists to select suitable plants for pollinators. Whilst these lists are useful, there is evidence to suggest that many lack consistency and are based upon anecdotal evidence. The majority of studies investigating seed mixes for pollinators have been focused on agricultural landscapes, with few looking at seed mixes used in gardens and urban green spaces. Results of preliminary research carried out at the National Botanic Garden of Wales investigating commercially available, pollinator friendly seed mixes, found that only 20% of species included in a seed mix designed to attract bumblebees were visited by bumblebees. The results infer that there is potential to improve these seed mixes. The aim of this investigation was to develop and test annual flowering seed mixes to attract a diversity of wild pollinators, using plant-pollinator interaction data obtained systematically from published literature. Two annual flowering seed mix treatments, each consisting of twenty species were developed using data collated systematically from over 500 published, peer reviewed articles, selecting plant species that attracted a diversity of wild pollinator species and were horticulturally suitable. Seed mix treatments were compared to commercially available seed mixes by carrying out observational surveys of the pollinators visiting each seed mix treatment. Floral surveys were carried out both within the treatment plot and in the surrounding Botanic Garden to determine which species were available to pollinators compared to those they visited. Since observational surveys provide only a snapshot of information about foraging behaviour. DNA metabarcoding methods using ITS2 and rbcL markers were also used, to investigate the proportion of plant species used by wild pollinators within the seed mix treatments, compared to the surrounding Botanic Garden. This research will be used to improve seed mixes for the conservation of wild pollinators in gardens and urban green spaces.

Flight Dispersal Capabilities of Spotted Lanternflies

Authors: Wolfin Michael[3], Myrick Andrew[3], Roberts Dana[3], Binyameen Muhammad[1], Baker Thomas[3] and Wang Yanchen[2], [1]Bahauddin Zakariya University, Pakistan, [2]Northeast Forestry University, China, [3]Pennsylvania State University, United States

Abstract: The spotted lanternfly, Lycorma delicatula (White), is an orchard and forest pest native to China. Since its detection in Pennsylvania, USA in 2014, it has spread to other US states as well. We conducted experiments to determine the flight capabilities of L. delicatula adults to assess the relative threat posed by each type with regard to expanding the infestation area through their natural flight behaviors. To understand the effect of mating status, females were collected from mating pairs, captured on plants, and netted during flights averaging 24 m, then dissected and examined for male spermatophores, a diagnostic character for determining mating status. The weight, amount of yellow area on the abdomen, wing area, and body length and abdominal width was recorded from these females. Sedentary females on plants were selectively collected for their large and swollen abdomen. They were capable of only flying ~4 m when forcibly launched and were significantly heavier than the in-flight-captured females. More than 93% of these large, sedentary females had mated whereas <5% of the flight-captured females had mated. Spontaneously flying females weighed significantly less, and had significantly smaller and less yellowed abdomens than sedentary females captured on plants. We concluded that nearly all the observed spontaneously flying L. delicatula females were unmated and therefore pose a lower threat to spread the infestation than previously thought. We then explored the upper limits of flight to help determine the capability of the insects to fly long distances and rapidly expand the infestation range. We observed the behavior of tethered spotted lanternflies to record the number of successive flight bouts, and for how long individuals can fly while tethered. Additionally, we recorded the flight distance and duration of spotted lanternflies in the field that had spontaneously taken flight or been manually launched. We found that females can perform at least 20 successive bouts with only 1 min between bouts when flight durations were limited to 20 s per bout. Bouts averaged 97.9 ± 11.4 s when bout durations were unlimited with some adults flying bouts that lasted over 400 s. If performed naturally, these bouts in quick succession could result in the female flying a distance of over 1000 m in less than half an hour. However, adults spontaneously taking flight in the field flew for an average of only ~13 s and traveled an average of ~29 m before landing on the ground or on nearby objects such as light lamp posts, grapevines, or trees. This information is key in determining how far a locally dispersing adult L. delicatula can fly before finding a suitable host to finish feeding and attain reproductive maturity. We also hypothesize that these thinner, spontaneously flying females embark on these 10–50-m-long flights because they need to find new trees on which to feed to complete their egg maturation in order to oviposit successfully.

Direct and delayed effects of exposure to a sublethal insecticide concentration on food consumption and reproduction of a leaf beetle

Authors: Wolz Marina[2] and Müller Caroline[1], [1]Bielefeld University, Faculty of Biology, Department of Chemical Ecology, Germany, [2]Bielefeld University, Faculty of Biology, Department of Chemical Ecology, Germany

Abstract: The global use of agrochemicals has increased dramatically and pesticides have become a serious source of environmental pollution. With the use of insecticides not only pests of crop plants are affected, but also non-target organisms. The toxic chemicals are present in varying concentrations in the environment and even in sublethal concentrations they can affect the development or behaviour of the exposed organisms. Next to detrimental effects caused by direct exposure to sublethal insecticide concentrations, organisms may also have to cope with delayed effects after exposure to this environmental stress. To elucidate such direct and delayed effects of exposure to a sublethal insecticide concentration within one generation, we chose the mustard leaf beetle, Phaedon cochleariae, which we considered as a non-target organism. Adult beetles were either non-exposed or exposed to a sublethal concentration of a pyrethroid and the effects on food consumption and reproduction were investigated at three time points, during, immediately after, and at a delayed time after insecticide exposure. We hypothesized that during insecticide exposure food consumption and reproduction will be reduced compared to non-exposed beetles, but that beetles may recover with time after ending the insecticide exposure. As expected, during the insecticide exposure food consumption and reproduction were lower than in control beetles. Directly after ending the insecticide exposure, beetles from both treatment groups showed a similar consumption rate, which kept comparable over time. The number of eggs was still lower directly after ending the insecticide exposure, but at a delayed time the initially exposed beetles had caught up with the reproduction of the non-exposed beetles. Likewise, at the delayed timepoint the hatching success of the two groups did not differ any longer. Thus, individuals may be able to recover from insecticide exposure after a certain time. In conclusion, our results highlight that both direct and delayed effects of environmental stressors on fitness-related traits need to be considered. Consequently, we provide evidence that organisms may recover from an exposure to a toxic chemical.

Of insects and decorations: behavior of insect pollinators on conspicuous sterile flowers of Hydrangea spp. (Hydrangeaceae)

Authors: Wong Sato Akira Armando[2] and Kato Makoto[1], [1]Kyoto University, Graduate School of Human and Environmental Studies, [2]Universidad Nacional Agraria la Molina, Department of Forest Management, Peru

Abstract: Decorative flowers (sterile yet conspicuous flower) can be found in various angiosperm families. Adoxaceae and Hydrangeaceae have a unique flower arrangement: a cluster of small fertile flowers is surrounded by larger decorative flowers. These decorative flowers have been largely hypothesized to attract pollinators. To identify whether the decorative flowers have pollination related functions, we carried out field manipulation experiments in nine Hydrangea species, from which only one species does not present natural decorative flowers. The results showed that for most of the studied species, the presence of decorative flowers increased the frequency of visits and weakly increased the frequency of visits per unit area to inflorescences. Decorative flowers also appeared to act as landing-sites for three species that had a high ratio of the surface area of decorative-flowers to the total surface area of the inflorescence. The results suggest that the main function of decorative flowers of the studied Hydrangea species is to boost attractiveness to pollinators by increasing the inflorescence surface area, whereas the landing-site function was evident only in certain species. It is likely that species without natural decorative inflorescences use other attraction enhancing mechanisms, in the case of this study, coloration and odor cues for H. hirta.

Evaluation of acaricidal and antimicrobial activity of entomopathogenic fungal metabolites against the two-spotted spider mite, Tetranychus urticae

Authors: Woo Rami[1], Lee Jinyong[1], Kim Hyunsoo[1] and Woo Soodong[1], [1]Chungbuk National University, Republic of Korea

Abstract: Entomopathogenic fungi are widely used for controlling various pests as representative biological control agents, and their metabolites have also reported various biological activities such as plant growth promotion, antioxidant activity and antibacterial activity. This study was conducted to evaluate the possibility of simultaneous control of pests and plant diseases using fungal metabolites. The acaricidal activity and antimicrobial activity against plant pathogens were evaluated for metabolites of entomopathogenic fungi with high virulence against the two-spotted spider mite, Tetranychus urticae. As a result, the fungal metabolites showed antibacterial and antifungal activity against various plant pathogens such as Botrytis cinerea and Colletotrichum acutatum along with acaricidal activity. These results showed that entomopathogenic fungal metabolites can be effectively used for simultaneous control of both plant diseases and the two-spotted spider mite.

Effects of drought stress on subcortical beetle assemblages may be mediated by fungal communities in beech

Authors: Work Timothy[2], Queloz Valentin[1], Beenken Ludwig[1], Gossner Martin[1] and Brockerhoff Eckehard[1], [1]Swiss Federal Institute for Forest, Snow and Landscape Research WSL, [2]Université du Québec à Montréal

Abstract: Severe droughts are likely to increase in coming decades with subsequent impacts on bark beetles, other subcortical insects and fungi. We exposed standardized beech logs and branches from trees affected by severe drought in 2018 at 9 sites located throughout the Ajoie region of Switzerland and reared beetles and assessed fungi (% cover) after one year. Beetle assemblages (18,500+ beetles and 60+ species) were dominated by Taphrorhycus bicolor (bark beetle) and Xylosandrus germanus (invasive ambrosia beetle) but also included a rich fauna of subcortical fungivores and predators. Fungal assemblages were dominated by Biscogniauxia nummularia (facultative pathogen induced by drought) and Hypoxylon fragiforme (common decay fungus) on bole sections and branches. We found colonization by fungi was strongly linked to both drought intensity and tree condition. We then compared beetle assemblages to drought severity, tree health and fungal abundance using multivariate regression trees to identify key factors determining composition of the subcortical beetle assemblages. We found that extensive colonization by fungi can in some instances supersede the importance of drought intensity or tree condition for determining beetle composition. This highlights an important, indirect role that secondary pathogens and decay fungi may play during droughts.

Detection of toxins in nectar by bees

Authors: Wright Geraldine, Department of Zoology, University of Oxford, United Kingdom

Abstract: Bee species forage for nectar offered by plant mutualists in return for pollination services. Though nectar is mainly composed of sugar, it can also contain compounds which are potential toxins for insects. Here I will show data that describes the detection range for several potential toxins, including pesticides, on the mouthparts of honeybees and bumblebees. I will show how the concentration and the nature of the sugars found in nectar affect the detection of compounds like pesticides.

Immune stimulation reduces the duration, frequency and transfer of trophallaxis in honeybees (Apis mellifera)

Authors: Wright Owen, University of Exeter, United Kingdom

Abstract: Group living social insects are at a greater risk of infectious diseases due to their close relatedness, high densities and frequent social contacts. One social behaviour of honeybees (Apis mellifera) is trophallaxis, which allows the transfer of nutrients and information between individuals and throughout the hive but poses a risk of disease transmission. To examine the effect of immune stimulation on trophallaxis, I used bacterial lipopolysaccharides to stimulate the immune system of harnessed honeybees in the laboratory and manipulated the satiation of the bees to produce donors and recipients. I then recorded and compared the behaviour of the bees during trophallaxis in dyads with an immune stimulated donor or recipient with a healthy partner bee, against dyads with a saline control. I found that the dyads with immune stimulated bees had a reduced duration of trophallaxis compared to that of control dyads. Fewer trophallactic events occurred and less trophallactic fluid was transferred in dyads with immune stimulated recipients. As hunger and motivation of immune stimulated bees was not found to be altered, I suggest this change in trophallactic behaviour is indeed a form of social immunity to prevent the transmission of disease between nestmates.

The evolution of insecticide resistance in the brown planthopper (Nilaparvata lugens Stål) and the rice stem borer (Chilo suppressalis) of China

Authors: Wu Shun-Fan[1], Gao Cong-Fen[1], [1]College of Plant Protection, Nanjing Agricultural University, State & Local Joint Engineering Research Center of Green Pesticide Invention and Application, Weig, China

Abstract: The brown planthopper (BPH), Nilaparvata lugens, and the rice stem borer (RSB), Chilo suppressalis, are economically important pests on rice in Asia. Chemical control is still the most efficient primary way for these two pests control. However, due to the intensive use of insecticides to control these two pests over many years, resistance to most of the classes of chemical insecticides has been reported. We will talk on the status of insecticides resistance in BPH and RSB collected from China over the period 1996–2019 and 2001-2019. We also showed some case studies of the biochemical and molecular mechanisms underlying resistance in BPH and RSB. The insights study of this presentation has provided on how resistance evolves, and the selectivity of insecticides. These results will be beneficial for effective insecticide resistance management strategies to prevent or delay the development of insecticide resistance in BPH and RSB.

CRISPR-mediated Gene knockout reveals role of P450s in xenobiotic resistance and detoxification in Helicoverpa armigera and Spodoptera exigua

Authors: Wu Yidong[2], Wang Huidong[1], Zuo Yayun[1], Yang Yihua[1] and Shi Yu[1], [1]College of Plant Protection, Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China

Abstract: The cotton bollworm (Helicoverpa armigera) and beet armyworm (Spodoptera exigua) are two major agricultural pests of global importance. Resistance cases to most insecticide classes have been reported for these two pests. Management of these two pests in agroecosystems relies on a better understanding of how it copes with phytochemical or synthetic toxins. We have developed a new strategy (gene cluster knockout), which can rapidly identify the contributions of insect P450s in xenobiotic detoxification and serve to identify candidate P450 genes for insecticide resistance.

For H. armigera, we deleted a 85 kb genomic fragment covering all nine P450 genes from the CYP6AE subfamily by the CRISPR-Cas9 method, and assayed toxicities of diverse phytochemicals and insecticides against both the background strain and the knockout strain. We then functionally expressed recombinant CYP6AE enzymes to identify the specific P450s involved in detoxifying xenobiotics. Several of CYP6AEs involved in detoxifying plant toxins and chemical insecticides were rapidly identified through the CRISPR-based reverse genetics approach in conjunction with in vitro metabolism.

For S. exigua, a genetic locus for abamectin resistance was mapped on 15.5-17.5 Mbp of Chr17. Conserved synteny in the Lepidoptera suggested that a CYP9A gene cluster in this location may harbor one or more P450 genes responsible for abamectin resistance. By large fragment knockouts, P450 gene sequence alignment and functional expression, we identified that a mutation (F116V) within substrate recognition site 1 (SRS1) region of CYP9A186 results in acquiring the capacity to detoxify abamectin and thus conferring resistance in S. exigua.

Current status and genetic basis of field evolved resistance to Bt cotton in cotton bollworm from China

Authors: Wu Yidong[2], Guan Fang[2], Wu Shuwen[2] and Yang Yihua[1], [1]College of Plant Protection, Nanjing Agricultural University, Nanjing, China, [2]Nanjing Agricultural University, China

Abstract: Transgenic cotton expressing a single Bt protein Cry1Ac has been planted in China since 1997. Management of Cry1Ac resistance in the cotton bollworm, Helicoverpa armigera, has been largely dependent on the “natural refuge strategy” for more than two decades. The effective refuge percentage was estimated to be 56% during 2010-2013 based on non-Bt hosts (mainly corn, peanut and other legumes) in northern China. From 2010 to 2019, Bt cotton planting area decreased by 70% in northern China, which further increases the effective refuge size. Although the natural refuge delayed resistance evolution, the percentage of resistant individuals increased from 1% in 2010 to 8% in 2019. Further, the resistant individuals with non-recessive inheritance of resistance increased from 37% in 2010 to 86% in 2019. Genome-wide association studies (GWAS) was employed to screen diverse resistance loci to Cry1Ac in field-derived resistant individuals of H. armigera from northern China. The GWAS results showed the tetraspanin gene HaTSPAN1 with T92C mutation was the most abundant resistance gene conferring dominant resistance to Cry1Ac Bt cotton. Phylogenetic analysis reveals the HaTSPAN1 mutation arose from at least three independent origins in norther China. Considering current Cry1Ac resistance status, pyramided Bt cotton producing two or three Bt proteins is urgently needed for resistance management of H. armigera in northern China.

Global threats to Bt resistance management in Australia

Authors: Wu Yidong[4], Downes Sharon[1], Walsh Tom[2] and Tek Tay Wee[3], [1]CSIRO Agriculture and Food, Australia, [2]CSIRO Land and Water, Australia, [3]CSIRO, Acton, Australia, [4]Nanjing Agricultural University, China

Abstract: Pathways to pest incursions can involve natural events (i.e., relating to climatic patterns), or human-mediated actions that relate to trade and/or human movements. Understanding the population genetics of targeted pests, especially of a cosmopolitan and widespread species, may distinguish introduced populations from local populations but do not enable pathways of introduction and associated biosecurity risks to be assessed. An example of this is the recent introduction of the Old World bollworm Helicoverpa armigera into Brazil, where genetic research was able to demonstrate multiple introductions but failed to establish factors that underpinned the catastrophic biosecurity breach. In Australia natural movements of insects including H. armigera, from Asia/South East Asia into northern Australia, have been detected using genetic markers, and represents the current recognized biosecurity risk to Australia’s agricultural industries including the cotton-growing sector. Although H. armigera have repeatedly evolved resistance to insecticidal chemistries used for their control and resistances to the Bt Cry toxins that are expressed in the Bollgard II cotton variety are also known, their management has nevertheless been successful in Australia through strict industry practices that incorporate a well-developed resistance pest management strategy. Successful management of Bt resistances is less well-established in some neighboring countries and movements of individuals carrying undesirable resistance traits into Australia would rapidly undo decades of robust scientific-based H. armigera management practices. Although biosecurity risks associated with natural incursion are difficult to control, research can identify appropriate pathways to target with actions to reduce accidental introductions due to trade. We integrated genetic data with information on international trade movements to assess biosecurity risks that are associated with accidental introduction of novel Bt resistance genes in H. armigera into Australia. We further considered the case of an incursion into Australia of the dominant Cry1Ac gene present in Chinese populations of H. armigera and the implications in terms of function of the existing pre-emptive resistance management plan for recessive resistance currently in place for Bt cotton.

Snellenius manilae bracovirus-encoded microRNAs as regulators in host immune responses

Authors: Wu Yueh-Lung[1], Tang Cheng-Kang[2], [1]Associate professor of the Department of Entomology in National Taiwan University, Taiwan, [2]Ph.D. candidate of the Department of Entomology in National Taiwan University, Taiwan

Abstract: Parasitoid wasp eggs are easily attacked by the immune systems of their insect hosts during parasitism. In response to this, parasitoid wasps have developed several mechanisms to inhibit the immune and physiological responses of the host, such as the production of venom and specialized wasp cells, and symbiosis with polydnaviruses (PDVs). These factors alter the host physiology to give the wasp offspring a greater chance of survival. However, the molecular mechanisms for most of these alterations remain unclear. Here, we found that the bracovirus of Snellenius manila (SmBV) encoded miRNAs into the host larvae, Spodoptera litura, during parasitism. Two of these miRNAs blocked the host's immune responses by regulating the signaling pathways, which enabled the survival of S. manilae larvae within the S. litura host. Microinjecting the inhibitors of these two miRNAs into parasitized S. litura restored their immune responses and significantly decreased the S. manilae pupation rate. These results show that these two SmBV-encoded miRNAs play an important role in regulating host immune responses. Overall, we demonstrate a cross-species regulation by miRNAs in animal parasitism and its possible function in the alteration of the host immune system during parasitism.

DiversityScanner 4K: A high resolution extended focus camera setup as an extension module for the DiversityScanner

Authors: Wuehrl Lorenz[1], Meier Rudolf[2], Giersch Matthias[1], [1]Karlsruhe Institute of Technology, [2]Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Manual investigation of invertebrate biodiversity and abundance in Malaise trap samples is a time-consuming and cost-intensive task that requires expert knowledge. New approaches have shown that automated solutions based on Artificial Intelligence can support experts in evaluating the large number of samples collected. Especially if the phenotype of individual species in a bulk sample has to be evaluated. Therefore, we presented the DiversityScanner as a robotic solution that offers the opportunity to automatically image, measure, and classify invertebrates (< 3 mm) and sort them into 96-well microplates for barcoding [Wührl et al. 2021]. To significantly improve image quality, an optimized camera system was integrated into the DiversityScanner 4K. Thanks to an extended focus system and a 12-megapixel camera, the image quality has been improved to such an extent that even the smallest structures, such as tiny bristles are now shown in detail. By using a focus tunable lens, extended focus images can be generated from several images with different focus planes. Therefore, an algorithm automatically aligns the images, recognizes sharp areas, and generates a high-resolution extended focus image. Finally, the object can be classified by a Neuronal Network and the biomass of the insect can be estimated from the image.

Genomics of the common pine sawfly (Diprion pini)

Authors: Wutke Saskia[1], [1]University of Eastern Finland, Finland

Abstract: Understanding outbreaks of forest pest insects has become increasingly important as mass outbreaks occur more and more frequently. With the help of constantly advancing genomic methods, we can now gain new insights into the adaptive mechanisms involved in insect outbreaks. During mass outbreaks larvae of the common pine sawfly (Diprion pini) cause severe defoliation of pine forests. Despite the impact of this species on forest ecosystems and economy, almost nothing is known about its genomic architecture. One particularly interesting aspect is its resistance to baculoviruses. These viruses can be used as biological control for other pine sawfly pests but are ineffective against the common pine sawfly. We sequenced the genome of the common pine sawfly based on a combination of sequencing technologies (Nanopore long-reads, Illumina short-reads, and 10X Genomics linked-reads). We used functional and comparative methods to investigate genomic innovations and the immunity to baculoviruses of this severe pest species. We present a high-quality genome assembly that extends our understanding of the evolution of sawflies and provides a resource for improved pest management and biological control strategies.

