Entomology for our planet

XXVI International
Congress of Entomology

HELSINKI, FINLAND, JULY 17–22, 2022

TABLE OF CONTENTS

THE IMPORTANCE OF ICE CONGRESSES

and the benefits that result from knowledge sharing

Welcome to the XXVI International Congress of Entomology ICE2022 in Helsinki. This congress is one in a series of over 100 years of ICE congresses. This history is reflected on the cover page of the program book. The impact of ICE congresses on the field of entomology for over a century is a strong motivation to be part of this great legacy. I am happy and proud to host you at the ICE2022Helsinki.

In the context of our contemporary world, in person meetings at congresses have become less frequent - and therefore immensely valuable. Personal meetings at congresses enhance, stimulate and create knowledge, innovation, and collaboration, which is vital to the success of our discipline. Congresses give opportunity for the further creation of knowledge and the application of that knowledge. These opportunities arise from different sources and come in many forms. They may be industrial innovations, or new scientific collaborations, new professional friendships, or perhaps the emergence of new clusters of expertise, centres of excellence, and collaboration. All of these are outcomes of successful congresses.

For organising a congress, one needs multiple skills. The congress host works with those colleagues who are willing, and in a position to influence the congress direction. To enable this, we have relied on scientists, academic leaders, political and social leaders, business leaders, as well as the trained professional staff of our congress venue and the PCOs. Organizing a congress requires a long-term commitment by the organising committee to the established program. This is no minor issue, given the long period between bidding for and, if successful, running the event. In the case of ICE2022 with two years of postponement due to restrictions caused by the covid19 pandemic, this period lasted for over seven years. The organizers need a core-group of hundreds of people distributed globally, with a long-term commitment to the ICE congresses. The colleagues all around the world helped the core organizing team in Helsinki to align our objectives with those of the key stakeholders in the area of entomology. For these reasons my sincere thanks and gratitude go out to all our section organisers, symposium organisers, sponsors, exhibitors, volunteers, and congress participants, as well as to the staff of our PCOs, the City of Helsinki, and the staff of the congress venue Messukeskus and the Finlandia Hall. In terms of practical support to the ICE2022 congress the most significant was provided by the Helsinki Region Transit Authority and the City of Helsinki Mayor`s office. All congress participants receive the ticket for public transportation system in and around Helsinki for the time of the congress. Many thanks to the HSL-HRT for giving us this environmental touch. Many thanks to the City of Helsinki Mayor for hosting the reception for our delegates.

For ICE2022Helsinki, universities and other educational institutions along with research institutes are the dynamic key elements of this event. They offered standing expertise and knowledge, but they also open paths of knowledge to be followed. These new knowledge designs attract interest in our discipline and facilitate cooperation.

Since the beginning of 2020 there have been serious public health issues around the globe, which have shown us how vulnerable we are as human beings and as societies. Measures enforced in the interest of public health have left their marks on ICE2022 Helsinki. Despite these events we carried on the planning of the congress while trying to avoid over-reactions; over-reactions can lead to wrong decisions. The fact that you now read my address in the program booklet means that we have successfully overcome these two years of restrictions on meetings and travels, thanks to the support of many groups and individuals.

My sincere thanks go to the support groups that we had nationally and internationally to make this congress happen. My personal thanks go in particular to the University of Eastern Finland, Department of Environmental and Biological Sciences, which allowed me to continue to work academically. I also want to thank the Southwest University, Chongqing, China, which adopted me during the last years as one of their staff members and gave me the opportunity to continue educating the next generations of entomologists.

The congress organising team has attended international meetings and events in entomology during the past six years. This has been rewarding, but also necessary for disseminating knowledge about the ICE2022Helsinki congress. Besides the members of the organizing committee, numerous colleagues have spread our promotional material at probably hundreds of meetings around the world.

Our sincere thanks go to the numerous sponsors, who have made this congress possible, in particular the sponsors of individual symposia. Our sponsors range from the City of Helsinki and the Helsinki Region Transit Authority to influential international organisations, companies, and professional associations. Last, but not least, my sincere thanks go to all our exhibitors, who travelled to Helsinki to meet the congress participants.