Automated Classification of Invertebrae Images by Neuronal Network based Algorithms

Authors: Wührl Lorenz[2], Rettenberger Luca[2], Kwak Mackenzie[1] and Meier Rudolf[3], [1]Department of Biological Science, National University of Singapore, [2]Karlsruhe Institute of Technology, [3]Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Automated image-based solutions for classification of invertebrae have become increasingly important for monitoring abundance and biomass [Høye et al, PNAS 2021]. Here we present different Convolutional Neuronal Network (CNN) based algortithms that are used for sorting and classification in the DiversityScanner [Wührl et al, MER 2021] and for classification of tic images taken with a smartphone. The image dataset consists of 8943 tic images and multiple data augmentation techniques were employed to increase the number of data. On the test dataset the CNN achieves an accuracy of 98% when predicting the developmental stage, 98% for the sex, and 94% for the genus. The distinction of the various species in the genus Amblyomma is particularly difficult.

How automation, machine learning, and DNA barcoding can accelerate species discovery in "dark taxa": Robotics and AI

Authors: Wührl Lorenz[1], Rettenberger Luca[1], Matthias Giersch[1] and Meier Rudolf[2], [1]Karlsruhe Instiute of Technology, Germany, [2]Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Robotics and artificial intelligence are two methods that are suitable for improving processes that are normally done manually. Therefore, these techniques also can be used when examining specimen-rich invertebrate samples, where traditional sorting methods are to slow and require expert knowledge. For that reason, we developed the DiversityScanner: a classification, sorting, and measurement robot for invertebrates. The 500 x 500 x 500 mm robot has three linear axes that enable a camera unit and an automated pipette to be moved over a square Petri dish, containing up to 150 specimens. After starting the DiversityScanner the image taken by an overview camera mounted directly above the Petri dish is utilised to calculate the position of the insects. Then the camera unit is moved over one specimen to capture high resolution detailed images. Convolutional neuronal networks (CNNs) are then used to classify the specimen into 14 different insect taxa (mostly families) and the specimen length and volume are estimated. In a final step the specimen is moved into a microplate using an automated pipette. In this talk we show how the DiversityScanner uses automation and artificial intelligence to take advantage of previously nearly untapped resources in the study of specimen-rich invertebrate samples.

Combining incompatible and sterile insect techniques to eliminate field populations of the mosquito Aedes albopictus

Authors: Xi Zhiyong[1], Yang Cui[2], Zhang Dongjing[2], Zheng Xiaoying[2], Li Yongjun[2], Wu Yu[2], [1]Department of Microbiology and Molecular Genetics, Michigan State University, United States, [2]Key Laboratory of Tropical Disease Control of the Ministry of Education, Sun Yat-sen University - Michigan State University Joint Center of Vector Control for Tropical Diseases

Abstract: Release of artificially-reared radiation-sterilized males has successfully suppressed field populations of several insect pest species, but its impact on mosquito vector control has so far been limited. A related approach uses the endosymbiotic bacteria Wolbachia to generate condition-dependent sterilization, but may be undermined by the accidental release of females. Here, we show how a combined incompatible and sterile insect technique (IIT-SIT) approach successfully suppresses and effectively eliminates field populations of the world's most invasive mosquito species, Aedes albopictus. Following the creation of a mosquito line with a novel triple Wolbachia infection, millions of competitive factory-reared males of this line were released. When mated with wild-type females, the mating incompatibility generated by the novel triple Wolbachia infection resulted in embryonic death. Pupal irradiation of the released mosquitoes prevented unintentionally-released triply-infected females reproducing in the field, enabling near elimination of wild populations in two release sites across two years. Community support for the IIT-SIT approach strongly increased following mosquito releases, as nuisance biting decreased. This successful field trial demonstrates the feasibility of area-wide application of IIT-SIT for mosquito vector control.

Functional identification of the serpin genes involved in melanization in Plutella xylostella

Authors: Xia Xiaofeng[1], Lin Junhan[1], You Minsheng[1], Tang Shanshan[1], [1]State Key Laboratory of Ecological Pest Control for Fujian and Taiwan Crops, Fujian Agriculture and Forestry University, Fuzhou, China

Abstract: Serine protease inhibitors (serpins) are widely distributed in animals, plants and prokaryotes, and participate in a broad spectrum of physiological processes. In the innate immune response of insects, serpins play a crucial role in the melanization reaction. In this study, two serpin genes, Pxserpin-3 and Pxserpin-6 from Plutella xylostella were cloned and identified. The ORFs of Pxserpin-3 and Pxserpin-6 encode 451 and 414 amino acid residues, respectively. The expression profiles of Pxserpin-3 and Pxserpin-6 genes at different developmental stages demonstrate that Pxserpin-3 has the highest expression at the adult stage, and Pxserpin-6 is highly expressed at the egg and pupal stages. We injected 4th instar larvae of P. xylostella with E. coli and S. aureus. The results showed that the mRNA levels of Pxserpin-3 have the highest expression after injection at 3 h and the highest expression of Pxserpin-6 was observed at 12 h after injection. PxSerpin-3 has a strong response to gram-negative bacteria, but the response of Pxserpin-6 to gram-positive bacteria was faster than gram-negative bacteria. RNAi analysis showed that the transcript levels of Pxserpin-3 was significantly decreased 6 h after injection, and Pxserpin-6 significantly decreased 24 h after injection. RNAi-mediated knockdown of Pxserpin-3 and Pxserpin-6 influences the expression of many genes involved in melanization, and antimicrobial peptides, as well as the Toll and Imd signal pathways. We further recombinant expressed the Pxserpin-3 and Pxserpin-6 in E. coli BL21. The UV CD spectrum shows that the different secondary structures of these two recombinant proteins which indicate their possible diverse functions. We then measured the inhibition activity of the purified recombinant proteins. PO activity was blocked after incubation of recombinant proteins PxSerpin-3 with the larval plasma of P. xylostella and E.coli, but activated by Pxserpin-6. Further transcriptome analysis suggest that the Pxserpin-3 and Pxserpin-6 were participated in the regulation of midgut immunity which response to Bacillus thuringiensis. Our results show that the important functions of Pxserpin-3 and Pxserpin-6 in P. xylostella immunity, especially in the regulation of prophenoloxidase activation.

The Movement and Spread of Oriental Fruit Fly (OFF), Bactrocera dorsalis (Hendel) (Insecta: Diptera: Tephritidae), in Asia – Need a Better Tool for Predicting the Invasion of the Pest

Authors: Xia Yulu, NSF Center for Integrated Pest Management, North Carolina State University, United States

Abstract: Abstract The Oriental Fruit Fly (OFF), Bactrocera dorsalis (Hendel) (Insecta: Diptera: Tephritidae), is an important quarantine pest worldwide. The pest damages more than 400 fruits and vegetables. Although OFF is regarded a tropical species, scientific reports suggest that the pest widely occurs in abundance in the temperate regions such as northern China. However, it is unclear whether the occurrences are due to migration and/or established populations. Authors tend to believe that the occurrences were migration populations which were introduced in the early season from the warm regions. Two primary factors might play key role here: 1) OFF is not on the list of quarantine pests in the major source countries such as China, it means that the host materials are free movement in large scale, 2) the emerging massive transportation systems were built in Asian countries in last decade or so. China’s Belt and Road Initiative (BRI) can facilitate the pest movement in the region. It presents more challenge to conduct risk analysis, and predict pest invasion. A new tool, which incorporates the population dynamics in the global scale, needs to be developed

Fly competitive ability and not temperature or species diversity determine population dynamics and stability on a Drosophila-parasitoid community

Authors: Ximenez-Embun Miguel G.[1], Hrcek Jan[1], Thierry Melanie[1] and Pardikes Nick[1], [1]Biology Centre, Czech Academy of Science, Czech Republic

Abstract: The role of diversity on the stability of communities is being debated for long in ecology. Communities with higher diversity are described to be more stable as they have lower population fluctuations reducing the risk of species lost. However, in a lot of ecological communities, the interaction dynamics of some species leads to an uneven distribution of species abundances with one dominating the others. Furthermore, this ecological dynamic can be affected by abiotic factors like temperature. To determine which of these factors (diversity, temperature or species interaction) determines the dynamics of drosophila-parasitoids communities we performed a microcosm laboratory experiment. During five months, we recorded the dynamics of twelve different food webs (different combinations of flies and parasitoid species with two diversity levels) at two temperature regimes. We didn´t observed any major effect of temperature or diversity on community stability, with parasitoids playing a minor role. In contrast, we observed an important fly species effect with a gradient on its competitive ability and dominance. Strong competitors exclude all the rest of the species while weaker ones allowed coexistence and increased diversity. We concluded that the presence of dominant species determines fly community composition and stability.

Molecular basis of response to (sub)lethal stresses

Authors: Xu Wei[1], Papanicolaou Alexie[2], Avgoustinos Antonios[3], Anantanawat Kay[3] and Hill Kelly[4], [1]Food Futures Institute, Murdoch University, WA 6150, Australia, [2]Hawkesbury Institute for the Environment, Western Sydney University, Richmond, Australia, [3]Murdoch University, Australia, [4]South Australian Research and Development Institute, Australia

Abstract: Tephritid fruit flies, including Queensland fruit fly (Qfly, Bactrocera tryoni) and Mediterranean fruit fly (Medfly, Ceratitis capitata) are destructive insect pests of fruits and vegetables, affecting world trade in horticultural products. With the discontinuation of chemical control options in Australia, such as Fenthion and Dimethoate for the treatment of commodities susceptible to fruit fly infestation, it has become urgent to understand how stress-based control techniques such as heat, cold and irradiation can be used to effectively kill fruit fly without affecting fruit quality or environmental health.

This project aimed to uncover the molecular-level response of fruit fly to stressors including heat and cold. This has never been done before in other insects except some basic work on Drosophila flies. We developed a molecular model system based on Medfly and Qfly that can be run in a controlled, molecular laboratory. We achieved that by developing highly controlled bioassays that induced a 75% fly mortality on third instar larvae. We further improved a method for acquiring gene expression data and used it to build the first atlas of stress-response in Tephritid fruit flies.

For example, in Medfly, our results showed that during heat treatment and recovery, 31 genes were differentially regulated.

Overall, we found that heat treatment had considerably less variance than cold treatment. These differentially regulated genes span a specific class of molecular functions related to protein biosynthesis, including heat-shock proteins (HSPs), metabolic enzymes, RNA-binding proteins, translation initiation factors, and transcription factors.

A pronounced feature of our data is the regulation of a panel of Heat Shock Proteins (HSPs) in both heat and cold treatments. Gene expression data is correlative. To investigate causality, we established the RNA interference (RNAi) technique and used it to study the function of HSP in the molecular response to stressors.

This project provides new knowledge on the disinfestation mechanisms for two of Australia’s most economically destructive horticultural pests. This understanding will enable more effective approaches to be trialled for pre-export treatment and assist in market access negotiations with trade partners. Ideally, this will benefit growers in the future with more efficient treatment alternatives for fruit fly control and reduced treatment costs. Less use of toxic chemicals is of direct benefit to both the environment and to people. The research underpins the development of next generation tools to safeguard fresh produce from fruit fly damage.

Unfolding the truth behind refolding of Odorant Binding Proteins

Authors: Xu Wei[2] and Zareie Reza[1], [1]Director, Proteowa Pty SABC, Murdoch University, Australia, [2]Food Futures Institute, Murdoch University, Australia

Abstract: Like many other organisms, insects use chemical stimuli to regulate behaviors including feeding, egg-laying, and mating. Odorant binding proteins (OBPs) are one of the crucial aspects of insect chemosensory system, which plays an essential role in transporting the hydrophobic volatile odorant molecules to the olfactory receptors. Most of these insect OBPs are expressed at large scale using bacterial host due to its relatively less complicated and high production mechanism. However, one of the major concerns of bacterial expression is that the protein is expressed in an unfolded state in inclusion bodies (IBs), which require further in-vitro protein refolding step to make the protein biologically active. While doing this, there are always high chances of protein misfolding which results in soluble or insoluble protein aggregation. Thus, it is highly important to confirm the efficiency of each refolding method, used for OBP refolding, in terms of getting the correctly folded structure of the target protein. Instead, it has been observed that many of the past insect OBP studies have shown insufficient results to confirm the success of their respective refolding method. This insufficiency of proof for validation of the refolded protein structure generates significant doubts on many of these functional studies of insect OBPs. In this study, we used four Helicoverpa armigera OBPs, HarmOBP2, HarmOBP5, HarmPBP1 and HarmGOBP2, as model proteins to compare the different protein refolding strategies and their success in resulting in correctly folded proteins. Along with that, we have developed a novel pH-dependent method of protein refolding which demonstrated as a better strategy for some of these HarmOBPs refolding compared to other used methods. Further, we compared and validated the binding patterns of these refolded OBPs with the reporter and natural ligands. Finally, we used a reverse chemical ecology methodology to isolate and identify the natural ligands for HarmOBP2 and HarmOBP5. This study points out a crucial but largely ignored step of insect OBP research, protein refolding and the loopholes associated with it in previous studies.

Challenging of Intergrated Management for Resurgent Aedes aegypti in St. Augustine, Florida

Authors: Xue Rui-De, Anastasia Mosquito Control District, St. Augustine, FL, United States

Abstract: Aedes aegypti L. is a primary vector for Zika, Dengue, Chikungunya, and yellow fever viruses. The species of mosquitoes was a major container-inhabiting mosquitoes in Florida. Since 1986 Ae albopictus, the Asian Tiger Mosquitoes was found in Florida and Houston, Texas and the fast spread of the mosquitoes, Ae. aegypti gradually disappeared from North Florida. In 1992 Ae. aegypti totally disappeared from Northeastern Florida. In Feb 2016, Ae. aegypti was collected from downtown St. Augustine, Florida ad Anastasia Mosquito Control District (AMCD) collaborated with the County Department of Health (DOH) launched an eradication program. We divided the city into 5 routes and each route with 2 technicians (one from DOH for education and inspection and one from AMCD for inspection and making the necessary control action). The teams visited/inspected all residents through streets by streets and doors by doors to educate residences and inspect/make necessary treatment for the residential property where we found the adult or larval mosquitoes. We used the BTi and Altosid for larval control except for emptying containers and educating people how to prevent from breeding mosquitoes, and conducted adulticides with ULV, thermal, and barrier spraying of permethrin, sumithrin, and bifenthrin products based on justification with positive landing rate counts, ovitraps and other type of traps with collection of this species of mosquitoes. We conducted the inspection and control every Wednesday for about 2 years. During the 2 year efforts, there were No outbreak of Zika and Dengue even if there were several imported cases. However, the species of mosquitoes had not been limited for spread. Now we often collected and found the mosquitoes in south, west, and north areas. Based on our ovitraps and BG sentinel trap surveillance, the species of mosquitoes are still spreading to other areas. Also, the mosquitoes collected from different spots of St. Augustine showed different levels of resistance based on the cooperation study with the University of Florida/IFAS/Florida Medical Entomology Laboratory.

It is a big challenge for us to control the spread of the mosquitoes in north Florida. Since 2018 we've collaborated with University of Florida/Department of Entomology and Nematology and USDA/ARS/Center for Medical, Agricultural, and Veterinary Entomology, Gainesville, FL to study and evaluate the control efficacy by SIT (released male mosquitoes treated by radiation to the partial area of the city) and collaborated with MosquitoMate to release Wolbachia-infected male mosquitoes, and cooperated with SpringStar to mass deployment of the AGO traps in the city to control of Aedes mosquito population. Also, we hired more intern students and visiting scientists each year to join our team to study the basic biology, behavior, survival, sugar/plant feeding, and breeding habitants, especially bromide plants as one of major sites, and other novel control method and technology.

Sugar feeding ecology of Aedes aegypti in Mali and its control with Attractive Toxic Sugar Baits (ATSB)

Authors: Xue Rui-De[1], C. Muller Gunter[4], Junnila Amy[4], Traore Cheik[4], E. Revay Edita[4], Beier John[2], M. Traore Mohamad[4], Gergely Petranyi[5] and D. Kravchenko Vasiliy[3], [1]Anastasia Mosquito Control District, St. Augustine, FL, United States, [2]Department of Public Health Sciences, Miller School of Medicine, University of Miami, Florida, United States, [3]Department of Zoology, Tel Aviv University, Israel, [4]Malaria Research and Training Centre, Faculty of Medicine, Pharmacy and Odonto-Stomatology, University of Sciences, Techniques and Technology of Bamako, [5]SNSB-Zoologische Staatssammlung München, Germany

Abstract: It is common knowledge that Ae. aegypti can take blood and convert it to triglycerides and glycogen that provide energy, and this led to subsequent observations in the field that female Ae. aegypti were taking multiple blood meals within a single gonotrophic cycle. Accordingly, it was assumed that Ae. aegypti may be less dependent on sugar for energy than other mosquito species and presumably rarely feed on sugar. This assumption has changed in recent years and there is increasing evidence that Ae. aegypti are frequent sugar feeders, given the right environment.

In Urban Bamako, Mali, West Africa we determined the relative attraction of Ae. aegypti males and females to a variety of sugar sources including flowers, fruits, seedpods, and honeydew in the laboratory and using plant-baited traps in the field. We observed the rhythm of blood feeding versus sugar feeding activity of Ae. aegypti in vegetation and in open areas. Finally, we studied the effectiveness of spraying vegetation with ATSB on Ae. aegypti in sugar rich (lush vegetation) and in sugar poor (sparse vegetation) urban environments.

In urban Bamako, Ae. aegypti depend on environmental resources of sugar for feeding and survival. The demonstration that Ae. aegypti populations rapidly collapsed after ATSB treatment, in both sugar rich and sugar poor environments, is strong evidence that Ae. aegypti are sugar-feeding frequently. This study demonstrates that Ae. aegypti mosquitoes depend on natural sugar resources, and a promising new method for vector control, ATSB, can be highly effective in the fight against Aedes-transmitted diseases.

maintaining genetic structure of industrial mass reared beneficial insects

Authors: Yaacobi Gal, Research and Development, BioBee Sde Elyahu LTD, Israel

Abstract: Mass rearing of beneficial insects for commercial use in agriculture and diseases control is limited to few dozens of species. Maintaining production stability or low variation, is a major challenge for the mass rearing facilities worldwide which face industrial and economic constrains. While high fitness for target organism is the main driving forces of the mass rearing facilities, other traits can be in favor for the application in sites. However, sustaining genetic variation within the mass rearing processes is crucial for both ideal aims. Usually, mass rearing facilities are managing stock culture, which harbor disease free colony in a relief conditions allowing sufficient population size. Such population should be reliable and post-adopt source tor the industrial production. Never the less, following changes in the genetic structure can be difficult, especially when production accelerate with scales. This paper present overview on applicable tools and measurements that can be use in the maintain of the genetic structure of industrial mass reared populations with special emphasis on Tephritidae.

Conservation of ladybirds: Malaysia insights

Authors: Yaakop Salmah[2], Haelewaters Danny[3], Musa Nadia Nisha[4] and Riza Hazmi Izfa[1], [1]Centre for Insect Systematics, Department of Biological Sciences and Biotechnology, Faculty of Science and Technology, Faculty of Science and Technology, National University of Malaysia, [2]Centre for Insect Systematics, Faculty of Science and Technology, Faculty of Science and Technology, National University of Malaysia (UKM), Bangi Selango, Malaysia, [3]Ghent University, Czech Republic, [4]Universiti Kebangsaan Malaysia

Abstract: Ladybirds (Coleoptera: Coccinellidae) are predator species that prey on aphids and scale insects. In Malaysia, this family has not been actively studied using molecular phylogenetic methods even though many species have the potential to be applied as biological control agents. Therefore, inventory studies were conducted in several ecosystems. We surveyed both the ladybirds as well as their host plants that had been infested by aphids or scale insects. DNA barcode analysis (cytochrome c oxidase subunit I, COI) was to resolve identification problems due to morphological variability. We observed a total of 17 species of ladybirds. These are Cheilomenes sexmaculata, Chilochorus nigritus, Coccinella transversalis, Coelophora inaequalis, Henosepilachna pusillanima, Henosepilachna vigintioctopunctata, Henosepilachna kaszabi, Heteroneda reticulata, Illeis koebelei, Megalocaria dilatata, Rodolia rufopilosa, Micraspis discolor, Harmonia octomaculata, Cryptogonus orbiculus, Cryptogonus fractemaculatus, Nephus sp., and Scymnus posticalis. We also identified host plant species, which helps our understanding of which pest species infest which plants. From our study and previous work, it seems that the invasive alien species Harmonia axyridis has not (yet) arrived in Malaysia. As part of our surveys, we screened ladybirds for the presence of natural enemies such as fungal ectoparasites (Ascomycota: Laboulbeniales: Hesperomyces virescens sensu lato) and parasitoid wasps (Hymenoptera: Braconidae: Dinocampus coccinellae) prior to the potential arrival and spread of Ha. axyridis. We have thus far found He. virescens s.l. on three specimens of Coccinella transversalis.

Potential bio-molecules related to male reproductive physiology for bio rational pest suppression of Spodoptera litura(Fabricius) (Lepidoptera: Noctuidae)

Authors: Yadav Priya[1], Seth Rakesh Kumar[2], Kant Rao Dev[1], SETH RANJANA[1] and Arora Simran[1], [1]Applied Entomology and Radiation Biology Unit, Department of Zoology, University of Delhi, India, [2]Department of Zoology, University of Delhi, India

Abstract: Spodoptera litura (Fabr.) is a nocturnal tropical pest damaging a wide range of important agricultural crops. Ecologically sound strategies are required to control this pest due to its immense resistance against all conventional pesticides. In this study a novel strategy is discoursed for the development of bio-molecules to be integrated with other biorational pest control tactics. Here, we are intending to target male reproductive physiology for pest suppression approach.
In vitro-sperm activation assay was designed to test the presence of sperm activating biomolecules in different prostatic parts of male reproductive tract. This assay confirmed the higher concentration of activator molecules in the lower prostatic part of reproductive tract. The activator biomolecule was proteinaceous in nature and was identified as trypsin like serine protease. Proteome-profiling of prostatic part further confirmed the presence of trypsin like serine protease of molecular weight 27kDa with 254 amino acids. Sperm activation assay using trypsin enzyme (in lieu of prostatic activator) leads to sperm activation and trypsin inhibitor (ex. Soyabean) ceased motility in sperm in presence of its natural activator from the prostatic part. dsRNA of trypsin like serine protease, administered to larvae and pupae, affected the growth index and inhibited the sperm activation in the adult moths. Further, the feasible modalities regarding use of sperm activation inhibitors are being exploited for their use as potential bio-pesticides. The role of sperm activation inhibitors is discussed to act as potent environment friendly bio-molecules to be integrated in radio-genetic method (Inherited Sterility Technique) for an effective suppression of this serious polyphagous pest.

Regulation of dopamine neurons for proper valuation

Authors: Yamagata Nobuhiro[1] and Tanimoto Hiromu[1], [1]Tohoku University, Japan

Abstract: During olfactory associative learning of Drosophila melanogaster, neurotransmission from the protocerebrum anterior medial (PAM) cluster dopamine neurons signal reward and drive appetitive memory. Precise activity regulation of the PAM neurons is therefore critical for proper reward values. Here we show that genetic disruption of GABA signaling in the PAM neurons causes cognitive bias. Disrupting the expression of a metabotropic GABA receptor, GABA-B-R3, in the PAM neurons enhanced appetitive memory. This memory increment was due to increased learning asymptote but not acquisition speed. In accordance, we observed augmented calcium responses of the PAM neurons to sugar ingestion, consistent with the increased subjective reward signals. We further identified that the anterior paired lateral (APL) neuron is a cellular source of GABA for the PAM neurons. Strikingly, PAM disinhibition involved not only increased appetitive learning but also broader generalization and cognitive judgment bias to reward predicting cues. We thus concluded that GABA signaling onto appetitive dopamine neurons are crucial for proper valuation, perturbation in which causes delusional optimism bias.

Brain insulin-producing neurons directly respond to light and temperature in controlling reproductive dormancy in Drosophila melanogaster females

Authors: Yamamoto Daisuke, Neuro-Evolution Project, Advanced ICT Research Institute, National Institute of Information and Communications Technology, Japan

Abstract: In response to the combination of low temperature (~10°C), short-day photoperiod (10L:14D) and starvation (water only), D. melanogaster females exhibit reproductive dormancy, in which ovarian maturation is arrested without yolk accumulation in the oocyte. Insulin-producing cells (IPCs) in the brain play a pivotal role in the control of dormancy: reduced activity of IPCs promotes dormancy whereas increased activity stimulates ovarian maturation. We endeavor to unravel how environmental cues are integrated by IPCs for their regulation of dormancy by in vivo whole cell patch clamp recording. We find that IPCs hyperpolarize their membrane potential upon light-illumination even after the conduction block with tetrodotoxin (TTX), indicating that IPCs directly respond to light. A decrease of temperature from ~25°C to ~10°C depolarizes IPCs, which as a consequence generate action potentials, even in the presence of TTX, indicating that they also directly respond to temperature. We further show that a seven-pass gustatory receptor and two-pore-domain K+ channel represent integral components of the temperature sensing mechanism in IPCs, as deficits of these two proteins lead to impaired responsiveness of IPCs to temperature and concomitant disturbance of reproductive dormancy.

Finding indications of lag time, saturation, and trading inflow in the emergence record of exotic agricultural insect pests in Japan

Authors: Yamanaka Takehiko[4], Kiraitani Keizi[3], Yamamura Kohji[1] and Morimoto Nobuo[2], [1]Institute for Agro-Environmental Sciences, NARO, Japan, [2]Institute of Livestock and Grassland Science, NARO, Japan, [3]Ito-shi, Shizuoka, Japan, [4]Research Center for Agricultural Information Technology, NARO, Japan

Abstract: Agricultural imports are the primary pathway for the introduction of exotic insect pests. The invasion records of exotic insect pests are also influenced by the lag time before detection and saturation caused by the limited species pool of potential invaders. We compiled an exhaustive list of exotic insect species in mainland Japan and tried to evaluate the connection between the commodity types (flowers, fruits, vegetables, cereals, and timber) and agricultural pests types (outdoor, stored product, greenhouse, forest, and timber pests), in addition to the effects of lag time and saturation. We found that lag time was prominent when all pest types were merged into one group, while saturation always existed when we divided the records into the four agricultural pest types. We suspect that the saturation effect was masked by admixture amongst pests with different saturation patterns. Our findings indicate that all commodities, i.e. flowers, fruits, vegetables, cereal, and timber, contributed to invasion of pest insects as potential pathways. However, it was unclear if certain items had comparatively greater significance in this process.

Comparing the performance to forecast pest outbreaking risks between statistical modelling and machine learning in the case of Japanese cucumber.

Authors: Yamanaka Takehiko[1], Kishi Shigeki[1], Kawaguchi Akira[3], Sun Jianqiang[1], Yoshida Megumi[2] and Ochi Sunao[1], [1]Research Center for Agricultural Information Technology, NARO, Japan, [2]Tohoku Agricultural Research Center, NARO, Japan, [3]Western Region Agricultural Research Center, NARO, Japan

Abstract: Forecasting the pest outbreaking risks has been primary important in modern pest management. Historically, the statistical modelling has long played a central role in the pest-risk forecasting, while an alternative approach, i.e., machine learning, recently is getting popular. A machine learning may be advantageous since it automatically produces plausible forecasts without any statistical assumptions while a statistical modelling generally has a theoretical structure and thus it allows us to interpret the forecasts logically. We compare the performance of these two different approaches by using survey records of cucumber diseases for 20 years in all Japanese prefectures which were collected in the national program for plant-pest monitoring, called “Prevalence Reconnaissance Business”. As for the statistical modelling and machine learning, we employed the state-space modelling and the neural network, respectively. Both approaches were challenging because the dataset has many missing records and the relative/categorical order of the visual infection rate and the actual infection rates are mixed up. Traditional statistical approaches will not be applied to such the type of data sets. Comparing the results from these two confronting modern approaches, we will discuss how the recent advantages in data-sciences can change methodologies and improve the accuracy in future pest management.

Plant-to-plant communication aboveground reduces root nodule symbiosis

Authors: Yamawo Akira[3], Shiojiri Kaori[1] and Takahashi Yuta[2], [1]Department of Agriculture, Ryukoku University, Otsu, Shiga 520-2194, Japan, [2]Department of Biology, Faculty of Agriculture and Life Science, Hirosaki University, Japan, [3]Department of Biology, Faculty of Agriculture and Life Science, Hirosaki University, Japan

Abstract: Volatile organic compounds (VOCs) mediate plant-to-plant communications in many species. Injured plants release specific VOCs, such as methyl jasmonate and methyl salicylate, that induce defense and reduce herbivory in undamaged recipient plants. However, their effects on belowground responses have not been elucidated. We hypothesized that aboveground plant-to-plant communication reduces root nodule symbiosis via a resource-based trade-off with induced defense in leaves and shoot-root signaling. Soybeans were exposed to the volatile organic compounds (VOCs) of damaged leaves of Solidago canadensis var. scabra, and leaf defense traits (leaf mass per area (LMA), C/N ratio, total phenolics) and root nodule symbiosis (number and biomass of root nodules) were measured. LMA and total phenolics were not affected, however plants that received VOCs had higher C/N ratios and fewer root nodules than untreated plants. The number and dry weight of nodules was negatively correlated with the C/N ratio in leaves. Thus, plant-to-plant communication aboveground led not only to changes in leaf traits, but also to reductions in root nodule symbiosis in soybean for expression of induction defenses. Previous studies on aboveground plant-to-plant communication focused on changes in aboveground plant traits and associated communities. In this study, we found that aboveground plant-to-plant communication affected belowground root nodule symbiosis. Future studies of the effects of plant-to-plant communication on belowground plant tissues may find broader effects.

Development of Odorant Receptor Neurons in Ants

Authors: Yan Hua[2], Sieriebriennikov Bogdan[1], Sieber Kayli[2] and Jafari Shadi[1], [1]New York University, United States, [2]University of Florida, United States

Abstract: Animal behavior is based on the dynamic interpretation of sensory stimuli by the brain. Eusocial insect, including ants, display striking phenotypic differences between castes, including their behavioral responses to chemical stimuli. To precisely distinguish the social cues, ants evolved more complex chemosensory system, where odorant receptor genes (ORs) were dramatically expanded during social evolution. Using germline mutation in orco (OR co-receptor) in the ant Harpegnathos saltator, we found that OR functionality is essential for pheromone-induced social cooperation, reproductive physiology and proper development of odorant receptor neurons (ORNs). Interestingly, although male and female ants display striking differences in the OR expression pattern, most neurons die in the absence of orco. However, the survival of a small group of ORNs is likely independent of orco. This study may reveal how olfactory neural development is regulated in eusocial insects.

Nutritional stress negatively impacts life history traits and antiviral immunity but enhances susceptibility to dengue virus infection in Aedes aegypti

Authors: Yan Jiayue (Gabriel)[2], Kim Chang-Hyun[2], Chesser Leta[2], Ramirez Jose[1] and Stone Chris[2], [1]National Center for Agricultural Utilization Research, USDA, [2]University of Illinois at Urbana-Champaign

Abstract: Diet-induced nutritional stress plays a key role in regulating health and disease outcomes, because of its interaction with the immune system. In mosquitoes, diet-induced nutritional stress may affect their vectorial capacity through its impact on phenotypic traits, infection susceptibility and immune performance. However, how these three factors are affected by larval and adult nutritional stress remains unclear. Here, we manipulated mosquito diet to create two levels of nutrition at both larval and adult stages and evaluated the effects of low nutrition (nutritional stress) on mosquito Aedes aegypti. We demonstrate that larval and adult nutritional stress negatively affects adult size and survival, respectively, and synergistically reduce the fecundity. Mosquitoes that experienced nutritional stress as adults, but not as larvae were more susceptible to becoming infected with dengue virus after ingesting an infectious blood meal, but developed lower viral titers than their unstressed counterparts. In addition, the mosquito immune response to dengue virus infection appears to be suppressed by both larval and adult nutritional stress with distinct involvement of key immune signaling pathways. Overall, our findings demonstrate a crucial role of nutritional stress in mosquito life history traits, infection outcome and immune response which in turn influence vectorial capacity for dengue virus.

Research on spotted wing drosophilia(swd) in northeast of China

Authors: Yanan Zheng, College of Forestry, Shenyang Agricultural University, China

Abstract: 1. Occurrence of spotted wing drosophila (swd) in northeast of China, based on data collected from 16 locations (orchards), 7 cities, during 2016 to 2019. Including the host range and damage regularity. We found the population of adults reaching to the top from the middle of July to the end of August, depending on different fruits maturation periods, and there are 9-10 generations per year of swd in northeast of China.

2. Control management. The current control of swd in China is not very clear or standard, because of ignorance or less recognition of the pest. Local growers generally consider swd as a saprophytic fruit fly, and are lack of the knowledge of this unique fruit fly. By our research work, more and more growers recognize it is significant to monitor and control swd in their fields. Trapping is the most effective and safe management to control swd, according to our research these years. So new bait formula from raspberry and new style of trap container have been developed and applied in fields in Liaoning.

3. Phylogenetic analysis of Wolbachia in different geographical populations of swd. The genetic differences of different geographical swd are helpful to explore how does it spread and diffuse worldwide.

Resistance of Helicoverpa zea to Bt crops in the United States

Authors: Yang Fei[1], Kerns David[1], [1]Texas A&M University, United States

Abstract: The cotton bollworm or corn earworm, Helicoverpa zea, is a major target of Bt cotton and pyramided Bt corn in the U.S. In recent years, field-evolved resistance of H. zea to Cry1 and Cry2 proteins has been widely reported in the U.S., especially in the southern states. In addition, a recent study provided strong evidence that H. zea has developed field-evolved resistance to Vip3Aa protein in the southern U.S. that meets the criteria for early warning of resistance but not practical resistance. Currently, high dose/refuge and gene-pyramiding are the two main IRM strategies implemented for planting Bt crops in the U.S. Information on the susceptibility of the field populations, resistance allele frequency, genetic basis and cross-resistance of Cry and Vip3Aa resistance can help evaluate the risks associated with the resistance in the field. In this study, we evaluated the susceptibility of the field populations of H. zea against Cry and Vip3Aa proteins, estimated its resistance allele frequency, characterized the genetic basis of Cry2Ab and Vip3Aa resistance, and finally checked the cross-resistance patterns of Cry and Vip3Aa resistance in H. zea. These information are valuable for testing assumptions of IRM for resistance management of H. zea.

Vibrational communication of insects: the intra- and inter-specific communication

Authors: Yang Man-Miao[3], Liao Yi-Chang[2], Yang Chin-Cheng[4], Billen Johan[5], Lin Yueh-Hsien[1] and Hsu Yu-Feng[1], [1]College of Life Science, National Taiwan Normal University, Taiwan, [2]Department of Entomology, National Chung Hsing University, Taiwan, [3]National Chung Hsing University, Taiwan, [4]Research Institute for Sustainable Humanosphere, Kyoto University, Japan, [5]University of Leuven, Zoological Institute, Belgium

Abstract: Vibrational communication is a primitive yet widespread mode of communication in insects. The vibrational signals are transmitted through solid substrates and usually inaudible to human, and hence attract limited attention to scientists in the past. Nowadays, more than 195,000 of insect species covering 17 orders have been reported to use this mode of signal, and many of which are hemipterans. Psyllids are one group of insects that utilize vibrational signals, especially during the course of reproductive behavior. These signals are species- and sex-specific, and usually characterized by more complex male signals that may have been driven by sexual selection. Closely related taxa tend to share a similar pattern of signals, indicating the vibrational signals is a promising systematic character with phylogenetic significance. Not only for the intra-specific communication, vibrational signals also have been found to be involved in communication at inter-species level such as ant and butterfly symbiosis. Larvae and pupae of myrmecophilous butterfly species produce vibrational signals to attract their attending ants in order to obtain care and protection from ants. Although the vibrational signals seem to be an effective communication mode, utilization of vibrational signals may be confronted to varied biotic and abiotic challenges. For examples, some signals may be eavesdropped by predators or conspecific competitors. The natural background noise including rain and wind can also interfere the signal transmission efficiency. To conclude, how these factors shape the evolution of vibrational communication and its application into systematics requires more empirical evidence and possibly represents a core issue in the field of biotremology, the study of organismal vibrational behavior, in the near future.

Evaluation of pest control efficiencies for different banker plant systems with a simple predator-prey model

Authors: Yano Eizi[2], Hemerik Lia[1], [1]Biometris, Wageningen University, Netherlands, [2]Center for Ecological Research, Kyoto University, Japan

Abstract: In Japanese glasshouses, the banker plant system has been introduced for biological control of different pest species. To evaluate the effectiveness of such a continuous way of releasing predators from the banker plant for controlling pests on the crop, we developed a simple model for the interaction of the pest and predator in the crop. We parameterized the model for three different pest-predator systems, namely (1) Thrips palmi with its predator Gynaeseius liturivorus on sweet peppers, (2) Tetranychus urticae with its predator Neoseiulus californicus on peppers, and (3) Aphis gossypii with its predator Aphidoletes aphidimyza on eggplants. We used the parameterized models to predict under what conditions biological control in a banker plant system is successful. Therefore, we defined successful as keeping the pest below the economic injury level of the crop. Our main analytical result is that for successful control the maximum lifetime consumption of immigrating predators should exceed the daily prey growth at half saturation value. For practical purpose this translates into the fact that the immigration of predators when the initial pest density is low is crucial for successful control.

Release strategy of natural enemies in augmentative biological control in greenhouses

Authors: Yano Eizi[2], Hemerik Lia[1], [1]Biometris, Wageningen University, Netherlands, [2]Center for Ecological Research, Kyoto University, Japan

Abstract: The release strategy of natural enemies is an important factor affecting the suppression of pests in augmentative biological control in greenhouses. Conventional methods to release natural enemies are to introduce natural enemies several times weekly or biweekly. The same number of natural enemies can be released once or can be divided into several releases. The predatory hemipteran bug Nesidiocoris tenuis (Reuter) is used to control the whitefly Bemisia tabaci (Gennadius) infesting tomatoes in greenhouses around the world. We developed a simple predator-prey model for the interaction of B. tabaci and N. tenuis on tomato crops in a greenhouse. We parameterised the model and performed numerical simulations using the model to predict under what conditions biological control is successful. A specific total amount of natural enemies was divided over 1 to 12 weekly releases at different initial numbers of B. tabaci. We defined that control was successful when the pest was below the economic injury level of the crop throughout the simulation that spanned a half year (182 days). The results of our simulations suggest that multiple, but not too many, introductions of N. tenuis are necessary for successful control. Moreover, the number of introductions of the predator should be increased for successful control when the total number of predators increased. This is due to the fact, that a certain kind of dilution will make that the predators do not overexploit the prey initially. Overexploitation causes the predators to go extinct, and the small number of prey that survives can thereafter grow freely exponentially. These findings indicate the importance of multiple introductions of natural enemies or their continuous release from the banker plant system for successful control of pests.

An automatic monitoring system for paddy light-trap pests based on machine vision and deep learning

Authors: Yao Qing[1], Tang Jian[2], Yang Baojun[2], Feng Jin[1], Xu Weigen[3] and Zhu Xuhua[4], [1]School of Information Science and Technology, Zhejiang Sci-Tech University, China, [2]State Key Laboratory of Rice Biology, China National Rice Research Institute, China, [3]Zhejiang plant protection and quarantine station, China, [4]Zhejiang Top Yunlong technology Company Limited, China

Abstract: Monitoring pest populations in paddy fields is important to effectively implement integrated pest management. In the world, current field pest monitoring practices involve manual field investigation, sweep nets, pheromones, sticky trapping boards, light traps or other insect traps.

Light trap can attract many species of pests by different optical spectrum. Light trap is widely used to monitor field pests all over the world. In China, some intelligent light traps of crop pests can automatically turn lights on and off, kill insects by far infrared light and automatically exchange insect recycling bags every day. In one week, technicians take the insect bags back and pick the target pests up from the trapped insects and count them . However, the manual approach of identifying and counting pests from lots of trapped insects is time-consuming, labor-intensive and error-prone, especially in pest peak periods.

In this paper, we developed an automatic monitoring system of paddy light-trap pests based on machine vision and deep learning. This system is composed of an intelligent light trap, PC or phone client platforms and a cloud server. The light trap firstly traps, kills and disperses insects, then collects images of trapped insects and sends each image to the cloud server. To avoid light-trap insects pile up, a vibration plate and a moving rotation convey belt are adopted to disperse these trapped insects. Two residential networks (ResNets) are loaded in server and used to automatically identify five target pests from lots of light-trap insects. One ResNet-50 has 4 output units corresponding to 4 categories (three species of moth pests and one category of non-target big insects), and the ResNet-18 has 3 output units corresponding to 3 categories (two species of rice planthopper pests and one category of non-target small insects). To compare with the identification performance of different CNNs for five pests, we trained other four state-of-the-art convolutional neural network architectures, namely CaffeNet, VGG-19, GoogleNet, ResNet-152 in big insect training sets, and also trained other four CNN, namely cifar10, VGG-6, ResNet-16 in small insect training sets. To evaluate the correlation of daily data between manual identification and image automatic identification of pests, their correlation coefficient was computed.

The moth identification results show that CaffeNet obtained small AP and mAP values of three pests and non-target-big insects. ResNet 50 and ResNet-152 gained higher AP values than CaffeNet, VGG-19 and GoogleNet. Although ResNet-152 obtained higher AP results of three big pests, the AP value of non-target big insects was only 65.8%. It means the ResNet-152 leaded to overfitting because of deeper net layers and many non-target big insects are misjudged. ResNet-50 achieved the highest AP value with 88.9%. So we chose the ResNet-50 to identify the big light-trap pests. The planthopper identification results show that Cifar model obtained

Sexual dimorphism in wing shape of the Dacus ciliatus Loew, 1862 (Diptera: Tephritidae): A geometric morphometric analysis

Authors: Yaran Mehmet, Gaziantep Universtiy

Abstract: Dacus ciliatus Loew, 1862 (Diptera: Tephritidae), lesser pumpkin fly, is a major pest of a wide range of Cucurbitaceae in many parts of Africa, some parts of Asia and the Middle East. D. ciliatus is a polyphagous fly, and damages crops in the Cucurbitaceae. D. ciliatus is classified as an A1 quarantine pest by the European and Mediterranean Plant Protection Organization (EPPO) and significant in terms of quarantine for CPPC (Caribbean Plant Protection Commission). The fly was recorded first time in cucumber cultivation areas of South-eastern Anatolia Region (Diyarbakır, Mardin, Siirt and Şırnak) in Turkey. This study contributes the literature in the field of sexual dimorphism by comparing wing shape. In the study fifty males and fifty females Dacus ciliatus specimens were used. Fifteen-homolog landmark used for geometric morphometric analysis of wings, which were modified from Schutze et al., 2012. MANOVA (multivariate analysis of variance) was performed in Morpheus to see differences in wing shape of sexes. In analyses, statistically significant differences were found among the wing shape of male and female specimens. Finally, results showed that landmark-based geometric morphometric analysis could be a powerful discriminator to determine sexual dimorphism of D. ciliatus.