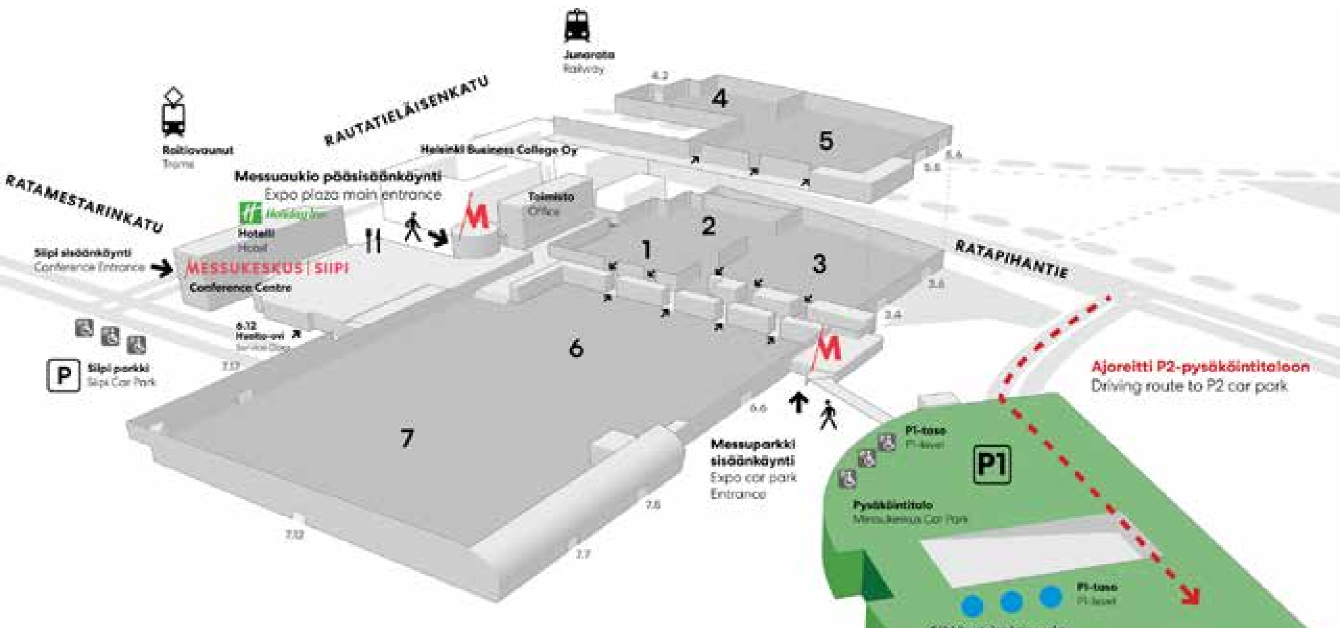
Let me close off by stating that we need nature and insects for our existence: to support our lives and our lifestyle. Insects are one of the most speciose taxa on our planet. They sustain life on Earth and fulfil many critical ecosystem functions, from pollination and biocontrol to being human food. This is the reason for us to choose as the core message on the ICE2022Helsinki congress “bear-mat”: “Insects feed the belly of nature”. This “bear-mat” every participant will find in their congress package.

Thank you all for being here, and for making ICE2022Helsinki happen. We hope the congress will contribute to a sustainable co-existence of humans and insects.