Consequences of male- female fly ratios on reproductive potentiality and longevity of Blow fly, Lucilia cuprina (Diptera: Calliphoridae)

Authors: Yasmin Muhsina[3], Fayezul Islam ATM[1], Mosharraf Hosain Md.[2] and Shahinur Islam Md.[2], [1]Chief Scientific Officer Bangladesh Atomic Energy Commission, Bangladesh, [2]Scientific Officer Bangladesh Atomic Energy Commission, Bangladesh, [3]Senior Scientific Officer Institute of Food and Radiation Biology, AERE Bangladesh Atomic Energy Commission Dhaka, Bangladesh

Abstract: In Bangladesh, every year a huge amount of dried fish has been damaged due to the blow fly (Lucilia cuprina, Diptera: Calliphoridae) invasion which is responsible for both health and currency hazards. As a result, blow fly has been regarded as one of the most destructive pests for fish drying industries in Bangladesh. Keeping these issues in mind, we are focused to develop and apply Sterile Insect Technique (SIT) towards blow fly control/suppression. Optimizing the male and female fly ratio is an essential part of an effective SIT program. Different sexual proportion of flies have significant effect over the biotic potential and adult longevity. Hence, in this research we are trying to identify the best ratio of male and female blow flies which in turns will maximize the productivity and potentiality of the flies. With a view to produce a good number of potential blow flies for SIT program, a good proportion of male and female flies have been combined in laboratory condition. The combinations were listed (male: female) as 1:1, 1:2, 1:3, 1:4 and 1:5 respectively. The ratios of female flies have been combined per male to observe the reproductive potentiality and longevity for each ratio. The highest number of egg mass was revealed from 1:4 ratios of male and female flies. But there was no significant (p > 0.01) differences in egg mass number from 1:1 to 1:5 ratio. Whereas the weight of the total egg mass was significantly (p < 0.01) varied among the ratios. Female flies showed a more or less similar linear situation for longevity while male flies ended up with a short-lived phenomena. From this experiment it can be concluded that there must be at least four female per male for a mass production and a good number of potential progenies. In order to keep the mass rearing process upright and for a good number of potential flies we can prepare our laboratory cages with a good proportion of female flies per male fly (1:4) which in turn will surely put a positive feedback for our blow fly SIT program.

Selection on gustatory receptors at early stages of host plant specialization in an island Drosophila population: a genomic perspective

Authors: Yassin Amir, EGCE - CNRS, Université Paris Saclay, IRD, France

Abstract: Most Drosophila species are generalists feeding on decaying plant materials. A peculiar case was the discovery of the specialization of Drosophila sechellia on toxic fruits of noni (Morinda citrifolia) on the Seychelles. Although genomic comparisons with its closest generalist species have revealed a rapid rate of evolution of chemosensory genes including olfactory and taste receptors, the possible order by which those changes occurred remains unknown. We have recently discovered another case of specialization on toxic noni implying a population of the generalist species Drosophila yakuba on the island of Mayotte. Behavioral assays confirmed the higher olfactory and taste preference of island flies for noni toxins compared to mainland D. yakuba. The close relationship between island and mainland population permits the fine dissection of the evolution of the chemosensory, highlighting a potential genetic parallel evolution between D. sechellia and D. yakuba during their independent specialization on the same toxic host.

Sexual dimorphism of wing coloration in Numenes moths as possible sex-limited mimicry

Authors: Yazaki Hidemori[1] and Hayashi Fumio[1], [1]Tokyo Metropolitan University, Japan

Abstract: Theoretically, the following four patterns of relationships between mimicry and sexual dimorphism in coloration are distinguished; unimodal mimicry (both sexes of mimic species resemble the same model species), female-limited mimicry (females of mimic species resemble the model species, males do not), male-limited mimicry (males of mimic species resemble the model species, females do not), and dual mimicry (each sex of mimic species resembles a different species of model). Although unimodal mimicry and female-limited mimicry have been well studied, there were only a few descriptive studies about male-limited mimicry and dual mimicry, and there was no empirical research for the function and evolutionary process of these mimicries yet.

Two moths, Numenes albofascia and Numenes disparilis, belong to the genus Numenes (Lymantriidae) in Japan, have distinctive sexual dimorphism in their colorations. Male Numenes albofascia closely resembles Pidorus atratus (Zygaenidae) in its coloration, and female Numenes albofascia resembles Arctia caja (Arctiidae) and/or Pericallia matronula (Arctiidae). Likewise, male Numenes disparilis resembles Neochalcosia remota (Zygaenidae), and female Numenes albofascia resembles Arctia caja and/or Pericallia matronula. The emerging seasons also correspond between suspected mimic and model species. We examined them in wing color patterns in visible and ultraviolet light, wing size, daily activities both in the laboratory and field, and unpalatability.

As a result, coloration patterns of each species have no significant difference in visible and ultraviolet light. Both Numenes albofascia and Numenes disparilis have sexual dimorphism also in their wing sizes, and the differences of wing size are correspondent to those of suspected model species. The activity times of suspected mimic species and model species are overlapping, and Numenes albofascia and Numenes disparilis have also the difference in their activity times between sexes. Predation experiments show that Numenes albofascia and Numenes disparilis are palatable to predators, On the other hand, all suspected model species have repellent effects.

Numenes albofascia and Numenes disparilis have a possibility of rare example of Batesian dual mimicry (each sex of mimic species resembles a different species of model). The conspicuous sexual dimorphism in coloration of them may result from the difference in warning colors between the model species. In Lymantriidae, adult moths lack mouthparts in both sexes and do not fly for searching for their food. Therefore, the flight activity of males is limited to search for females expelling pheromones, and the flight activity of females is limited to the search for oviposition sites. Once the flight time differs between the sexes, it is possible that sexual dimorphism in coloration occurs due to invisibility and mimicry toward different models in each sex.

Rebooting the systematics of Australian Culex (Culex) mosquitoes (Diptera) using whole genome shotgun data and morphology

Authors: Yeates David[2], Zwick Andreas[1], Lessard Bryan[2], [1]Commonwealth Scientific and Industrial Research Organisation, Australia, [2]CSIRO Australian National Insect Collection, Australia

Abstract: Australia is home to 12 described species of Culex (Culex) Linnaeus, 1758, including the common banded mosquito Culex (Culex) annulirostris Skuse, 1889 which is a known vector of Japanese Encephalitis virus, Ross River virus, Murray Valley encephalitis virus and Kunjin virus. Despite their medical importance, the taxonomy of Australian mosquitoes has waned since the passing of prominent mosquito taxonomist Dr Elizabeth ‘Pat’ Marks. She designated three unnamed species in the subgenus Culex, including species Culex “Marks No. 32”, a manuscript name that has since been used for decades by Australian mosquito workers. An additional two undescribed species and six proposed cryptic species have also been identified in the subgenus. Recent advances in whole genome shotgun sequencing technology has enabled sampling of mitochondrial genomes from historical pinned collections. We have digitised and sequenced mitochondrial genomes from authoritatively identified pinned mosquito specimens held in the CSIRO Australian National Insect Collection to reconstruct the phylogeny of Australian mosquitoes, with a focus on subgenus Culex. This data is being used to accurately identify freshly collected specimens, assign authoritative species names to molecular clades and inform the description of new species.

Transcriptomic effects of larval dietary conditions on adult Aedes aegypti and potential effects on vectorial capacity

Authors: Yee Donald[3], King Jonas[1], Drury Austin[2], Dean Catherine[4], [1]Department of Biochemistry, Molecular Biology, Entomology and Plant Pathology Mississippi State University, United States, [2]Mississippi State University, United States, [3]School of Biological, Environmental, & Earth Sciences The University of Southern Mississippi, United States, [4]The University of Southern Mississippi, United States

Abstract: The yellow fever mosquito, Aedes aegypti, is a major vector for several arboviruses including dengue, chickungunya, and zika, and can be found in many tropical regions around the world where its larvae develop in a wide variety of aquatic environments. The physiological state of individual adult Aedes mosquitoes can also clearly be expected to affect several parameters related to vectorial capacity. Therefore, it seems likely that highly variable larval environmental factors influencing adult mosquito physiological and immune systems, such as larval nutrition, are important for our understanding of vectorial capacity. In this study, two groups of Ae. aegypti larvae were reared in conditions supplied with either a nitrogen rich detritus or nitrogen poor detritus as their diet source. Total RNA was then extracted from multiple adults from each treatment group at days 1, 5 and 15 post emergence and Illumina based RNA-seq differential gene expression analyses were performed using a standard analytical pipeline. Along with significant lifelong changes seen in core cellular machinery, such as ribosomes and amino acid metabolism pathway components, important changes were also seen in certain immune genes, odorant receptor genes, and genes related to pesticide metabolism. An improved understanding of changes in mosquito physiology based on carbon:nitrogen levels in larval environments will form a framework for future studies investigating the relationship between larval environment, adult physiology and vector competence.

Wherefore art thou mosquito? The historical and contemporay distribution of Aedes aegypti in the United States.

Authors: Yee Donald[2] and Mackey Nicole[1], [1]School of Biological, Environmental, & Earth Sciences The University of Southern Mississippi, United States, [2]School of Biological, Environmental, & Earth Sciences The University of Southern Mississippi, United States

Abstract: The distribution of Aedes aegypti (L.), the yellow fever mosquito, has been difficult to map as data on the occurrence of this species is often absent across much of its United States range. This poses serious challenges for control efforts and for predicting where outbreaks of arboviruses like Zika and dengue could occur, both of which are transmitted by this species. Historically, yellow fever plagued the United States across the 18th to early 20th centuries, resulting in thousands of deaths and many more illnesses. Up until the discovery that Aedes aegypti (L.) was the causative agent of the disease, no records were kept on the distribution of this species, complicating our understanding of its historical distribution and the factors important for its contemporary locations within the U.S. To determine the historical range of Ae. aegypti within the U.S. we examined the range of yellow fever epidemics across time and space. We tested the hypothesis that the distribution of Ae. aegypti was driven by human population density. This was tested by compiling a list of all yellow fever incidence in the U. S., human population density for that time period based on U.S. census tracks (analyzed in ten year intervals from 1870-1910), the number of people infected at the census and city level, and the human mortality when data were available. We found no relationship between infected individuals and human population size during each decade at the census track level, however a strong positive relationship did exist between infected humans and population size when epidemics with human population data at the city level. To understand the current distribution of this species, we also examined the hypothesis that climate (mean maximum and minimum temperature, mean rainfall) and anthropogenic factors (human population density, average household income, and percent of abandoned properties in neighborhoods) would explain the current range of Ae. aegypti. These factors and occurrence data for both spring and summer months were incorporated into a machine learning species distribution model to predict habitat suitability for Ae. aegypti. We found that anthropogenic factors, specifically human population density, had a large effect on explaining the distribution of Ae. aegypti regardless of season. Thus, both historical examinations and contemporary data strongly suggest that the distribution of Ae. aegypti is based on human population density within the United States, a fact that has been generally overlooked until now. Such information is important as this species continues to experience range expansion under a rapidly changing climate.

Phylogenetic pattern of the mimicry within the genus Euploea (Lepidoptera: Nymphalidae, Danainae)

Authors: Yen Shen-Horn[2], Wei Chia-Hsuan[3], Lohman David[1] and Yan Hsin[2], [1]Biology Department, City College of New York, United States, [2]Department of Biological Sciences, National Sun Yat Sen University, Taiwan, [3]National Cheng Kung University, Taiwan

Abstract: The alpha-taxonomy, mimicry, mating strategy, overwintering ecology and chemical defense of the butterfly genus Euploea have been studied extensively during the last decades. The wings pattern and unpalatability of them are known to be significant in driving the convergent evolution of colour-patterns of other butterflies and diurnal moths in Indo-Pacific region. Up to date about 61 species and numerous subspecies of Euploea are recognized. Although the genus is very often mentioned in studies on butterfly biology and mimicry, the majority of the studies confines to less a dozen of the species. The phylogenetic relationships within the genus was only studied once during the 1980s based on morphological characters and a Hennigian approach. The previous study, however, neither successfully resolve the phylogeny nor re-organize the classification. Meanwhile, morphological characters are not sufficient to distinguish species with extreme sexual dimorphism, polymorphism, internal mimicry and high individual variability. In order to evaluate the correlations between divergence times, clade age, speciation, biogeography and hostplant associations, we reconstructed the first Bayesian phylogenetic trees of Euploea butterflies using sequence data of 5 loci (COI, EF1a, RPS2, cytochrome b and wingless) from 40 species, and use this tree to assess the correlation between the diversity of mimicry ring and the landmass in SE Asian islands. Our phylogenetic analysis reveals that: (1) Euploea is a monophyletic group comprising at least 9 morphologically distinct and well-supported clades; (2) extreme sexual dimorphism has evolved only once in E. mulciber + E. configurata clades; (3) convergence in wing pattern appears in every clades with sympatric distribution; (4) the area of island correlates with diversity of mimicry rings, while this phenomenon is not detected in continent; and (5) species diversity of the genus is underestimated.

Toward a better understanding of the phylogeny of Epicopeiidae (Lepidoptera, Geometroidea), a small family with remarkable diversity in mimetic morphology and behavior

Authors: Yen Shen-Horn[1], Wei Chia-Hsuan[2], [1]Department of Biological Sciences, National Sun Yat-Sen University, Taiwan, [2]National Cheng Kung University, Taiwan

Abstract: The family Epicopeiidae is a small moth group comprising xx species in 10 genera distributed throughout the eastern Palaearctic and Oriental regions. All the species exhibit remarkable variations in size, wing shape and wing patterns that involve various mimicry rings dominated by toxic butterflies and moths. Although the extraordinary mimicry of this family has attracted attention from lepidopterists since the 19th century, a robust phylogeny, on which the systematics is based, is still unavailable due to rarity of most taxa in both the field and museum collections. In the present study, we included 8 of the 10 known genera in the analysis and also included various samples to represent the phenotypic diversity of some polymorphic taxa for a more accurate inference of phenotypic evolution. We used 6 protein-coding genes and employed maximum likelihood and Bayesian inference to reconstruct the phylogeny. We also examined the morphological characters that were used to reconstruct the preliminary phylogeny by previous authors. Our results clearly show existence of polyphyly in two genera and the separation between genera is also supported by morphological characters. The “swallowtail butterfly wing shape” has evolved independents at least twice and this suggests that wing shape evolution is highly plastic in this family. Polymorphic mimicry is also confirmed in four species and is highly correlated with diversity of models. Our finding reveals that Epicopeiidae has demonstrated a remarkable evolutionary history that is accompanied with dramatic changes in morphology as well as adult and larval biology.

Performance Comparison of Population Modelling on Different Pest Scenarios

Authors: Yeow Kin Woon, Human-Computer Interaction Group, Leibniz Universität Hannover, Germany

Abstract: Over the past decades, the use of pest population modelling has been vast in Decision Support System (DSS) and Integrated Pest Management System (IPM). Various simulation models are designed in order to model the dynamic development of pest population. There are huge challenges in pest population dynamic simulation. However, this field of research contains high impact factor on greenhouse growers and the pest management industry. In order to understand the importance of this research, the knowledge of common practices in the greenhouse is crucial. These knowledge inclusive of observation methods used to estimate the overall pest population with larvae and adult counts gathered. Two typical circumstances are investigated in this paper, the accuracy, behavioral analysis, and computational performance of the designed models are evaluated.

The first circumstance is that unique pest stages that consists of both larvae and adult counts are used as initial simulation input into the simulation models, whereas the second circumstance is that balanced pest population is distributed with either the larvae or the adult counts across all the other stages as initial simulation input into the simulation models. In this research, two simulation methods are evaluated, namely, the boxcar train model and the simplified phenological degree-day model. The results from both of the evaluated models shows that the balanced pest population input provide a result closer predicted values as compared to the unique pest stages of larvae and adult counts. The outcome of these two circumstances is evaluated in the simulation models and the result obtained is able to operate as a guidance for simulation model developer of the future.

Testing and developing automated pheromone traps for forestry and crop protection

Authors: Ylioja Tiina[4], Dorairaju Ganeas[4], Mustajärvi Jari[2], Laitinen Jukka[3], Kauppi Katja[5], Aarnio Leena[4], Nguyen Linh[8], Aaltonen Marja[5], Pakkanen Petri[1] and Seppälä Simo[6], [1]Häme University of Applied Sciences (HAMK), Hämeenlinna, Finland, [2]Häme University of Applied Sciences (HAMK), Hämeenlinna, Finland, [3]Natural Resources Institute Finland (Luke), Suonenjoki, Finland, [4]Natural Resources Institute Finland (Luke), Helsinki, Finland, [5]Natural Resources Institute Finland (Luke), Jokioinen, Finland, [6]Yield Systems, Espoo, Finland

Abstract: Pheromone traps are used for insect pest monitoring in crop protection, solving research questions and as early warning systems for emerging pests, either native or non-native. Traps that lure insects with synthetic pheromones come in different shapes and sizes, with or without glue papers, depending on the expected catch. However, the goal is the same: 1) identify the catch 2) time the catch and 3) count the catch. The major shortcoming of traditional traps is the need for manual checks at certain intervals. The Internet of Things (IoT) opens new opportunities for developing real-time insect monitoring on 4 and 5G networks with remote sensor devices globally.

In 2019, we firstly developed, automated pilot traps based on mobile phone technology to monitor the European spruce bark beetle, Ips typographus (Coleoptera: Curculionidae). Secondly, we tested commercially available traps (Trapview© and iScout Metos©) with pea moth, Cydia nigriana (Lepidoptera: Tortricidae) in a pea field of southwestern Finland. All the traps incorporated machine learning algorithms for image recognition.

For bark beetle monitoring two different traps “wet” and “dry” were assembled using field durable cell phones that were powered with 20W solar panels with external batteries for backup. The setup was in operation for over two months. The traps took three images per day that were stored in Amazon Web Services (AWS) cloud environment. The accuracy of the photos was inadequate in “wet” trap for counting the individual beetles. In “dry” trap the counting become only problematic when the beetles accumulated into the collection container. Image segmentation and counting process utilized the Unet convolutional neural network and the OpenCV library. A total of 42 images were manually annotated and the remaining images only processed. System performance was evaluated by using 10 non-annotated images as the test set. From 10 test images, error percentage was estimated to be <10 % based on manual counting.

During the June-July monitoring period of pea moth the commercial traps operated as expected and species identification succeeded at varying levels. The user also trained the system by identifying the pest monitored. The trap captures were comparable to manually checked delta traps. With the automatic monitoring the farmer would have been able to make his pest management decisions two days earlier than with manual traps. The commercially available traps, however, need modification regarding battery consumption, power generation of the solar panels and durability of the trap in Fennoscandian field conditions.

As a conclusion more research and development activities are needed to produce easily operable, reliable, durable and reasonably priced products. The results with the pilot remote monitoring funnel traps for the bark beetles indicate that a functioning prototype needs low-cost components and further development of the trap’s cleaning mechanism by com

Comprehensive collection and analysis of environmental DNA of arthropods remained on a plant

Authors: Yoneya Kinuyo[1], Ushio Masayuki[2] and Miki Takeshi[3], [1]Faculty of Agriculture, Kindai University, Japan, [2]Hakubi Center, Kyoto University Center for Ecological Research, Kyoto University PRESTO, Japan Science and Technology Agency, Japan, [3]Ryukoku Univ., Japan

Abstract: For community ecology of arthropods and pest control on plants, the survey of the arthropods on plants is a crucial step. However, its effectiveness is often hindered by many lines of problems in collecting small organisms on plants as well as high levels of skills required for species identification. In aquatic systems, to solve such problem, environmental DNA (eDNA) based techniques of metabarcording have been remarkably improved. However, application of eDNA-based metabarcording to terrestrial arthropod communities on plants remains rarely explored due to the difficulty of collecting eDNA of the organisms from plants tissues. To solve this problem, we developed a new eDNA collecting method for the arthropods on plants and crops using eggplant and cabbage as model systems. DNA barcode region, Cytochrome c oxidase subunit I (COI) gene, of the collected eDNA was comprehensively sequenced by a high-throughput sequencer after being extracted, purified, and amplified. As the result, more than 21 arthropod species were detected. It includes four parasitoid species and one predator species that were not observed by visual survey. This high coverage and sensitivity imply the effectiveness of the developed method despite of its simplicity. In this presentation, we are also going to show the results of monitoring arthropods and eDNA on rice plants in experimental rice field every two weeks for 5 months.

Seasonal adaptation of embryos and larvae of the Antarctic midge

Authors: Yoshida Mizuki[4], Denlinger David[3], Lee Richard[2] and Goto Shinsuke[1], [1]Graduate School of Science, Osaka City University, Japan, [2]Miami University, United States, [3]Ohio State University, United States, [4]Osaka City University, Japan

Abstract: The Antarctic midge, Belgica antarctica is the only insect endemic to the Antarctic Peninsula and its offshore islands. It has a 2-year life cycle and spends most of this period as a larva. Embryos, pupae, and adults are present only during the austral summer. Although its physiology has been extensively studied, there is little information on how they adapt to the Antarctic seasons. First, we investigated embryonic thermal tolerance and found that almost all embryos developed to the 1st instar larvae at temperatures ranging from 0 to 15 °C. These results indicate that immobile embryos have sufficient thermal tolerance to withstand fluctuating summer temperatures. Contrarily, the 1st instar larvae could develop to the 4th (final) instar larvae only at 4 °C. Mobile larvae may escape adverse temperatures behaviourally. The 1st instar larvae could develop to the 4th (final) instar stage, but the 4th instar larvae arrested their development and no pupae appeared. The observation revealed the 4th instar larvae enter obligatory diapause. In general, diapause can be terminated by winter cold. We found that the 4th instar larvae exposed to the simulated Antarctic winter conditions for 3 and 6 months successfully resume their development after cold exposure, whereas only a small portion of control larvae under Antarctic summer conditions resumed their development. The longer chilling treatment made more larvae resume their development. We found the Antarctic insect uses obligatory diapause to set the timing of the emergence of short-lived adults.

Peptidergic networks in circadian clock neurons regulate locomotor activity rhythms in Drosophila melanogaster

Authors: Yoshii Taishi, Graduate School of Natural Science and Technology, Okayama University, Japan

Abstract: All lifeforms on our planet have been subjected to 24-h environmental changes caused by the earth's rotations. To cope with the dynamic changes of 24-h cycles, circadian clock has been evolved from a very ancient organism such as cyanobacteria. The fruit fly Drosophila melanogaster is an excellent model for studying the molecular mechanism and neural network of animal circadian clocks. One of the most successful examples is the discovery of the period gene in 1971 by Konopka and Benzer —the first clock gene. The period gene is expressed in about 150 neurons in the fly brain, and those neurons are supposed to be involved in behavioral rhythms. Among them, a cluster of four small neurons located in the lateral brain, so-called ventrally located small lateral neurons (s-LNv), has been proposed as master pacemaker neurons, which express a neuropeptide, Pigment-dispersing factor (PDF). A loss of PDF causes a diminished morning activity, a phase-shift of evening activity toward the midday and weak activity rhythms under free-running conditions. The s-LNv neurons send signals to other pacemaker neurons through the PDF-receptor. We recently found that a cluster of two pacemaker neurons located in the dorsal brain, so-called anteriorly located dorsal neuron 1 (DN1a), express a neuropeptide, CCHamide1 (CCHa1) and this signal goes to the s-LNv neurons through the CCHa1-receptor. A loss of CCHa1 reduces the overall activity level. The double knockout of PDF and CCHa1 causes an additive phase-shift of evening activity and this phenotype was even more pronounced under a long-day condition. These results suggest that s-LNv and DN1a are reciprocally coupled via a neuropeptidergic circuit, which delicately regulates the daily activity pattern.

Impact of radioactive Cs on freshwater biota by the Fukushima nuclear power plant accident

Authors: Yoshimura Mayumi[1] and Akama Akio[1], [1]Forestry and Forest Product Research Institute, Japan

Abstract: During the Fukushima Daiichi nuclear power plant accident, radioactive substances were emitted into the environment, which contaminated forest litter as well as algae, sand substrates, aquatic invertebrates, and fish in freshwater streams. Because these substances have substantial effects on stream ecology over many years, it is necessary to clarify the diffusion and decay mechanisms of radiocesium is needed. Radioactive Cs contaminations of aquatic insects in pools were consistently higher than those in stream riffles. Contamination by the radioactive Cs differed depend on species, location and stream velocity. Contamination of fishes, those are used by human for food, is considered to be occurred via dietary uptake, and consequently, the degree of fish contamination was diet-dependent. The ecological half-life of cesium and the transfer coefficient also differed among aquatic invertebrate groups and location. The radiocesium concentration in algae was related to stream current velocity. These trends would lead to a longer period of freshwater contamination. Radiocesium concentrations would continue to decrease in more highly contaminated areas, but it is difficult to reduce radiocesium concentrations in less-contaminated areas because different contamination mechanisms would be at work. Controlling the water flow is key to regulating radiocesium concentration in freshwater ecosystems.

Phylogeny and higher systematics of Psocodea

Authors: Yoshizawa Kazunori[1], De Moya Robert[3] and Johnson Kevin[2], [1]Hokkaido University, Japan, [2]Illinois Natural History Survey, [3]University of Illinois

Abstract: Long-recognized as two insect orders, Psocoptera (booklice and barklice) and Phthiraptera (chewing and sucking lice) have recently been integrated into a single order, Psocodea. Morphology, Sanger-sequence and NGS techniques have been adopted to elucidate the higher-level phylogeny of Psocodea and, overall, these data sets converge on common ground. Psocodea is divided into three monophyletic suborders, Trogiomorpha, Troctomorpha (in which Phthiraptera is embedded), and Psocomorpha, and the latter two suborders are sister taxa. Monophyly of Phthiraptera was once questioned but is now corroborated. Taxonomically, Phthiraptera should be treated as an infraorder within Troctomorpha, and the widely recognized four subgroups of parasitic lice (Amblycera, Ischnocera, Rhynchophthirina and Anoplura) can be maintained as “parvorders”, with establishment of an additional new parvorder for the mammal-parasitizing ischnocerans (family Trichodectidae) which is placed as the sister of Rhynchophthirina + Anoplura. A couple of uncertainties remain for the higher-level phylogeny even with genomic dataset and extensive taxon sampling: e.g., monophyly of the family Prionoglarididae is ambiguous, although the family retains the most primitive forms and thus is key to understand the origin and evolution of Psocodea; placement of the genus Lachesilla and the family Peripsocidae is highly unstable, which made monophyly of the infraorder Homilopsocidea ambiguous.

Control of North American Planthopper, Metcalfa pruinosa on Sesame Fields

Authors: Young Uk Park[1], Jong Woo Han[1], Gil-Hah Kim[2], Young Ho Kim[1] and Cheol Ku Youn[1], [1]Chungcheongbuk-do Agricultural Research & Extension Services, South Korea, [2]Dept. Plant Medicine, Chungbuk National University, South Korea

Abstract: Since Metcalfa pruinosa was first reported in Koera, it has continually caused damage to many crops. Metcafa pruinosa exist not only in farmland but also in forest areas, and are difficult to control due to the influx of individuals from near forest. M. pruinosa has been occurred in orchard and its surroundings because of various host range. Thus, it has been difficult to decide spatial range and control time for efficient management. In this study, occurrence and dispersal pattern of M. pruinosa in sesame field were surveyed using clear sticky traps, and spatial patterns were analyzed with SADIE(Spatial Analysis by Distance IndicEs), based on location information at sticky traps. Results showed that the population density of M. pruinosa began increasing in early June. M. pruinosa nymph mainly dispersed in mid July and in late July, emerging season of adult. The distribution of in early June in sesame field was aggregative pattern in the area adjacent to the mountain. Therefore, if the seeding time is delayed in areas that are not in contact with mountain-area, it may be possible to reduce the damage of M. pruinosa.

Multitrophic interactions among plants, insect pests and their natural enemies regulated by endophytic entomopathogenic fungi

Authors: Yousef Meelad[1], Quesada-Moraga Enrique[1], Gonzales-Más Natalia[1] and Miranda-Fuentes Pedro[1], [1]Department of Agronomy, ETSIAM, University of Cordoba, Cordoba, Spain

Abstract: Entomopathogenic fungi (EPF) are now known to act as endophytes and therefore EPF leaf sprays may lead to both direct effects on the insect pest via contact with the fungal spores and direct and indirect effects on the pest when it feeds on endophytically colonised leaves. However, knowledge is limited concerning the possible impact of this endophytic behaviour on the plant chemical ecology, on the relationship insect pest-plant and insect-pest-natural enemies. In this sense, our studies have addressed the efficacy of the natural enemies (predators and parasitoids), when offered both sap-sucking and chewing pests that had been feeding on melon plants endophytically-colonized by the entomopathogenic fungi. The lacewings, Chrysoperla carnea consumed the same number of aphid prey in the same time in treatments and control. In a choice bioassay, C. carnea larvae preferred to feed on aphids reared on B. bassiana colonized plants compared with control plants. From other hand, the number of aphids parasitized by Aphidius colemani and their sex ratio were not influenced by whether the aphids had been feeding on B. bassiana colonized plants or not. However, the reproductive potential of Hyposoter didymator was significantly reduced in Spodopetra littoralis larvae fed with colonized plants if compared with larvae fed with non-inoculated plants, with parasitisation percentages of 32.6 and 67.7%, respectively. Our findings support the use of endophytic entomopathogenic fungi in combination with other natural enemies, such as predators and parasitoids, in Integrated Pest Management programs, whereas their use should be evaluated on a case-by-case basis.

Role of entomopathogenic fungus Metarhizium brunneum (Ascomycota: Hypocreales) in integrated management of olive fruit fly Bactrocera oleae (Diptera: Tephritidae)

Authors: Yousef Meelad[1], Garrido-Jurado Inmaculada[1] and Quesada-Moraga Enrique[1], [1]Department of Agronomy, ETSIAM, University of Cordoba, Cordoba, Spain

Abstract: The olive fruit fly Bactrocera oleae (Rossi) (Diptera: Tephritidae) is the most destructive pest to the olive crops worldwide. The control of this monophagous tephritid fruit fly is now at a critical moment because of the resistance developed by this pest against the chemical insecticides hardly available for its control. Soil treatments with the Metarhizium brunneum (Petch) (Ascomycota: Hypocreales) strain EAMa 01/58-Su targeting third-instar larvae in the soil during autumn and emerging adults from the soil during spring, under different climatic conditions, is considered as a pioneer method that can reduce the B. oleae population density emerging from the soil during spring up to 70%. This fungus can be mixed with the herbicides in the atomizer tank to do a simultaneous application which reduces the application costs. From other hand, our studies have demonstrated the lack of negative direct or indirect impact of such treatments on both the soil-dwelling non-target arthropod population and the parasitoid Psyttalia concolor (Szépligeti) (Hymenoptera: Braconidae). In addition, soil application of this fungus to control B. oleae leaves no residues in olive oil, in contrast to the use of chemical insecticides. Our works highlight the adaptation of the olive fruit fly control method based on soil application of M. brunneum to the IPM approach.

Management strategies for almond pests in Australia

Authors: Yousuf Fazila, Agriculture Victoria, DJPR Australia, Australia

Abstract: Australia's almond industry, valued at around AUD $1 billion, is threatened by two destructive insect pests that damage the almond kernel: Carpophilus truncatus (Coleoptera: Nitidulidae) and Apomyelois (=Ectomyelois) ceratoniae (Lepidoptera: Pyralidae). Presence of unharvested nuts (mummy nuts) in orchards is positively related to higher numbers of these pests and crop damage. A two-year field study was conducted to determine the spatial distribution and prevalence of these pests in almond orchards and their relationship to mummy nuts and crop damage. Targeting mummy nuts with orchard hygiene practices is expected to reduce pest damage.

Modified trapping systems are being developed for both pests as timely and accurate monitoring is critical for pest management. Field trials evaluating the response of adult carob moth to ten different coloured delta traps showed that clear traps were twice as effective as any of the coloured traps in trapping male moths, and that black traps were more effective for female moths. Pheromones and fungal odour attractants for the beetle have been identified and successfully tested in the field. These results will help almond growers monitor pest infestations more effectively.

Parasitism of Hypothenemus hampei adults by Phymastichus coffea (Hymenoptera: Eulophidae): effects of parasitoid diet, age, and temperature.

Authors: Yousuf Fazila[1], WRIGHT MARK[2] and Follett Peter[3], [1]Agriculture Victoria, DJPR Australia, Australia, [2]University of Hawaii at Manoa Honolulu, Hawaii, United States, [3]USDA, United States

Abstract: The coffee berry borer, Hypothenemus hampei (Ferrari), (Coleoptera: Scolytinae) is the most destructive insect pest of coffee globally. A biological control wasp, Phymastichus coffea LaSalle (Hymenoptera: Eulophidae) is a gregarious endoparasitoid of H. hampei adult females. It has been introduced to Central and South American countries for the biological control of H. hampei. To release the parasitoid in Hawaii, host specificity was tested by exposing P. coffea to a range of coleopteran beetles. The effect of different temperatures (20 °C, 23 °C, 25 °C, 28 °C and 30 °C) on the developmental time, adult longevity, and sex ratio of the progeny were determined. The effect of diet on the longevity and oviposition was also determined. Results showed that the parasitoid is restricted to the genus Hypothenemus only and did not parasitise any other beetle. The optimum temperature for development was 24-26 °C. Higher temperature was detrimental for the development. The diet of 50% honey solution increased the longevity and oviposition.

Volatile-mediated between-plant communication in Scots pine and the effects of elevated ozone

Authors: Yu Hao[1], Kivimäenpää Minna and Blande James[1], [1]University of Eastern Finland, Finland

Abstract: Herbivore-induced plant volatiles (HIPVs) convey information between damaged plants and their neighbors. Coniferous trees release substantial quantities of HIPVs upon bark-beetle attack, representing a strong indicator of herbivore presence. However, plant-plant interactions mediated by bark-feeding-induced volatiles have not been investigated. Importantly, elucidation of plant responses to HIPVs has focused on defense, whereas effects on primary metabolism are largely unknown, vastly limiting our understanding of this ecological phenomenon. Here, we show that HIPV-exposure induces and primes volatile emissions, increases stomatal conductance and net photosynthesis rate, alters resin duct traits, and ultimately reduces damage caused by herbivores. Elevated ozone, an important tropospheric pollutant and threat to volatile-mediated interactions, alters the plant responses. However, the final defense outcome was not significantly affected. These findings demonstrate that HIPVs modulate conifer metabolism through responses spanning photosynthesis and chemical defense. The responses are adjusted in the presence of ozone pollution, but the defense benefits remain intact.

Unravelling 150 million years of evolution between termites and their gut microbiome using metagenomics

Authors: Yukihiro Kinjo[1], Zifcakova Lucia[1] and Bourguignon Thomas[1], [1]Okinawa Institute of Science & Technology Graduate University, Japan

Abstract: Termites are amongst the most abundant terrestrial animals on earth largely due to their ability to digest lignocellulose, the most abundant organic molecule on earth. Lignocellulose is broken down in the termite gut with the help of symbiotic bacteria. Studies have shown that most termite gut microbes are found nowhere else than in termite guts, and that they are acquired by vertical transfer from parent to offspring, and horizontal transfer between colonies. Up to now, most studies have used 16S rRNA marker to determine the bacterial community composition, preventing any functional analyses. Additionally, most studies focused on distantly related species, preventing any attempt to analyze the interactions between termites and their microbiome at evolutionary timescale. To address these questions, I sequenced gut meta-genomes of 150 termites, selected to represent host diversity across the termite tree of life. In this talk, I will describe how bacterial communities and their function varies within and between termite species. I will also discuss how the gut bacterial community evolved across the termite tree of life.

Parasitic characteristics of Asobara japonica on alternate host and photoperiod for mass production

Authors: Yun Seung-Hwan[1], Young Kim A[2], Hye Ham Eun[3], Seo Hong-Yul[2], Park In-Tae[1], Eun Jang Jae[1], A Han Jeong[1], Lee Jingu[1], Kim Sang-Woo[1] and Soon Lee Young[1], [1]Gyeonggi-do Agricultural Research and Extension Services, South Korea, [2]National Institute of Biological Resources, South Korea, [3]Osang kinsect Co., Ltd, South Korea

Abstract: In General, pest infected with parasitoid was released when applying a parasitoid to a filed. In this case, there are concerns of artificially inoculating non-infected pests with parasitoid. To solve this problem, the technique of screening infected pests with natural enemies and alternate host that do not harm crops can be used. This study was carried out to confirm the parasitic features of A. japonica on alternate host: Drosophila melanogaster and photoperiod for mass production of natural enemies. A. japonica was parasitic on D. melanogaster larvae and the emergence of adults were observed from D. melanogaster pupae. Just like the D. suzukii, black spots(larvae) and white spots(pupae) were observed in D. melanogaster. The parasitic rate in D. melanogaster according to the evolution of generations was similar to that of D. suzukii up to the third generation. The parasitic rate of D. suzukii according to the generation progress of D. melanogaster as host was slightly decreased, but it was similar to that of D. suzukii as host. The effect on generation progression by photoperiod was not significant in short day and neutral day conditions.

The fauna of cerci-bearing apterygotes (Diplura, Archaeognatha and Zygentoma) from China

Authors: Yun-Xia Luan[1], Luan Yun-Xia[2], [1]Guangdong Provincial Key Laboratory of Insect Developmental Biology and Applied Technology, Institute of Insect Science and Technology, School of Life Sciences, [2]South China Normal University

Abstract: As the largest country in Asia and the third largest country in the world, China harbors nearly 20% of all known insect species on earth due to dramatic differences in topography, climate and vegetation across China. However, the species diversity of the apterygotes is highly underestimated so far, especially for the representatives equipped with leg-derived cerci classified in the taxa Diplura, Archaeognatha and Zygentoma. This study summarizes the current knowledge on Chinese records of Diplura (six families, about 50 species), Archaeognatha (two families, 31 species) and Zygentoma (three families, 10 species) and surveys their distribution and phylogenetic relationships. Further steps of our project on the biodiversity of basal hexapods from China will be outlined, including the application of modern information technologies currently promoted by the Specialized Information Service Biodiversity Research (BIOfid).

Phylogeny, taxonomic revision, and evolution of brachyptery in the New World leafhopper tribe Faltalini (Hemiptera: Cicadellidae: Deltocephalinae)

Authors: Zahniser James[1], [1]USDA-APHIS-PPQ, National Museum of Natural History, Smithsonian Institution, Washington, DC, United States

Abstract: The deltocephaline leafhopper tribe Faltalini currently consists of 11 genera and 27 described species. The tribe occurs in the New World from the southwestern United States through Argentina and Chile. Existing records and observations indicate that most members are endemic to grasslands and live and feed on grasses (Poaceae), although some have been collected in or near tropical forests. Recent field work in South America, especially in Argentina, and examination of specimens from multiple institutions has revealed the existence of two new genera and 35 new species of the tribe. Many more are expected to be discovered with more field work, especially in understudied grassland regions of South America. In light of the discovery of the new taxa, the tribe is taxonomically revised, including an account of its taxonomic history, a key to the genera, defining morphological characters for the tribe and for generic groups, descriptions of all genera including two new genera, descriptions of 35 new species, and a phylogenetic analysis based on a dataset of 51 morphological characters scored 40 taxa.

The morphological phylogenetic analysis of members of the tribe and outgroup taxa resolved Faltalini as monophyletic, resolved three well-supported relationships among generic groups, and resolved all genera for which multiple taxa were included as monophyletic. The phylogeny suggests a stepwise reduction in wing length. Macroptery is the ancestral condition and sequential reduction in wing length culminated in a clade including seven genera which are completely brachypterous. The nature and morphology of brachyptery, especially of the hindwing, is explored using SEM imagery and instances of brachyptery in Faltalini are compared to other independently evolved instances in the subfamily Deltocephalinae.

Managing Helicoverpa armigera (Noctuidae) in Australian Grain Crops: Current Status and Future Prospects

Authors: Zalucki Myron[5], Volp Trevor[2], Furlong Michael[4], Brier Hugh[1], Miles Melina[3], [1]Agri-Science Queensland, Department of Agriculture and Fisheries, Kingaroy, Queensland, Australia, [2]Agri-Science Queensland, Department of Agriculture and Fisheries, Toowoomba, Queensland, Australia School of Biological Sciences, The University of Queensland, , [3]Agri-Science Queensland, Department of Agriculture and Fisheries, Toowoomba, Queensland, Australia, [4]School of Biological Sciences, The University of Queensland, Australia, [5]The University of Queensland, Australia

Abstract: Helicoverpa armigera Hübner (Lepidoptera: Noctuidae) is a major pest of broadacre crops in north-eastern Australia. Prior to the introduction of transgenic cotton in the 1990s, high levels of insecticide resistance in H. armigera almost caused the collapse of the Australian cotton industry.

The Australian Grains industry is still heavily reliant on conventional insecticides to control H. armigera. Subsequently, resistance of H. armigera to the frequently used insecticides is an ongoing challenge. In particular, the development of resistance to more selective options (e.g. indoxacarb and chlorantraniliprole) is closely monitored and managed.

Integrated Pest Management (IPM) can improve H. armigera control and help mitigate the threat of resistance. Several measures have been developed to provide better information and enhanced management tactics for growers:

1. Wide-scale pheromone trapping to detect mass moth movements.
2. Development of economic thresholds for H. armigera in several summer and winter grain crops.
3. Development of NPV (nuclear polyhedrosis virus) as a biological control.
4. Evaluation of improved control measures for other grain pests, the management of which affect H. armigera
5. Development and release of an insecticide resistance management strategy for H. armigera.

However, there are still major limitations to the adoption of IPM of H. armigera in Australian grain crops. The inexpensiveness of broad-spectrum insecticides and the difficulties associated with incorporating natural enemies into management decisions are particularly problematic. Moving forward, a promising avenue of research for some crops, for example the summer grain crop pigeonpea, is selecting crop varieties that are resistant or tolerant to injury from H. armigera and other pests.

Population regulation of caterpillars in northern hardwood forests

Authors: Zammarelli Miranda[2], Holmes Richard[2], Rodenhouse Nicholas[4], Sillet Scott[3], Lany Nina, Pardo Linda, Fahey Timothy[1], Hallworth Michael and Ayres Matthew[2], [1]Cornell University, [2]Dartmouth College, United States, [3]Smithsonian Institution, [4]Wellesley College, United States

Abstract: Interannual variation in caterpillar abundance can fluctuate by greater than 20-fold in northern hardwood forests; however, the broad-scale drivers of this variation are not well understood (Reynolds et al. 2007). We illustrate continuous large annual variation in caterpillar abundances at Hubbard Brook Experimental Forest, New Hampshire, USA from 1986 to 2019 and reapply a thermal sum model to explore how temperature influences caterpillar abundance. When observing the density dependence of caterpillar populations, we aim to see if the equilibrium abundance remains stable or changes between years. We observe if the equilibrium abundance varies between different host trees, American Beech (Fagus grandifolia) and Sugar Maple (Acer saccharum), to understand how changing species composition may influence the stability or instability of caterpillar populations. Finally, we hypothesize the role of 1) foliar Nitrogen, 2) phenology of leaves, 3) air temperature during leaf expansion, 4) snow depth, and 5) variation in Ichneumon wasp abundance in changing caterpillar abundance based on long-term correlating datasets. Understanding these drivers of variation in annual caterpillar abundance informs us about potential changes in host availability for parasitic insects such as wasps and the food availability to many birds, as well as contributing to our understand of global insect decline.

Demography and fitness of Anastatus japonicus reared from Antheraea pernyi as a biological control agent of Caligula japonica

Authors: Zang Lian-Sheng[1], Chen Yong-Ming[2] and Wei Xiao-Yan[2], [1]Institute of Biological Control, Jilin Agricultural University, China, [2]Jilin Agricultural University

Abstract: Japanese giant silkworm (JGS), Caligula japonica Moore, is an emerging defoliator pest of forest and fruit trees in East Asia, causing severe economic losses. To develop a cost-effective biological control program against JGS, we used eggs of the Chinese oak silkworm (COS) Antheraea pernyi Guérin-Méneville as an alternative host to rear the most dominant JGS egg parasitoid Anastatus japonicus Ashmead. We compared the demographic parameters and total parasitism (killing) rates of A. japonicus parasitizing JGS and COS eggs using an age-stage, two-sex life table method. The results showed that A. japonicus performed differently on these two different hosts. Anastatus japonicus reared from COS eggs had a higher fecundity (369.7 eggs per female) and a longer oviposition period (35.9 days) on the COS than JGS eggs (180.9 eggs; 24.0 days). Consequently, A. japonicus parasitizing COS eggs had a higher intrinsic rate of increase ($r = 0.1466$ d–1), finite rate of increase ($\lambda = 1.1579$ d–1) and net reproductive rate ($R0 = 284.9$ offspring) than those parasitizing JGS eggs ($r = 0.1419$ d–1, $\lambda = 1.1525$ d–1, $R0 = 150.0$ offspring). The total net parasitism rate (the number of parasitized hosts in which the parasitoids successfully developed) of A. japonicus parasitizing COS eggs was 284.9, significantly higher than that of A. japonicus parasitizing JGS eggs (150.0), while the net non-effective parasitism rate (the number of parasitized hosts in which the parasitoids failed to develop) of the former (0.0) was significantly lower than that of the latter (9.6). These results suggest that A. japonicus can be efficiently reared on the alternative (or factitious) COS eggs, and the reared parasitoids have a high biological control potential against the target JGS.