Heikki Hokkanen
President of the ICE2022Helsinki Organizing Committee

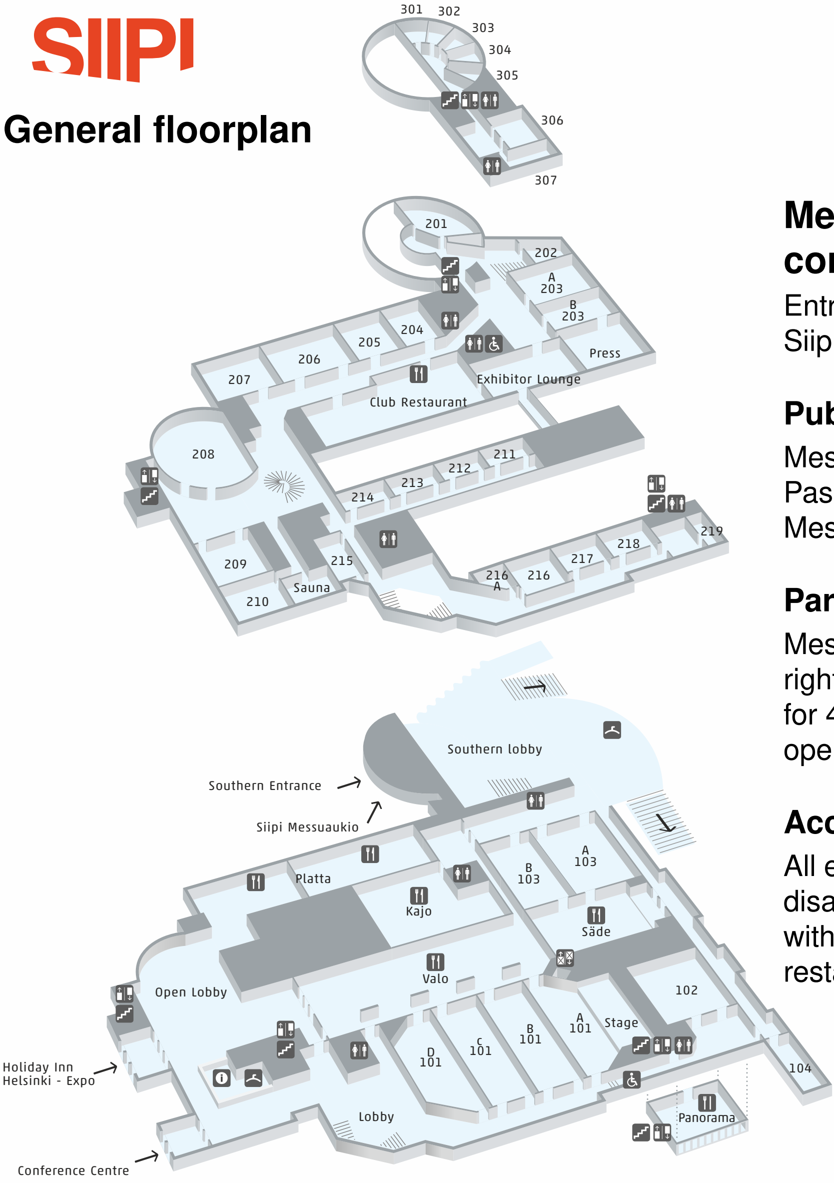
MAPS AND FLOOR PLANS

Messukeskus Siipi Entraces



SIIPI

General floorplan



Messukeskus Siipi conference centre

Entrance | Rautatieläisenkatu 3
Siipi Car Park | Ratamestarinkatu 13

Public transportation

Messukeskus is situated right next to Pasila train station. You can also reach Messukeskus easily by bus or tram.