Multiparasitism: an innovative mean for mass production of Trichogramma on the large eggs of Chinese silkworm, Antheraea pernyi

Authors: Zang Lian-Sheng, Institute of Biological Control, Jilin Agricultural University, China

Abstract: Trichogramma parasitoids are important biological control agents for insect pest management. However, efficient means for mass production of Trichogramma parasitoids are needed. Large eggs of the Chinese silkworm, Antheraea pernyi, have practical advantages as hosts for Trichogramma production such as the high parasitism rate, low cost, and easy storage and transport, which has been regarded as among the best factitious hosts for mass production of Trichogramma parasitoids. However, the thick and hard chorion of the large eggs is a limiting factor for some dominant parasitoids against insect pests, such as T. ostriniae and T. leucaniae, which are unable to normally form emergence holes to escape and consequently are fatally trapped. Recently, we found the feasibility of mass production of Trichogramma via multiparasitism with T. dendrolimi (or T. chilonis) on these originally nonpermissive host eggs of A. pernyi. The results indicate that T. ostriniae and T. leucaniae could be normally emerged from the large eggs through multiparasitizing with T. dendrolimi (or T. chilonis). Particularly, the outcome of multiparasitism between Trichogramma parasitoids is significantly impacted by factitious host species and parasitoid age. These findings encourage production of some dominant Trichogramma species on industrial scale for IPM programs.

Performance of two egg parasitoid species from Zambia and four indigenous Trichogramma species from northeastern China against fall armyworm, Spodoptera frugiperda

Authors: Zang Lian-Sheng[1], DAI PENG[1] and Sun Jia-Wei[1], [1]Institute of Biological Control, Jilin Agricultural University, China

Abstract: Fall armyworm Spodoptera frugiperda (Smith) (Lepidoptera: Noctuidae), is a new invasive pest causing serious damages in Asia and Africa. Trichogramma are the dominant biological control agents that has been applied to control lepidopteran pests worldwide. To prevent the outbreak of invasive S. frugiperda in China, performance of the two egg parasitoids collected from Zambia and four native species of Trichogramma egg parasitoids from northeastern China were studied. The two egg parasitoids from Zambia were identified as Trichogramma sp. nr. mwanzai and Trichogrammatoidea sp. by using combination of both molecular and morphological characters. The results showed that both parasitoid species from Zambia significantly preferred to 1-day-old age eggs of S. frugiperda. These two imported parasitoid species can be massively reproduced on Corcyra cephalonica eggs. In native species, all four Trichogramma species could accept S. frugiperda eggs and complete development successfully, but significant differences in fitness parameters were found among them. The parasitism of T. dendrolimi, T. ostriniae and T. leucaniae was higher than 80% on S. frugiperda egg masses, while only T. dendrolimi females offered to S. frugiperda eggs parasitized higher number of eggs among all the tested species. Finally, the performance of two parasitoid species from Zambia and four native Trichogramma species on S. frugiperda eggs were compared. The present study provides useful information on mass breeding and releases of indigenous egg parasitoids against the invading S. frugiperda in Africa and China in future.

Recent advances toward the sustainable Nesidiocoris tenuis exploitation in tomato crops

Authors: Zappalà Lucia[1], Biondi Antonio[2], Siscaro Gaetano[2], Tropea Garzia Giovanna[2] and Ricupero Michele[2], [1]Department of Agriculture, Food and Environment, University of Catania, [2]University of Catania, Department of Agriculture, Food and Environment, Catania, Italy

Abstract: Generalist predators are often highly efficient biocontrol agents of various crop pests. Besides, they can also feed on various non-pest foods. The zoophytophagous mirid bug Nesidiocoris tenuis (Reuter) (Hemiptera: Miridae) is largely employed in biocontrol programs in tomato crops in Euroafroasia through augmentative releases and conservative strategies. Under certain circumstances, it can cause economic losses by its repeated feeding on tomato plants. Here we report recent experimentations on various aspects of potential N. tenuis exploitation in tomato crops, such as banker plants, variety susceptibility, induced plant defenses, insecticide selectivity. The results of our recent experiments provide new insight useful for optimizing Integrated Pest Management tomato packages.

BugMap: understanding the expansion of Halyomorpha halys with the support of citizens

Authors: Zapponi Livia[4], Anfora Gianfranco[3], Eriksson Anna[1], Mazzoni Valerio[2], Andreis Daniele[5] and Corradini Stefano[5], [1]Assomela, [2]Fondazione Edmund Mach Center for Research & Innovation, Italy, [3]Fondazione Edmund Mach, Università di Trento, [4]Research and Innovation Center, Fondazione Edmund Mach, Italy, [5]Technology Transfer Center, Edmund Mach Foundation, Italy

Abstract: Tracking the invasion of alien species requires the rapid gathering of a vast amount of data, a goal that can be achieved with the coordinated work of researchers and citizens. In this context, the application of citizen science programs to the monitoring of alien species is becoming particularly popular, although its efficacy should be object of more accurate evaluation through specifically designed experiments. BugMap is a smartphone app specifically designed to track the expansion of Halyomorpha halys, the brown marmorated stink bug (BMSB) in Trentino, Northern Italy. In the present study, we compare the BMSB distribution provided by data obtained with standard monitoring methods (i.e. attractive traps, visual sampling) and BugMap, in terms of time and spatial coverage.

From 2016, BugMap collected more than 3000 records, thanks to the contribution of technicians, farmers and citizens. The photographic validation associated with BugMap showed good accuracy since the vast majority of the records targeted the correct stink bug species. The heat maps generated with these records showed a reliable evolution of the areas with higher concentration of BMSB with time, coherent with the data obtained with the traditional monitoring. Furthermore, BugMap data has proved to be particularly useful to monitor both the BMSB phenology (e.g., first appearance of nymphs and eggs) and presence in different environments (e.g., cultivated areas, woods, parks), throughout the year. Our conclusion is that the real time information provided by BugMap could be employed as an instrument for timely decision-making and to support IPM strategies.

Managing Spider Mites, Banks grass mite (Oligonychus pratensis (Banks) and Two-spotted mite (Tetranychus urticae Koch) on Corn

Authors: Zarrabi Ali[2], Royer Tom[1], Wallace George[1], Levy Grace[1] and Giles Kristopher[1], [1]Oklahoma State University, United States

Abstract: Insecticide choice for controlling spider mites (Bank grass mite - BGM and Two-spotted mite - TSM) on corn is critical because most pyrethroid and organophosphate insecticides used have a disproportionately adverse effect on beneficial species which contributes to mite flare ups. During management decisions, producers must document the mite species and life stage proportions as available miticides have variable effects on these two species: TGM is less susceptible to most available products compared to BGM, and not all miticides are capable of killing adults (adulticidal) and eggs (ovicidal). Data from spider mite control studies in the US Southern Plains is sparse, and therefore, in an effort to provide producers with efficacy data that will inform their management decisions, we conducted two studies at OPREC (Oklahoma Panhandle Research and Extension Center) in Goodwell, OK during the summer of 2019. In the first replicated study, we evaluated the effectiveness of 5 available miticides with variable modes of action and predicted efficacy for controlling spider mites in corn. In the second study, we evaluated two miticide products ('Onager' and 'Zeal') that were predicted to conserve beneficial species. In both trials, the results clearly indicated that all miticides tested were effective at suppressing spider mites in corn and producers can reliably choose among these products dependent upon their management goals that may include conservation of beneficials.

Back to the origin: the importance of considering genetics and sources of natural enemies' populations in classical biological control programs

Authors: Zaviezo Tania[1] and Astorga Ilania[2], [1]P. Catholic University of Chile, Chile, [2]Servicio Agrícola y Ganadero, Chile

Abstract: Classical biological control depends on the importation and successful rearing of natural enemies' populations, and many times when a successful program has been carried out in one region natural enemies are imported from this introduced area rather than from the area of origin. This often leads to populations experiencing strong founder effects, loss of genotypic variability and increased inbreeding. Here we show two biological control programs carried out in Chile, where evaluations lead to the decision that importations should be carried out from the area of origin. The first project deals with the importation of Trioxys pallidus (Hymenoptera: Braconidae) to control the walnut aphid, a pest detected in Chile in 2009. Initially, parasitoids were going to be imported from California (USA), but given the recent reports of a loss in effectiveness of biological control, the decision shifted to carry out foreign exploration in Iran, the area of origin, and made collections on the intended host. In 2011, mummified aphids were imported and in the 2012-2013 season they were released. Establishment and dispersal were confirmed, as well as a depression on the pest population. The second project deals with Mastrus ridens (Hymenoptera: Ichneumonidae) to control codling moth. In this case M. ridens had also been imported to California over 20 years ago, and from there laboratory populations were sent to other countries. We collected parasitoids in its area of origin, Kazakhstan, and imported insects from a laboratory colony in New Zealand, as well as samples from other laboratories. We found that this parasitoid presented complementary sex determination (CSD), and thus inbreeding could result in the generation of diploid males. Analyses revealed that populations in captivity had lower genetic diversity and a larger proportion of diploid males than those in the wild. In laboratory experiments we found no effects of inbreeding on several female life history traits, but in inbred lines females produced less daughters, male biased sex ratio and higher proportion of diploid males. Populations with lower initial genetic diversity, showed lower growth rate and less production of females. These projects highlight the importance of carrying out pre- and post-release population genetics and carefully considering the sources of natural enemies in classical biological control programs (Funding: FONDECYT 1181256).

Resistance mechanism of the brown planthopper, Nilaparvata lugens, to buprofezin

Authors: Zeng Bin[1], [1]College of Plant Protection, Nanjing Agricultural University, State & Local Joint Engineering Research Center of Green Pesticide Invention and Application, China

Abstract: Buprofezin is an insect growth regulator that inhibits chitin biosynthesis. It has been applied extensively on rice for the control of brown planthopper (BPH), Nilaparvata lugens. However, BPH has developed high level of resistance to buprofezin in the field. In this study, the molecular basis of buprofezin resistance was investigated in a buprofezin resistant strain from Wuxi field (Bup-R). The genetics of resistance was investigated by reciprocally crossing strain Bup-R with a susceptible strain (Bup-S) and revealed an autosomal incompletely recessive mode of inheritance. A synergistic study in vivo and a biochemical study in vitro indicated that an enhanced detoxification mediated by P450s to some extent contributes to the buprofezin resistance in the Bup-R strain. These data suggested that the P450-mediated metabolic detoxification of xenobiotics might be an important mechanism for buprofezin resistance in the BPH. The implementation of appropriate resistance management strategies is strongly advised to delay the further spread of resistance.

Terpenoids mediate interactions of the guava-citrus-psyllid

Authors: Zeng Xinninan[1] and Ling Siquan[1], [1]Guangdong Engineering Research Center for Insect Behavior Regulation, South China Agricultural University, Guangzhou, China

Abstract: Intercropping can reduce agricultural pest incidence, and shows great potential of an important sustainable alternative to conventional pest control means. Understanding the ecological mechanisms for intercropping could optimize its use, particularly in tropical systems which present a large number of potential intercropping possibilities. Citrus is threatened worldwide by greening disease (huanglongbing, HLB) vectored by the citrus psyllid, Diaphorina citri (Hemiptera: Psyllidae). Control of HLB/citrus psyllid can be partially achieved through intercropping with guava, Psidium guajava, but the mechanisms remain unclear. We tested the hypothesis that guava volatiles affect psyllid behavior by altering the attractiveness of citrus through plant-plant interactions. In choice and no-choice cage experiments, psyllid settlement was reduced on citrus shoots that had been exposed to guava shoots for at least 2h. In Y-tube olfactometer experiments, psyllids oriented to odors of unexposed, compared to guava–exposed, citrus shoots. Emission of volatile terpenoids was reduced in citrus shoots that had been enclosed with guava shoots, suggesting that citrus metabolically responds to the odors of neighboring guava plants. ß-caryophyllene was the most abundant and characteristic volatile terpenoid volatile compound of the flushing shoots from the tested ACP host-plant species. Tissue expression profiles of nine known DcitOBPs were analyzed based on the transcriptome database, DcitOBP3 and DcitOBP6 exhibited high expressions in the antennae of both sexes and the ovipositor of females, and qRT-PCR validated the result. The binding ability of two recombinant proteins to eight ligands was studied by competitive binding analysis, as a result, DcitOBP6 exhibited stronger binding ability to ß-caryophyllene. Behavioral trials indicated that the sexually mature female adult psyllids were significantly attracted to ß-caryophyllene at the concentration of 0.1µL/mL and 10µL/mL. RNAi analysis in female D. citri showed that the reduction of DcitOBP6 transcript abundance led to a decrease in behavioral responses to ß-caryophyllene. The results demonstrate that DcitOBP6 is involved in the perception of ß-caryophyllene. Further study is needed to reveal the semiochemicals emitted by guava plants which elicit citrus responds. Well understanding of the interaction of guava-citrus-psyllid could led to the development of sustainable and ecological pest management system.

Migration Processes and Patterns of Fall Armyworm in China: Comparing with the situation in the USA

Authors: Zhai Bao-Ping[2] and Li Xi-Jie[1], [1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China

Abstract: In January 2019, the invasive fall armyworm (FAW), Spodoptera frugiperda, arrived in China. Then, the southern half of the mainland of China has been covered by FAW during the first half year. By mid September of 2019, 26 (/30) provinces in China were covered by the invasive pest. What will be happened to this invader in China when their colonization complete? We draw up the migration processes and patterns of FAW in China by comparative perspectives on migration arena in the New World and East Asia.

1. The Asian Monsoon systems will provide dominant wind direction during spring, summer and autumn to accelerate the northward and southward migration processes of FAW in East Asia, from Indochina Peninsula to Russia Far East, Korea Peninsula and Japan Islands.

2. In the tropical New World, the round-year easterly prevent the moths of FAW immigrate to North America from Central and South America, that make a very small overwintering population of FAW located the most southern parts of Texas and Florida. So, the outbreak frequency of FAW in North America is not high and the outbreak areas are limited to local scale.

3. But in East Asia, all over the Indochina Peninsula are suitable habitats of FAW and will form the permanent year-round breeding areas of FAW and Infinite source populations of FAW for China. Meanwhile, the vast planting areas of staple grain crops in China will provide unlimited food resources to the pest. Therefore the population size of FAW in mainland of China will be larger and larger and FAW will outbreak year after year on multi-crop system in all over China.

4. The southwest low-level jets over the Great Plains shape the north and eastward migration patterns of FAW in North America, that make the moths get out of the wheat belt in northwest USA and mainly damage the corn belt in USA and Canada. But in China, there are no dominant winds before the summer monsoon emerged and during the transition period between summer monsoon and winter monsoon in spring and early autumn. The FAW will show multidirectional migration patterns to establish vast spatial distribution across the mainland, especially the westward migration to colonize the western China. So, FAW will become a super pest soon in China.

Connectivity of aerial corridors of hopper vector and epidemics of southern rice black-streaked dwarf virus

Authors: Zhai Bao-Ping[1], Li Xijie[1], Lu Jiahao[1], Guo Jiawen[1], [1]Nanjing Agricultural University, China

Abstract: Southern rice black-streaked dwarf virus (SRBSDV) is a virus can only be transmitted by white-backed rice planthoppers (Sogatella furcifera, WBPH), a pest feed on rice. SRBSDV disease broke out several times in southern China and north Vietnam, but the outbreak mechanism is not clarified. Since there is no rice planting in southern China and north Vietnam. This area is like an ecological trap formed for both WBPH and SRBSDV. Then, how could the virus appear in southern China and north Vietnam next year? Among the adjoining areas, Hainan Island and central Vietnam have rice planting in winter. These are places where the virus conserves. In this research, we explored a method to use connectivity index to describe aerial corridor for WBPH. Meanwhile, seek for the reason SRBSDV outbreak degree fluctuating among different years. The connectivity of aerial corridors of WBPH make the insects return central southern Vietnam in late autumn and immigrate into southern China and north central Vietnam in Spring to re-colonize in the new planting rice fields. Besides, the connectivity of the Hainan-north central Vietnam corridor would support the viruliferous WBPH from Hainan immigrate into north central Vietnam by easterly during March and April or land on north central Vietnam with summer Typhoon during June and July, with triggering the SRBSDV outbreak and epidemic.

Attract-and-kill: A feasible approach to manage cocoa pod borer infestation in cocoa plantation

Authors: Zhang Aijun[2] and Vanhove Wouter[1], [1]Laboratory of Tropical and Subtropical Agriculture and Ethnobotany, Department of Plant Production, Ghent University, Gent, Belgium, [2]USDA-ARS, Invasive Insect Biocontrol and Behavior Laboratory, Beltsville Agricultural Research Center-West, Beltsville, MD, United States

Abstract: The cocoa pod borer (CPB) is an insect pest for cocoa production in Southeast Asia. It could cause crop loss more than 80%. Currently, application of synthetic pesticides is only effective method for growers to control CPB population in cocoa plantation. The sex attractants of CPB has been identified in the 1980s, however, application against CPB was halted in the early 1990s due to economic reasons and lack of commercial quantities of sex attractant. We have modified synthetic method for more economical production. Effectiveness of an attract-and-kill strategy was then evaluated for two years in Malaysia cocoa plantation. Our results demonstrated that the attract-and-kill strategy was as good as ongoing conventional synthetic pesticide application. In addition, the killing stations with lower dose loadings of sex attractant could significantly reduce the number infested cocoa pods caused by CPB. Our finding will help growers and scientists to develop a feasible approach using semiochemcials based on natural product to efficiently, safely, and environmentally friendly manage cocoa pod borer infestation in cocoa plantation.

New advances on the functional genomics of the brown planthopper

Authors: Zhang Chuan-Xi, 1.Institute of Plant Virology, Ningbo University, China; 2.Institute of Insect Science, Zhejiang University, Hangzhou, China

Abstract: The brown planthopper (BPH), Nilaparvata lugens (Stål) (Hemiptera: Delphacidae), is a serious migratory rice (Oryza sativa L.) pest, which causes a conservative estimation of more than US$300 million per year world wide. Our new advances on its functional genomics includes: (1) A chromosome-level of the genome was assembled. (2) Whole genome sequencing of 358 brown planthoppers uncovers the landscape of their migration and dispersal worldwide (3)A comprehensive omics analysis and functional survey of cuticular proteins was revealed in the hopper and compared with other insects. (4) Plastic development of wing morphs and body colors was found to be determined by two different neoropeptides, respectively. (5) Salivary proteomes of planthoppers and their interaction with planthoppers. (6) Two new female determinants were identified in the planthopper sex determination pathway.

Competing beetles attract egg-laying in hawkmoth

Authors: Zhang Jin, Raza Syed Ali Komail

Abstract: Nutrition is crucial for survival, but that is only one of the countless factors. It's the wild west in nature, so smart choices must be made. Blindly, but with time and ingenuity on its side, evolution has provided species with diverse strategies to help them defuse the Darwinian struggle. In our study, contrary to our assumption we found that tobacco hawkmoths (Manduca sexta) preferentially oviposit on Jimson weed (Datura wrightii) that is already infested by a specialist, the three-lined potato beetle (Lema daturaphila). The fitness advantage was not found to be direct, as larvae developed more slowly when feeding together with Lema beetles. In nature, the caterpillars of M. sexta are heavily predated by a parasitic wasp, Cotesia congregata. Plants infested by their food competitor, the beetle L. daturaphila, kept this parasitoid away. Consequently, moths preferred the beetle-infested plants despite the availability of better food sources. Over time this preference is conceivably embedded in M. sexta biology. We identified that the volatile α-copaene, emitted by beetle-infested Datura, plays a role in this preference. We demonstrate that odorant receptor (Or35) is involved in α-copaene detection by performing heterologous expression and single-sensillum recordings. What at first appeared to be a counterintuitive strategy turned out to be a cooperation that has been molded by multi-trophic interactions.

RNAi interference on the chitinase gene HcChi for the control of Hyphantria cunea (Lepidoptera: Arctiidae)

Authors: Zhang Sufang, Key Laboratory of Forest Protection of the National Forestry and Grassland Administration of China, Research Institute of Forest Ecology, Environment and Protection

Abstract: Hyphantria Cunea is an important forestry quarantine pest in China. They frequently outbreak in Northeast, North and Central China, which lead to serious threat to forest health and ecological safety. In this study we explore the application of RNAi to control H. cunea. The result show that the injection of 5th instar larvae with dsChi doses 2.5μg could reduce the gene expression up to 66.8%, while 0.5μg lead to the pupation and eclosion stage deformity with a pupation rate of 31.03%. It also caused malformation during molting process of 4th instar larvae and lead to a pupation rate of 53.8%~77.8%. The chitinase dsRNA expression system was constructed using E. coli HT115 strain. 2nd and 3rd instar larvae were started to feed on dsRNA expressed by HT115, and caused the weight decrease of 40.7% and 10.7%respectively.

Full-length cDNA of SID-1 was cloned from H. cunea larvae by RT-PCR and RACE. The ORF of HcSID-1 is 2613 bp and encodes 870 amino acids. It is predicted that the gene has typical SID protein domains such as a long extracellular N terminal and 11 transmembrane domains. Phylogenetic analysis revealed the homology between HcSID-1 and other SID genes. Temporal and spatial expression patterns analysis showed that the gene was expressed in all tissues and all development stages of H. cunea, with the highest expression level in midgut. The expression of HcSID-1 could be reduced to 53.5% by RNAi. The down regulation of HcSID-1 could reduce the interference efficiency of dsChi up to 7.32 times, suggesting that Hc SID-1 may be involved in the systematic RNAi process in H. cunea.

A distinct strain of Arsenophonus symbiont decreases insecticide resistance in its insect host

Authors: Zhang Wenqing, Sun Yat-sen University, China

Abstract: Symbiotic bacteria are important drivers of phenotypic diversity in insects. One of the widespread symbionts to have emerged belongs to the genus Arsenophonus, however, its biological functions in most host insects remain entirely unknown. Here we report two distinct Arsenophonus strains in the brown planthopper (BPH), Nilaparvata lugens, a major pest insect in Asian countries that causes significant economic damage through rice crop destruction. Genomic resequencing data suggested that one Arsenophonus strain (S-type) negatively affected the insecticide resistance of the host. Indeed, replacement of the resident Arsenophonus with the S-type Arsenophonus significantly decreased host insecticide resistance. Transcriptome and metabolome analysis revealed down-regulation of xenobiotic metabolism and increased amino acid accumulation in the S-type Arsenophonus infected host. This study demonstrates how a symbiont-mediated phenotypic change can occur. The results of this study will aid in developing strategies that work through imposing an ecological disadvantage on insect pests, which will be of great value for pest control in agricultural industry.

A saliva protein 7 of the brown planthopper Nilaparvata lugens functions as an effector for defense responses in rice

Authors: Zhang Zhenfei[2], Gong Gu[3], Yuan Longyu[1], Li Yifeng[1], [1]Plant Protection Research Institute Guangdong Academy of Agricultural Sciences, Guangzhou, China, [2]Plant Protection Research Institute Guangdong Academy of Agricultural Sciences, Guangzhou, China; Guangdong Provincial Key Laboratory of High Technology, China, [3]Plant Protection Research Institute Guangdong Academy of Agricultural Sciences, Guangzhou, China; Laboratory of Insect Ecology, South China Agricultural University

Abstract: The brown planthopper (BPH), Nilaparvata lugens (Stål) (Hemiptera: Delphacidae), a major pest of rice in Asia, is able to successfully puncture sieve tubes in rice with its piercing stylet and then to ingest phloem sap. In this study, we investigated the potential role of saliva protein 7 (NlSP7) in N. lugens virulence and adaptation to host resistance. The results were showed that NlSP7 was highly expressed in the salivary glands of BPH, and it has two alternative splicing variants. Both of them are expressed at high levels during the adult stages. Simultaneously, knocking down the two NlSP7 variants by RNA interference inhibited salivary flange and resulted in a lethal phenotype within two days for BPH feeding on rice plants, indicating that the NlSP7 was essential for plant-associated feeding. Knocking down the expression of two NlSP7 variants resulted in reducing the intake of brown planthoppers. Furthermore, NlSP7 might help BPH deal with plant resistance, and altered gene expression was observed when BPHs were transferred from a susceptible rice variety to a resistant one. Infestation of rice by BPHs whose NlSP7 was knocked down elicited higher levels of tricin which a secondary insect-resistant substance of rice than did infestation by control insects. These results indicate that the salivary protein in BPH, NlSP7, functions as an effector and plays important roles in interactions between BPH and rice by mediating the plant's defense responses.

Ionotropic GABA receptor of Chilo suppressalis

Authors: Zhao Chun-Qing[1], Sheng Cheng-Wang[1], Liu Gen-Yan[2], Huang Qiu-Tang[1], Han Zhao-Jun[1] and Jia Zhong-Qiang[1], [1]Nanjing Agricultural University, China, [2]Wuhan Institute of Technology, China

Abstract: Insect ?-aminobutyric acid (GABA) receptor (GABAR) is one of the major targets of insecticides. In our study, cDNAs (CsRDL1A and CsRDL2S) encoding the two isoforms of RDL subunits were cloned from the rice stem borer Chilo suppressalis. Transcripts of both genes demonstrated similar expression patterns in different tissues and developmental stages, although CsRDL2S was ~2-fold more abundant than CsRDL1A throughout all development stages. To investigate the function of channels formed by CsRDL subunits, both genes were expressed in Xenopus laevis oocytes singly or in combination in different ratios. Electrophysiological results using a two-electrode voltage clamp (TEVC) demonstrated that GABA activated currents in oocytes injected with both cRNAs. The EC50 value of GABA in activating currents was smaller in oocytes co-injected with CsRDL1A and CsRDL2S than in oocytes injected singly. The IC50 value of the insecticide fluralaner in inhibiting GABA responses was smaller in oocytes co-injected with different cRNAs than in oocytes injected singly. Co-injection also changed the potency of the insecticide dieldrin in oocytes injected singly. These findings suggested that heteromeric GABARs were formed by the co-injections of CsRDL1A and CsRDL2S in oocytes. Although the presence of Ser at the 2'-position in the second transmembrane segment was responsible for the insensitivity of GABARs to dieldrin, this amino acid did not affect the potencies of the insecticides fipronil and fluralaner. These results lead us to hypothesize that C. suppressalis may adapt to insecticide pressure by regulating the expression levels of CsRDL1A and CsRDL2S and the composition of both subunits in GABARs.

In addition, the insect RDL subunit is an attractive target of insecticides and fluralaner is a novel isoxazoline insecticide with a broad insecticidal spectrum that mainly acts on the insect GABA receptor with an unique binding action. However, its molecular interaction with GABA receptor remains unclear. Therefore, we screened 14 potential binding residues (I258T and L275I in the first transmembrane (TM1);V288I, M298N, G303N and A304S in TM2; G319M (G3'M) /S, A327S, G336N, M338I and A339F, in TM3; M473V and I477D in TM4) in CsRDL1 using molecular modeling and verified the binding site with site-directed mutagenesis method and the TEVC technique. Compared to the wild-type (WT)-RDL, the G3'M mutation completely abolished the binding of fluralaner and mostly to avermectin, but not to fipronil on RDL of several insects (Apis mellifera, C. suppressalis, Drosophila melanogaster, Laodelphax striatellus, and Tetranychus urticae) expressed in Xenopus oocytes. Our results contributed to the understanding of the molecular interaction of fluralaner with RDL homomers and may be used to guide future modification of isoxazolines to achieve higher selective control of pests with minimal effects on non-targeted organisms.

Ultrabithorax is a key regulator for the dimorphism of wings, a main cause for the outbreak of planthoppers in rice

Authors: Zhao Muhua[1], Liu Fangzhou[1], Han Kehong[1], Guo Mengjian[1], Li Xiang[1] and Dong Xinxin[1], [1]Hubei Insect Resources Utilization and Sustainable Pest Management Key Laboratory, College of Plant Science and Technology, Huazhong Agricultural University, Wuhan, China

Abstract: Tremendous progress has been made on the understanding of body phan specification by the Homeobox-containing genes (Hox), since the appearance of the four-winged Drosphila Ultrabithorax (Ubx) mutant over forty years ago. In the current model of insect wing develpment, Ubx is expressed in hindwings but not in forewings. Rice planthoppers, the most devastating rice pests, occur in two wing forms: the short-wing form for rapid population growth and long-wing form for long-distance migration, which together devise the mechanism for outbreak. Here we show that Ubx is a key regulator for switching between the long- and short-wing forms of the rice planthoppers. Ubx is expressed in both forewing and hindwing pads, which is different from the canonical model of Ubx expression. In brown planthopper, expression of Ubx (NlUbx) is regulated by nutritional status of the rice host. High-quality young plants induce NlUbx expression leading to the short-wing form; low-quality ripe plants reduce NlUbx expression resulting in long-wing form. We also showed that NlUbx is regulatetd by the insulin receptors NlInRI and NlInR2. The default expression of NlInRI inhibits NlUbx resulting in long-wings, while high-quality host induces NlInR2 expression, which represses NlInRI thus promoting NlUbx expression to produce short-wings. We referred to these as the NlInRI/R2-NlUbx pathway of wing morph regulation in rice brown planthopper. It is likely that this pathway has evolved uriquely in the planthopper lineage, which facilitated the evolution of the wing polymorphism. Our findings raised a major question about the current conceptual models for wing development in insects.

An orphan gene is necessary for male sperm maturation and spem competence in diamondback moth

Authors: Zhao Qian[1], You Minsheng[1], Li Yaqing[1] and Li Yiying[1], [1]Fujian Agriculture and Forest University, China

Abstract: Novel genes, which are also named as orphan genes, are the gene with no homologous genes in other organsims. Here we identified 7 novel genes, which are highly expressed in male adult in diamondback moth. Further analysis showed that these genes were located in the male accessory gland, which suggested their role in male reproduction in diamondback moth. We knock out one gene named Tssor-1 using Crispr/Cas9 to reveal the molecular functions of this gene. The result showed that the mutant strain has less eggs and the hatch rate is significantly low comparing with the wild type. Furthermore, KEGG and GO analysis indicated that this novel gene maybe involved in pathways related with sperm development and maturation. Our sperm competence experiments further validates this result: the competitive of wild type is higher than the mutant type in diamondback. Our results give insights into the evolution and population expansion of diamondback moth.

Study of invading Aedes aegypti of Yunnan Province in China

Authors: Zhao Tong-Yan, State Key Laboratory of Pathogen and Biosecurity, Beijing Institute of Microbiology and Epidemiology, China

Abstract: Aedes aegypti, an important vector species of dengue, zika, distributed in Hainan, Guangdong provinces in China based on mosquito fauna. There was no distribution record of the species in Yunnan until 2002, Ae. aegypti is now continuously found in nine cities and counties in this province. It is important to study population genetics(including of invasion strategies, colonization and dispersal), vector competence to zika, and insecticide resistance, It was found continuous invasion contributes to maintenance of genetic diversity and different invasion accidents result in the genetic difference among populations of Ae. aegypti in Yunnan based on microsatellite DNA analysis, a strain of Ae. aegypti from Yunnan showed high level of midgut infection and highly disseminated infection of salivary glands and ovaries. It was found the evidence of transovarial transmission of the population to zika virus. Three sodium channel mutations were common in the Ae. aegypti strains sampled from Yunnan, the V1016G mutation appeared to be most important kdr mutation.

Heterogeneity of rice stripe virus from the vector insect and host plant

Authors: Zhao Wan, State Key Laboratory of Integrated Management of Pest Insects and Rodents, Institute of Zoology, Chinese Academy of Sciences, China

Abstract: As a persistent, propagative plant virus, rice stripe virus (RSV) is usually transmitted between the vector insect, small brown planthopper and the host rice plant. To adapt to these two different organisms, RSV shows distinct genomic replication or gene expression patterns, different pathogenicities, and different genetic variations under distinct selection pressures in the vector and host, and provoking distinct immune responses among these two organisms. These different survival strategies will enrich our understanding of why viruses leading distinct symptoms when adapt to vectors and hosts.

Global invasions: Dispersion patterns and processes of Bactrocera dorsalis

Authors: Zhao Zhao[1], Li Zhihong[1], [1]China Agricultural University, China

Abstract: Since the start of the 20th century, many invasive alien species (IAS) have spread rapidly around the world, causing serious threats to economies, societies and the environment. Bactrocera dorsalis (Hendel) (Diptera: Tephritidae) is an important quarantine insect pest in many countries that spread around the world over the last century. This review collected information on the global distribution of B. dorsalis to explore the patterns of its invasion expansion. We found B. dorsalis to be distributed in 75 countries (comprised of 124 geographical distribution regions: provinces or states) in Asia, Africa, North America, South America and Oceania up to 2017. Asia and Africa were the most represented regions, accounting for 86.3% of the total number of countries. Also, the South America has a large number of suitable habitats for colonization of the oriental fruit fly. Furthermore, the potential geographical distribution will significantly increase by 15% in 2050 and 20% in 2070, which indicate there is a great invasion pressure to South America. From 1910 to 1990, B. dorsalis was only found in 5 countries, but in the last three decades, it has experienced a sharp increase in its rate of spread, invading 70 more countries. Global temperature anomaly has significantly positive correlation with the spread of B. dorsalis. We proposed a conceptual framework of synergy model of climate change and transportation activities to illustrate invasion expansions of the oriental fruit fly. Also, our findings shed light on the spatial invasion dynamics of alien species, with potential implications for understanding the trajectories of biological invasions under changing future climates and transportation activities. The results of this work provide a theoretical basis for understanding and predicting the continued spread of B. dorsalis under global changes.

The occurrence of Mopane worm (Gonimbrasia belina) in north coastal region of KwaZulu Natal

Authors: Zharare Godfrey [2] and Buthelezi Makhosi[1], [1]Mangosuthu University of Technology, South Africa, [2]University of Zululand, South Africa

Abstract: The Emperor moth Gonimbrasia belina is an economically important insect consumed in central and southern African, where it is harvest from the wild. Generally, G. belina occurs within a tropic ecoregion feeding primarily on mopane trees (Colophospermum mopane). It has not been reported to occur in the sub-tropical region. Here, we report its occurrence in a subtropical region in KwaZulu-Natal province of South Africa. A phylogenetic analysis based on the CO1 gene indicated that the G. belina population in the northern coastal region of KwaZulu-Natal did not differ from that of the Mopane woodlands in the Limpopo province in the northern part of South Africa. This confirmed-that G. belina is indeed present in the northern coastal subtropical region of KwaZulu-Natal, this being so far the southernmost occurrence of G. belina. Sclerocarya birrea is its main host in this region, but was also observed feeding on Mangifera indica,Trema orientalis, Vochellia karoo, Sclerocroton intergerimus and Schotia brachypetala, Burkea Africana and Saba comorensis. This proved that G. belina is a polyphagous insect adapted to a wide range of climatic conditions, and does not seem to have host plant-related barriers than can impede its territorial colonization in southern Africa

The Northern Coastal Region of Kwazulu Natal is Identified as s Suitable Sanctuary Area for the Over Exploited Mopane Worm (Gonimbrasia belina

Authors: Zharare Godfrey [2], Buthelezi Makhosi[1], [1]Mangosuthu University Of Technology, South Africa, [2]University of Zululand, South Africa

Abstract: Gonimbrasia belina is a species of emperor moth whose edible larva is harvested from the wild for food in central and southern African tropical regions. It feeds primarily on Mopane tree (Colophospermum mopane). Hence, it is commercially harvested from Mopnane woodlands. Both over harvesting of its larvae and the destruction of the Mopane woodlands are threatening its biodiversity. This raises the need to create sanctuaries of G. belina that are safe from exploitation. The aim of this study was to evaluate the potential of the northern coastal region of KwaZulu Natal as a sanctuary for G. belina. The presence of G. belina in the subtropical biota along the northern coastal region of KwaZulu Natal was confirmed through Mitochondrion CO1 gene sequences. This being so far its southernmost occurrence. A survey revealed that it occurs over the entire Umkayakhude district, inclusive of the protected Ismamangaliso wetland Park and Hluhluwe game reserve. The survey further revealed there is currently very little utilization of G. belina by the local communities. A study of its biology revealed that its life-cycle is similar to those of G. belina populations elsewhere. It infests its plant hosts from the beginning of September to early November as does the populations in the Mopane woodlands, but differs from them by having one breakout per season instead of two. Marula (Sclerocarya birrea) is its main host, but was also observed feeding on seven other tree species. This proved that G. belina is polyphagous and adapted to a wide range of climatic conditions. Hence, there are no host plant-related barriers that can impede its territorial colonization in southern Africa. There is therefore scope to use northern KwaZulu Natal coastal region as a sanctuary for biodiversity conservation of G. belina. There are initiatives to cultivate Marula in the region for its fruits, which further increases the potential of the area as a sanctuary for G. belina by farming Marula for both its fruit and for G.belina. The protected nature reserves present in the region will ensure areas of non-exploitation by humans. To increase the genetic diversity, and hence biodiversity, of G. belina in the northern coastal region of KwaZulu Natal, it is suggested to import G. belina strains from other regions.

The potential contribution of inbreeding to the invasion success of a haplodiploid mite

Authors: Zhou Peng[1], Wang Qiao[1] and Zhao He Xiong[1], [1]School of Agriculture and Environment, Massey University, New Zealand

Abstract: Reproductive strategy (asexual and sexual reproduction) is associated with species' colonization because it helps to overcome the barrier of mate shortage at the invasion front. Haplodiploid females can reproduce asexually to generate sons and sexually to produce both daughters and sons. Mother-son and brother-sister matings may be common in these animals, which could be important for the colonization success of many haplodiploid species. We studied the mating modes of an invasive haplodiploid spider mite, Tetranychus ludeni, and examined whether inbreeding affected its reproductive fitness. We set up mother-son mating, sibling mating, and outbreeding treatments and recorded the mating success (the proportion of females that produced daughters), female fecundity, and the number of daughters produced for each of 11 generations. Our results show that the mating success of virgin females (around 75%) was similar in the three treatments. Inbred and outbred females produced similar number of eggs and daughters in every generation. We conclude that inbreeding may play an important role in establishment and colonization. In particular, the mother-son mating enables females, regardless of invasion stage, to establish a colony at a new site.

Genomic tales in the Asian honeybee: gene reuse facilitates rapid radiation and independent adaptation to diverse habitats

Authors: Zhou Xin[3], Hu Jiahui[2], Dong Jiangxing[2], Tang Junbo[2], Qiu Lifei[2], Niu Qingsheng[5], H. Parey Sajad[1], Liu Shanlin[4], Luo Shiqi[2], Ji Ting[7], Li Xingan[5], Zhou Xuguo[6] and Ji Yongkun[2], [1]Baba Ghulam Shah Badshah University, India, [2]China Agricultural University, China, [3]China Agricultural University, China, [4]China National GeneBank, BGI-Shenzhen, [5]Jilin Provincial Institute of Apicultural Sciences, China, [6]University of Kentucky, United States, [7]Yangzhou University, China

Abstract: Background:

Understanding how honeybees adapt to diverse habitats during colonization may help to predict their chance of survival under changing environments and habitat loss. We used population genomics to identify genomic features facilitating rapid evolutionary radiation in the Asian honeybee, Apis cerana. We hypothesize that genes associated with adaptation following independent colonization of novel habitats are frequently reused, representing a key adaptive innovation in insects surviving environmental changes.

Results:

By analyzing 362 A. cerana genomes, we showed that multiple peripheral population groups radiated from the same central ancestry and adapted independently to diverse habitats. We identified dozens of genes under repeated selection across multiple peripheral groups with one gene, the Leucokinin receptor (Lkr), under selection in almost all peripheral groups. Suppression of Lkr by in vivo RNAi led to significant reduction in sucrose responsiveness, which could predetermine foraging task division. Furthermore, Lkr expression was elevated in foragers when compared to nurse bees and differed significantly between pollen and nectar foragers, indicating that both collective colony strategy and individual foraging decisions could be tailored through Lkr regulation. Selection peaks were exclusively found in Lkr intron-1, some of which overlapped with antisense lncRNAs, possibly regulating Lkr.

Conclusions:

Gene reuse is frequently employed by A. cerana colonizing populations to cope with diverse habitats, where genes associated with foraging play a critical role in response to dietary shifts. Our study suggests that gene reuse functions not only in parallel adaptation to similar environments, but also in exploring different habitats with high dietary diversity.

GPCRs- new targets for managing gypsy moth

Authors: Zhu Fang[1], Moural Timothy[1], [1]Pennsylvania State University, United States

Abstract: G-protein-coupled receptors (GPCRs) comprise one of the largest and most diverse family of membrane proteins, which transduce extracellular signals into cellular responses to hormones, neurotransmitters, and environmental stimulants. The ligands of GPCRs are extremely diverse, including chromophores, neuropeptides and hormones, acetylcholine, biogenic amines, nucleotides and nucleosides, lipids and eicosanoids, olfactory and taste substances, and so on. The ligand binding triggers GPCRs conformational changes, activing complex cytosolic signalling networks and causing the intracellular responses. Therefore, GPCRs play various important roles and draw the most attention for drug discovery. However, there is very few insecticides that target on GPCRs except the octopamine receptor agonists. Here, we identified and characterized physiological functions of two GPCRs from the transcriptome of gypsy moth. Specifically, with functional genomics and reverse genetic approaches, we investigated the potential roles of these GPCRs in regulation of xenobiotic detoxification.

Characterization of a serine protease inhibitor in Leptinotarsa decemlineata

Authors: Zhu Fang[1], Moural Timothy[1], [1]Pennsylvania State University, United States

Abstract: The Colorado potato beetle, Leptinotarsa decemlineata is a notorious agriculture pest feeding on plants of the Solanaceae family including potato, tomato, and eggplant. Rapid evolving resistance to pesticides has contributed to its success in establishing populations across North America, Europe, and parts of Asia. Many studies have been performed to reveal molecular mechanisms contributing to insecticide resistance; however, other mechanisms related to basic biological processes have yet to be understood completely. In this study, a novel serine protease inhibitor (serpin) gene was selected from the transcriptome of L. decemlineata with bioinformatics and functional genomics tools. Feeding RNA interference (RNAi) of our target genes showed systemic knockdown of this specific serpin and caused feeding inhibition in both larva and adult stages. We performed quantitative real-time PCR (qRT-PCR) to investigate the expression patterns of this gene in all developmental stages and multiple tissues. To investigate the function and structure of this serpin gene, recombinant protein was expressed in a genetically modified Escherichia coli strain and the three-dimensional structure of this protein has been uncovered. Potential roles of this novel protein and the significance of our study will be discussed.