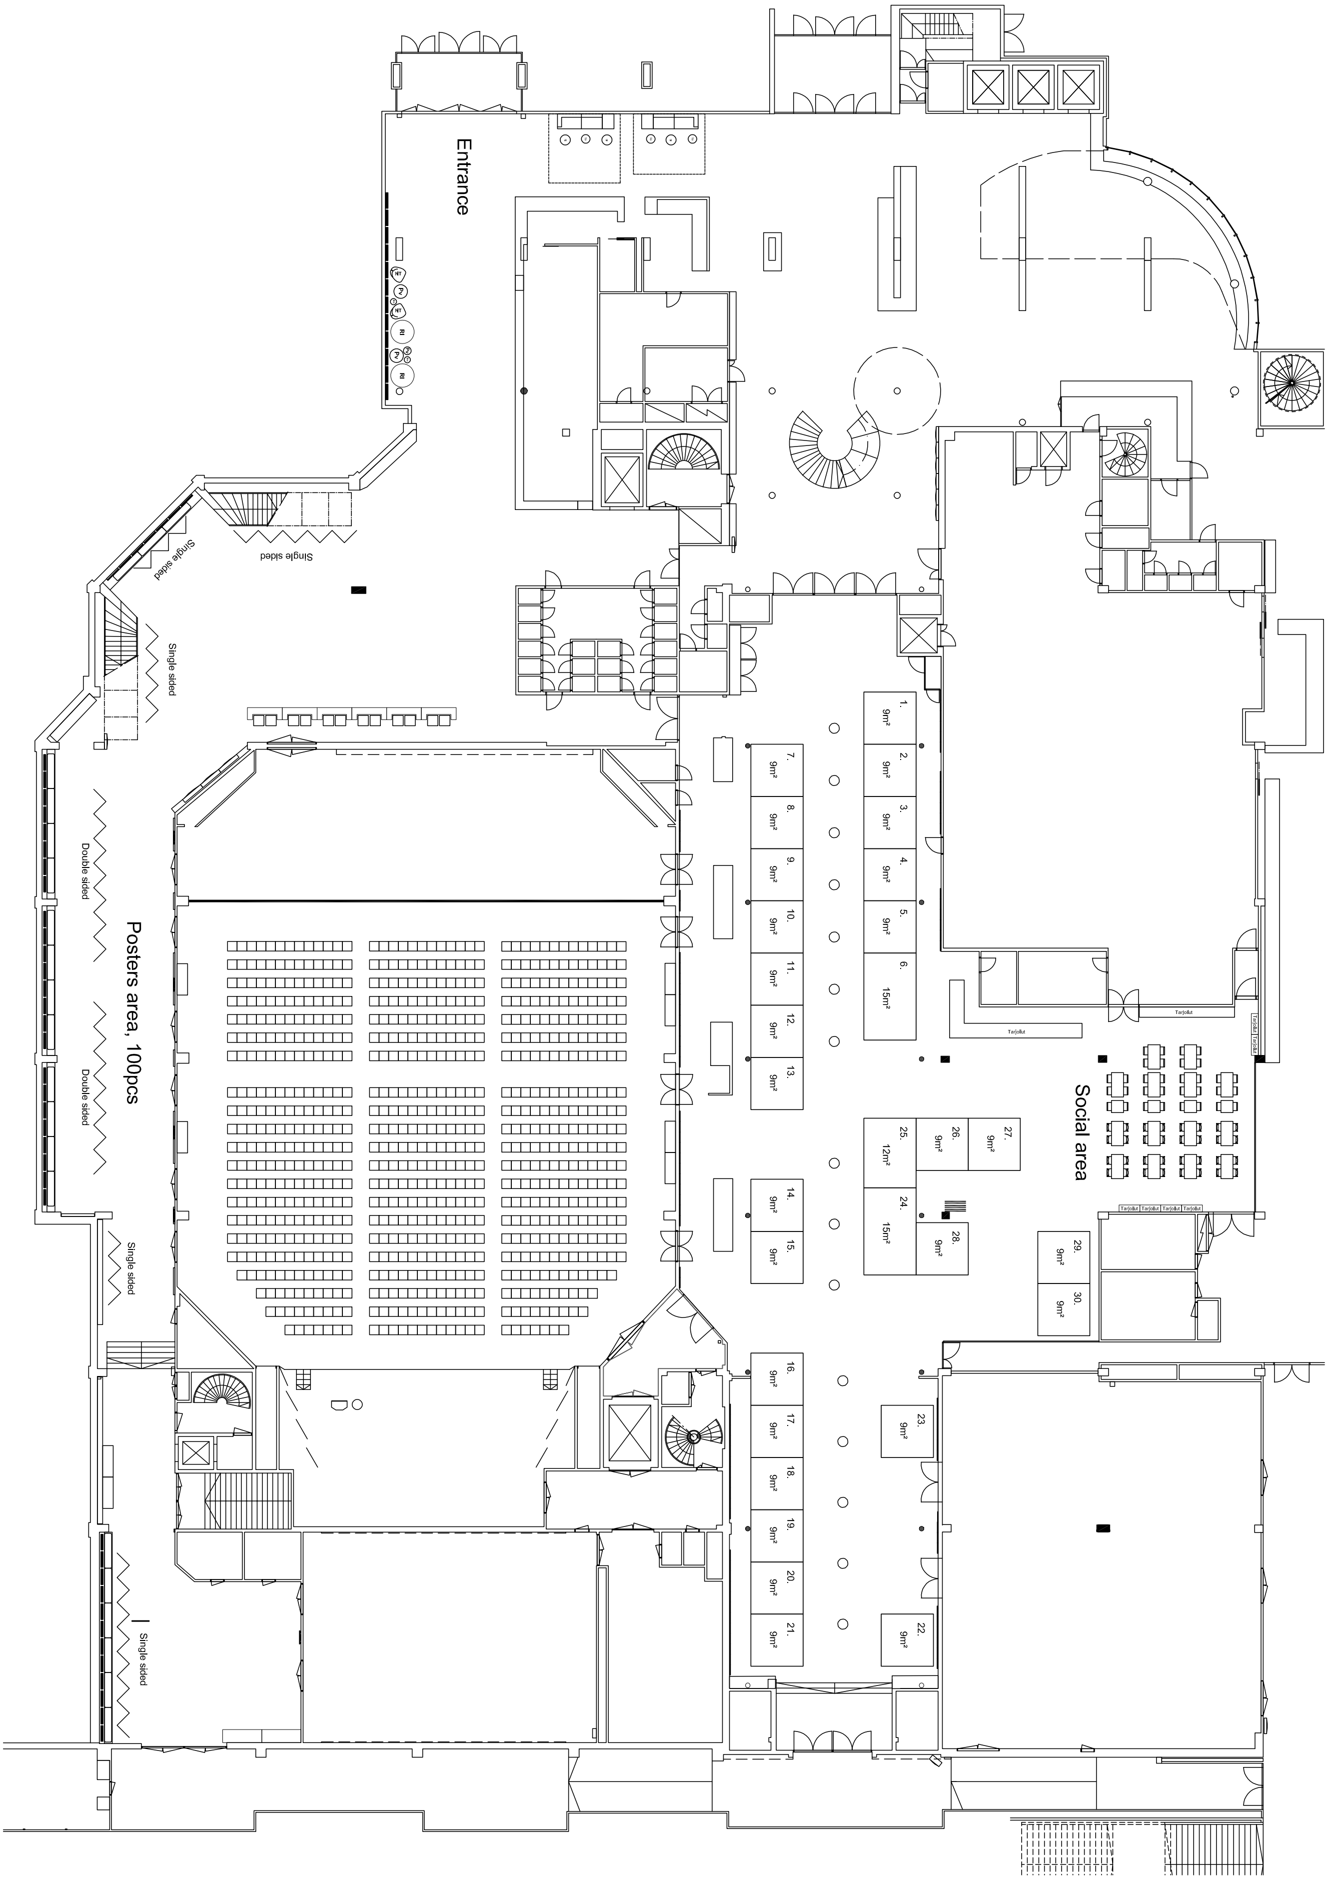
Parking

Messukeskus parking facilities are situated right next to Messukeskus and have room for 4 600 vehicles. Parking facilities are open 24/7.

Accessibility

All entrances are accessible for people with disabillities and all floors can be accessed with elevator. The majority of Messukeskus restaurants are also accessible.

1st floor exhibition stands and facilities



Congress Theme

ENTOMOLOGY FOR OUR PLANET

Insects are in many respects the backbone for Life on our Planet, being the major engineers of ecosystems and dominating organisms of the Animal Kingdom. “To a first approximation, every animal is an insect” (J. Kukalová-Peck). The biomass of insects ranges from over 2000 kg/ha in the tropics to around 1000 kg/ha in the temperate zone, while the biomass of human beings averages at only 7 kg/ha. The Theme for the ICE 2022 is “Entomology for our Planet”, in order to highlight the crucial role of insects in maintaining and shaping our lives, and overall, life on Earth. Specific emphasis includes topics such as:

Entomology for a hungry planet

Insects and mites are main competitors for humans for food, feed and fiber, requiring understanding of their properties for successful management. Progress in entomology is essential to coping with the ever-evolving race with insect pests. Insects and mites are also part of any solution to successful pest management, as more than half of all known insects are natural enemies of herbivorous insects. As the growing human population on our planet is seeking for alternative sources of animal protein to satisfy the world hunger, increasing attention is paid to the possibility to use insects as a major source of proteins for food as well as for feed.

Entomology for a diverse planet

Global biodiversity is the ecological base for sustainability of the world’s ecosystems and the ecosystem services they produce for humans, but also the resource base for and driver of bioeconomy and businesses arising from innovative uses of biomaterials, many of which originate from arthropods. Insects pay a key role in global biodiversity, as over ¾ of all known animal species are insects, and they outnumber known vascular plant species by 1-2 orders of magnitude. Furthermore, it is believed that the vast majority of all insect species have not been described yet (are unknown), and that most species will go extinct before they have been discovered.