Improved matting success in Hermetia illucens enabled by adults visual system

Authors: Zhu Fen[1], Wang Wanqiang[1], Liu Wen[1], Wang Xiao-Ping[1], Liu Xinhui[1] and Gao Zhenghui[1], [1]Huazhong Agricultural University, China

Abstract: When a substance reflects a light at a particular color, it often absorbs the light of its complementary colors. In Hermetia illucens, the relative reflectance of the dorsal side was the same in the head between the female and the male. The dorsal side of the male thorax had higher relative reflectance than that of the female. The abdomen of both sexes showed similar absorbed and reflected spectral signature. The ventral abdomen of the female thorax had higher relative reflectance than that of the male. The wings of the male had higher relative reflectance than that of the female. Females laid eggs under the light source at the wavelength of 375 nm, 420 nm, 465 nm, 505 nm, or 600 nm. We made a light with special wavelength. The light can help to improve the reproduction of H. illucens. Under this light, normal adults presented a high oviposit rate, which was about 90%. Adults with coated compound eyes showed a very low oviposit rate, which was less than 35%. In conclusions, visual system is very important for reproduction of H. illucens. The invented light can be used in mass production of H. illucens.

New repellent and deterrent for drosophilid and tephritid fruit flies

Authors: Zhu Junwei[3], Cha Dong[2], Loeb Gregory[1] and Roh Gwang-Hyun[2], [1]Cornell University Geneva, New York 14456, United States, [2]USDA-ARS Hilo, Hawaii, United States, [3]USDA-ARS Lincoln, Nebraska, United States

Abstract: Drosophilid and tephritid fruit flies are among the world's most destructive invasive pests. Frequent use of insecticides is generally necessary for effectively managing these flies. However, reliance on pesticides is costly and risky in terms of resistance development. To develop alternative control methods, we have been particularly interested in identifying chemicals that can repel flies from or deter oviposition on fruit. In this talk, we will report on experimental results from laboratory and field documenting significant reductions in infestation by spotted wing drosophila (Drosophila suzukii) and oriental fruit fly (Bactrocera dorsalis) in response to repellent and oviposition deterrent isolated and identified from microbial and plant sources. We will also discuss evolutionary context of fly avoidance on some of these chemicals.

Hypoxic Environment Protects Insects from Electron Beam Irradiation

Authors: Zhu-Salzman Keyan, Department of Entomology Texas A&M University, United States

Abstract: Ionizing irradiation, such as electron beam (eBeam), breaks nucleic acid strands by transferring energy directly to the molecules. Additionally, irradiation induces production of reactive oxygen species (ROS) that damages cellular structures, impairing multiple cellular pathways and processes. As a disinfesting technology to control storage pests, ionizing irradiation has expanded rapidly in recent years due to its detrimental effect on insects at all developmental stages. Modified atmospheres control storage pests by manipulating gas compositions in storage facilities. In a low O2 (hypoxia) environment, insects reduce their metabolic activities, and even cease to develop. Both eBeam irradiation and hermetic storage are safe and effective technologies to protect stored products. Although hypoxic environment improves performance of some irradiated insects, whether hypoxia affects irradiation of storage insects and impacts pest control efficacy remains to be investigated.

Using cowpea bruchid (Callosobruchus maculatus) larvae, we showed that, relative to eBeam irradiation under normoxia, the adult emergence rate increased substantially if they were exposed to hypoxia prior to and during eBeam treatment. Conversely, exposure to hypoxia only after eBeam irradiation did not have this protective effect. eBeam irradiation caused an increase in reactive oxygen species (ROS) in normoxic larvae but not in hypoxic larvae. The activity of citrate synthase, a pace-making enzyme in the citric acid cycle, was suppressed under hypoxia but resumed normal function within hours of reoxygenation, suggesting that reduced mitochondrial activity and thus less ROS production under hypoxia increased insect tolerance to irradiation. Furthermore, reoxygenation accelerated eBeam-induced glutathione S-transferase activation and potentiated eBeam-enhanced catalase activities. Faster and stronger detoxification capacity in eBeam-irradiated, hypoxic larvae may have protected them from oxidative damage. Taken together, hypoxic environment enhanced radiotolerance of bruchid larvae, presumably due to limited ROS production and elevated antioxidant enzymatic activities after reoxygenation. Therefore, as an important postharvest technology to protect stored grains, environmental factors must be taken into consideration when establishing irradiation doses. Information from this research is also useful in adopting irradiation technology in insect management in packaging, storing and shipping of commercial products, and in addressing concerns in international trade of agricultural products.

Phylogenetic relationships within the Cotesia ”tibialis” group and detection of potential new species (Hymenoptera: Braconidae: Microgastrinae)

Authors: Žikic Vladimir[1], Marczak Dawid[2], van Achterberg Kees[4], Lazarevic Maja[1], Mitrovic Milana[3], Stankovic Saša[1], [1]Faculty of Sciences and Mathematics, Department of Biology and Ecology, University of Niš, Serbia, [2]Faculty of Engineering and Management, University of Ecology and Management in Warsaw, Poland, [3]Institute for Plant Protection and Environment, Belgrade, Serbia, [4]Naturalis Biodiversity Center, Leiden, Netherlands

Abstract: The genus Cotesia includes koinobiont endoparasitoids of lepidopteran larvae. Most species are gregarious; the females superparasitize young caterpillars, usually first and the second instar, while parasitoid larvae emerge from mature ones. Upon the emergence Cotesia larvae spin their cocoons around or near the host, often connecting them into a unique ball-shaped mass cocoon. The way of cocoon spinning, its structure, colour and place of spinning relative to the host are, in addition to morphological differences between the specimens, also reliable characters for distinguishing species. In this study we selected a group of Cotesia species that form gregarious ball mass cocoons. Our goal was to analyse all specimens from this type of cocoons and to relate the results of their morphology, primarily the shape the forewings and the results of molecular analysis, thus revealing phylogenetic relationships of the studied taxa.

We compared several morphological characters of both males and females, while for the DNA analysis we used the barcoding gene COI. The sample analysed contained about 1000 individuals from seven countries. Six different taxa with European distribution are discovered within the tibialis group: Cotesia berberis (Nixon, 1974) – off-white ball cocoon; C. tibialis (Curtis, 1830) – cream ball cocoon; C. cf. tibialis – smoke white ball cocoon; C. ofella (Nixon, 1974) – yellowish ball cocoon; C. vanessae (Reinchard, 1980); – white ball cocoon and potentially new species, Cotesia sp. nov. – ivory elongated cocoon. Despite the extraction of the DNA from C. berberis, the sequencing failed, probably due to the oldness of the material. This species has been studied using only the cocoon structure and adult morphology. Cotesia berberis is very close to C. tibialis.

Presenting the results of geometric morphometrics of female forewings via CVA scatterplot, it is clearly visible that five distinct taxa occurred in the analysed sample. The CV1 strongly separates C. tibialis and C. cf. tibialis placed in the negative part of the CV1 while the rest of the taxa are placed in the positive part. Based on the general morphology of the wings, in the morphospace defined by the CV1 and the CV2, C. vanessae showed significantly different wing shape from the others, moving it away from the whole group.

According to molecular analysis C. vanessae is also positioned the farthest from the other species. Its genetic distance in relation to C. tibialis and C. cf. tibialis is 7.2% and 8% respectively, and it differs 8.5% from C. ofella. The genetic distance between C. vanessae and Cotesia sp. nov. is 7%. In the same time, Cotesia sp. nov. is genetically distant 2.5% form C. tibialis, 3.4% from C. cf. tibialis and 3.8% from C. ofella.

Investigating insecticide resistance in UK populations of cabbage stem flea beetle Psylliodes Chrysocephala

Authors: Zimmer Christoph[4], Willis Caitlin[1], Davies Emyr[2], Williamson Martin[2], Foster Stephen[2] and Chang Xianmin[3], [1]Rothamsted Research Royal Agricultural University, United Kingdom, [2]Rothamsted Research, United Kingdom, [3]Royal Agricultural University, United Kingdom, [4]Syngenta, United Kingdom

Abstract: The cabbage stem flea beetle (CSFB) Psylliodes chrysocephala, is a major pest of winter oilseed rape (OSR) in the UK and Northern countries in mainland Europe including Germany, attacking emerging plants in the autumn and causing severe damage to the crop if left unchallenged. Prior to December 2013, control of CSFB relied on the protection of OSR seedlings by neonicotinoid seed treatments in conjunction with subsequent application of foliar pyrethroids sprays. However, the EU-imposed restriction on the use of neonicotinoids has left growers with just pyrethroids for CSFB control. The increased selection pressure, caused by a lack of alternative control agents with different modes of action, has led to the emergence of pyrethroid resistance in this pest. As CSFB resistance to pyrethroids can cause significant yield losses in OSR crops, and the continued use of these pesticides in their current format will only exacerbate this problem, there is a need to understand the mechanisms by which resistance has developed and is sustained within CSFB populations. Despite the presence of the target-site mutation kdr in UK populations, resistance does not completely correlate with kdr genotype, suggesting another mechanism of resistance is also present. The current study reports the extent and geographical spread of pyrethroid resistance in UK CSFB populations, the contribution of kdr (L1014F) and super-kdr (L925I) to this resistance phenotype and our efforts to identify the enzyme(s) involved in conferring the additional metabolic resistance component using next generation transcriptomic approaches.

Multiple functions of ETH receptor networks in the silkmoth Bombyx mori

Authors: Žitňan Dušan[2], Daubnerová Ivana[1] and Roller Ladislav[1], [1]Institute of Zoology, SAV, Bratislava, Slovakia, [2]Slovakia

Abstract: Ecdysis triggering hormones (ETHs) from endocrine Inka cells act on target central neurons expressing two splice variants of ETH receptors (ETHR-A or ETHR-B) to activate the ecdysis sequence in insects. We detected expression of multiple excitatory and inhibitory neuropeptides in these receptor neurons using in situ hybridization and immunohistochemistry. Following activation of these neurons by ETHs, centrally released neuropeptides control the entire cascade of pre-ecdysis and ecdysis motor programs. Transgenic approaches using piggyBac vectors and electrophysiology techniques revealed specific roles of different neurons and neuropeptides during these processes. Careful examination of ETHR expression using in situ hybridization and qRT-PCR revealed expression of these receptors in specific cells of the corpora allata (CA), H-organ and Malpighian tubules (MT) prior to each ecdysis. In vivo and in vitro experiments indicate that ETHs are multifunctional hormones that act via ETHR-A/B to control various functions during the entire development; the ecdysis sequence and hindgut contractions by peptidergic neurons in the CNS, production of biogenic amines by H-organ, juvenile hormone production by the CA and water/ion balance by Malpighian tubules.

DNA metabarcoding in large scale insect diversity assessment

Authors: Zizka Vera[1], Schäffler Livia[1], Bourlat Sarah[1], Noll Niklas [1] and Kirse Ameli[1], [1]Leibnitz Institute for the Analysis of Biodiversity Change

Abstract: DNA metabarcoding is a promising tool for biodiversity monitoring, enabling the fast and high-resolution identification of insect communities from bulk samples. The method is based on the DNA extraction and simultaneous barcode amplification from samples containing a mixture of taxa and potentially also enables the analysis of intraspecific genetic diversity. This fast and cost-efficient approach enables taxonomic assignment of species hard to identify morphologically if those are listed in reference databases. To make metabarcoding applicable for upscaled biodiversity assessments, some challenges remain, which are tackled by testing and improving the laboratory and bioinformatic workflows. While comprehensive, high-resolution taxon lists can be achieved through DNA metabarcoding, there are still systematic biases within the workflow (e.g. taxonomic differences in primer efficiency, underrepresentation of small and rare taxa) while other issues arise when processing large numbers of samples for biodiversity monitoring (e.g. standardization of high-throughput protocols, lab and storage capacities). We have optimized critical steps in the molecular analysis within our projects (e.g. increased detection of low-biomass taxa) and continue to enhance the reliability of taxon identification from insect bulk samples and to improve the standardization of DNA metabarcoding methods for large-scale biodiversity monitoring.

Estimating species-abundance change with genomic tools

Authors: Zizka Vera, Leibniz Institute for the Analysis of Biodiversity Change, Germany

Abstract: The key dimensions of ecological community structure are species composition and species abundances. Metabarcoding of mixed-species arthropod samples can provide reliable presence-absence information (composition), but abundance information is obscured by a combination of species-specific biases in DNA extraction and PCR and of stochasticity in data-file sizes after library prep, sequencing, and bioinformatic processing. I review recent advances in using genomic tools to extract abundance information. DNA-standard spike-ins recover within-species abundance changes across samples. Creating sample dilution series additionally allows recovery of across-species abundance differences within samples. In short, it is now possible to recover both composition and abundance information from mixed-species arthropod samples. Spike-ins and dilution series can be used in both metabarcoding and mitogenomic approaches. Finally, I describe a method that makes it possible carry out metabarcoding without PCR: the targeted assembly of barcode genes from shotgun-sequence datasets, using the software Kelpie, followed by read mapping to the extracted barcodes.

120 years of change in Arctic plant-pollinator interaction networks

Authors: Zoller Leana[2], Bennett Joanne[1] and Knight Tiffany, [1]German Centre for Integrative Biodiversity Research (iDiv), Germany, [2]Martin Luther University Halle-Wittenberg, Germany

Abstract: The majority of the world´s plants rely on animal pollinators for reproduction, making pollination a key ecosystem service for the maintenance of natural and cultivated plant communities. However, pollinators are experiencing a severe global decline. Amongst other anthropogenic drivers, climate change is considered responsible for this decline. In arctic and mountainous regions, climate change is projected to be especially pronounced. Understanding the impact of climate change on ecosystems is challenging, since the effects may take decades to transpire. We aim to overcome that challenge by using a historical dataset collected by F. Silén in the summers of 1895-1900. Silén recorded flower visitors of 87 different plant species in the surroundings of Kittilä, Finland, providing us with a valuable insight on plant-pollinator interactions from over a century ago. For our project, we resampled plant-pollinator interaction networks in Kittilä and compared them with the historical data in order to explore the changes that occurred during the last century in plant-pollinator networks at high northern latitudes.

Vector Control Product Development in the US Department of Defense

Authors: Zollner Gabriela[1], Lindroth Erica[1], [1]Armed Forces Pest Management Board, United States

Abstract: The US Department of Defense (DoD) supports the research, development, testing, and evaluation of arthropod vector surveillance and control products to protect military personnel from vector-borne diseases. Diseases can significantly impact military readiness, and many vector-borne diseases have no vaccine or therapeutic treatment available. Therefore, the DoD uses vector control and bite protection technologies to prevent disease transmission. DoD laboratories around the world engage in research activities to develop new therapeutics, novel personal protective measures, and improved vector control tools. Several funding programs support product development from basic research through commercialization. The DoD frequently collaborates with other US Federal agencies, academic, and commercial partners to develop products that are useful both for military and civilian markets. This presentation will provide an overview of DoD research programs and priorities for vector control product development.

Identification and field verification of aggregation-sex pheromone from the predaceous bug, Arma chinensis, a natural enemy of the invasive fall armyworm Spodoptera frugiperda

Authors: Zou Deyu[2], Xu Jingyang[2], Chen Hongyin[5], Wu Huihui[1], R. Aldrich Jeffrey[4], Zhang Lisheng[6], A. Coudron Thomas[3] and Xu Weihong[2], [1]Agricultural Analysis and Test Center, Tianjin Agricultural University, China, [2]Biological Control of Insects Research Laboratory, Tianjin Institute of Plant Protection, Tianjin Academy of Agricultural Sciences, China, [3]Biological Control of Insects Research Laboratory, USDA-Agricultural Research Service, United States, [4]Department of Entomology and Nematology, University of California, Davis, United States, [5]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: Arma chinensis (Hemiptera: Pentatomidae) is a predaceous insect species that is native to China, Korean peninsula, and Mongolia. A. chinensis has received attention because of its ability to effectively suppress a wide range of agricultural and forest insect pests in the orders Lepidoptera, Coleoptera, Hymenoptera and Hemiptera. Both nymphs and adults of A. chinensis attack their insect prey, even when the prey are larger in size, and suck the body fluids from their prey with their proboscis. The fall armyworm Spodoptera frugiperda (Lepidoptera: Noctuidae) has currently become a new invasive species in China and recent outbreaks of this hungry caterpillar in Africa and southern Asia have resulted in maize yield losses as high as 50%. Preliminary tests indicate A. chinensis is able to control this voracious caterpillar in laboratory.

The pheromones are of two types: female produced sex pheromones which attract only males, and male-produced aggregation pheromones which typically attract both sexes. The latter type of pheromone has more recently been referred to as an aggregation-sex pheromone because its primary function is probably to bring the sexes together for mating. Adult A. chinensis males produce an aggregation-sex pheromone from dorsal abdominal glands and artificial aggregation-sex pheromone can attract adults of both sexes. The aggregation-sex pheromone consists of (E)-2-hexenal, (E)-2-hexen-1-ol, benzaldehyde and benzyl alcohol. Both antennae and proboscises of A. chinensis females and males responded to components from male dorsal abdominal gland extracts. (E)-2-hexenal and benzaldehyde elicited significantly higher EAG responses than those with (E)-2-hexen-1-ol and benzyl alcohol. Benzyl alcohol elicited the weakest EAG responses although benzyl alcohol was the most abundant of the four major components in male dorsal abdominal gland extracts. A field bioassay using trap catches demonstrated that (E)-2-hexenal and benzyl alcohol were key components of the pheromone for catching conspecific adults. Single pheromone components were the least attractive to A. chinensis in the field.

The successful application of augmentative biological control wherein natural enemies are released to control target pests requires colonization of the beneficial species. However, as we observed in field and forest land, many A. chinensis adults reared in laboratory disperse from release sites in a few days even though many prey were still present at the release site. Developing the aggregation-sex pheromone baits of A. chinensis to enhance the colonization of A. chinensis and the biological control of S. frugiperda seems to be a promising method in the future.

The amazing Maindronia species (Insecta: Zygentoma) and their evolution at the dry limit of the Atacama Desert

Authors: Zuniga Alvaro[1], Predel Reinhard[1], [1]University of Cologne, Institute for Zoology, Germany

Abstract: The silverfish family Maindroniidae (Insecta: Zygentoma) consists of three described species from desert biomes in Sudan, the Arabian Peninsula and Chile. This distribution is remarkable for closely related arthropods, suggesting a Gondwanan relict group. Extensive collecting efforts in Chile show a surprisingly widespread distribution in the Atacama. These insects were even found in hyperarid areas where no other metazoans could be observed. Maindronia can thus be considered as the most adapted desert animal in the Atacama, which in turn is one of the driest deserts in the world. The common habitat preference in the Chilean Atacama, and evidently also in Sudan, suggests that hyperarid environments have always been present, at least locally, in South America over the past 120 million years. Likely, Chilean Maindronia have evolved with and within the Atacama Desert. This scenario clearly differs from that shown for other animals or plants that have more recently migrated into suitable environments in the Atacama. Phylogenetic analyses show the presence of at least five clades derived from a single ancestor and diverging in the last 15 million years. The divergence times of the clades can be attributed to palaeoclimatic changes; mostly periods of extreme hyperaridity.

A comprehensive phylogeny of the species-rich Australian leafroller moths (Lepidoptera: Tortricidae) – the power of combining collection genomics and transcriptomics

Authors: Zwick Andreas[2], Sinclair Bronte[1], Hartley Diana[1], Nicholls James[1], Horak Marianne[1] and Bent Stephen[3], [1]Australian National Insect Collection, CSIRO, Australia, [2]Commonwealth Scientific and Industrial Research Organisation, Australia, [3]DATA61, CSIRO, Australia

Abstract: The Tortricidae are a species-rich family of moths with about 11,000 named species worldwide, and 1,200 named and unnamed species recognised in Australia. The group includes numerous economically important pest species (e.g., light brown apple moth, Epiphyas postvittana, and codling moth, Cydia pomonella), but relationships between these and between tribal groups are poorly understood. We present a phylogeny of all Australian tortricid species, robustly resolving tortricid relationships from the placement of the family to within species complexes. We demonstrate that the small subfamily Chlidanotinae is polyphyletic and that some Australian genera represent a further new subfamily that is sister to the diverse Tortricinae + Olethreutinae. With all but two recognised tribes occurring in Australia, our phylogeny also provides a well supported new working hypothesis for tribal relationships worldwide. Comprehensive taxon sampling and robust resolution across the entire depth of the phylogeny are achieved by combining collection genomics with transcriptomics. We developed a novel platform technology for low-cost, high-throughput collection genomics and used it to sequence old specimens of all identified named and unnamed tortricid species in the Australian National Insect Collection. To resolve deeper divergences we added transcriptomes for about 80 genera from freshly collected specimens. This approach offers a systematic and efficient way to revise the classification of the species-rich Tortricidae, and the model could be applied to many other mega-diverse groups of arthropods.

Effect of plant chemical variation and mutualistic ants on aphid herbivore populations

Authors: Zytynska Sharon, University of Liverpool, United Kingdom

Abstract: Plant within-species variation can alter direct and indirect interactions among species. In particular, host-plant genetic or chemical variation within a population creates a spatially heterogeneous habitat for specialized herbivores which can drive changes in the associated ecological community. Using a natural tansy plant (Tanacetum vulgare) population we showed that variation in plant volatiles, emitted from specialized storage structures on the plant surface, drive host selection of aphids (Metopeurum fuscoviride) in the early season when winged morphs have free choice among plants. Later in the season non-volatile metabolites in the plant were crucial for host selection by unwinged aphids. Host-choice by aphids was also driven by aphid genotype, with significant associations between plant chemotypes and aphid genotypes leading to non-random distribution of aphid genotypes across the plants in the field site. Furthermore, these associations were strengthened by interactions with ant mutualists, and had a cascading effect on aphid parasitic wasps. The approach used for plant chemical analysis allowed for the separation of the effects of volatile and non-volatile plant chemicals on the interacting species over the whole growing season. Follow-on empirical experiments were able to validate the field data to disentangle effects on aphid population growth, ant attendance of aphids, predation and parasitism across cloned plant chemotypes. Our work demonstrates how plant within-species chemical variation can structure the interacting community through direct and indirect multi-species interactions.