Entomology for a healthy planet

There is a dramatic increase in vector-borne disease epidemics over the past decades, and nearly all of the most important vector-borne human diseases have exhibited dramatic changes in incidence and geographic range. These include dengue fever, malaria, Lyme disease, West Nile virus, Rift Valley fever, chikungunya, yellow fever, and most recently, zika. Overall, vector-borne infectious diseases cause a significant fraction of the global infectious disease burden, and nearly half of the world’s population is infected with at least one type of vector-borne pathogen. Vector-borne plant and animal diseases not only pose serious health hazards to humans and reduce the quality of life, but also reduce agricultural productivity and disrupt ecosystems throughout the world. At the same time, the world is facing an extreme shortage of entomologists and vector control experts, as many countries do not have any entomology programs at the undergraduate university level, and some countries have only a handful of expert entomologists.

Entomology for a changing planet

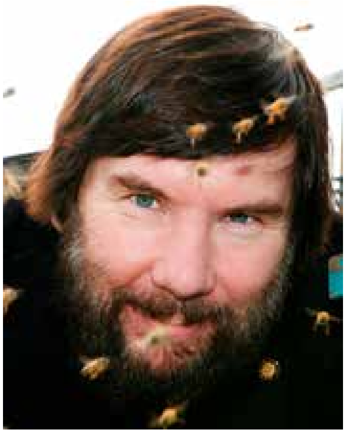
Global ecological challenges such as climate change, biodiversity loss, and invasive species all have a strong entomological component, and are usually interlinked. Thus climate change profoundly affects species distributions and abundances, exacerbates biodiversity losses, and facilitates invasions of harmful species into new geographical areas. Such drivers further disrupt critical ecosystem services such as biological control, pollination, and decomposition, in all of which insects play the determining role. Even a country like Finland records well over 100 new insect species per year, among them a recent, established invader Anoplophora glabripennis (the Asian long-horned beetle), found in 2015. In turn, we appear to be losing specialist arctic species at an accelerating pace, including some bumble bee species such as Bombus arcticus.

Entomology with latitude

Helsinki will be the northernmost ever location for the ICE Congress (at 60°10′N, equivalent to Seward, Alaska, or Nanortalink, Greenland). Thanks to the warm Gulf-stream, however, Finland enjoys (usually) warm and nice summers, and the world's northernmost agriculture (self-sufficiency in all key agricultural products). Also insect life is adapted to the white nights (i.e., practically no night in the summer), which the delegates to the ICE 2022 congress are welcome to experience and to explore.

Helsinki

President of the ICE2022Helsinki Organizing Committee Professor Heikki Hokkanen



Prof. Heikki Hokkanen is currently a visiting research professor at the Department of Environmental and Biological Sciences, University of Eastern Finland, Kuopio campus. He is professor Emeritus of agricultural zoology at the Faculty of Agriculture and Forestry, University of Helsinki. He holds a Lic. Phil. degree in ecology and natural resource management (1978. Univ. Jyväskylä. Finland), and a PhD in applied entomology (1983, Cornell University, Ithaca, NY, USA). After his PhD Heikki Hokkanen stayed for extensive periods as a visiting scholar at the Institute of Biological Control (Darmstadt, Germany), CABI Institute of Biological Control (Silwood Park, UK), University of Kiel, Germany, and at the OECD Directorate for Agriculture (Paris, France). In Finland his main work has been carried out first at the University of Kuopio (deputy professor), at the Agricultural research center of Finland (Jokioinen), and since 1990 until 2018 as a professor at the University of Helsinki. Currently he is the CEO of the SME Aasatek Oy.

His main interest and focus of work has been on all aspects of biological control, with emphasis on insect control. In recent years his interests have covered pollinators, and plant-derived bioactive compounds with an aim at plant protection applications. He has a long track record of coordinating international collaborative research, e.g., over ten years at the OECD Directorate for Agriculture (Paris). He coordinated the EU-project ERBIC (FAIR5), coordinated the FP7 project 'ForestSpeCs', and has participated in five other EU-RTD projects. Hokkanen is an active player in scientific publishing: Editor-in-Chief of BioControl (1997-2006); Founding EiC of Arthropod-Plant Interactions (2006-), editor of book series 'Progress in Biological Control', all by Springer. He recently established a new book series with CABI, called 'CABI Ecostacking Series', jointly with Dr. Ingeborg Menzler-Hokkanen (editors of the series). The first volume in this series is due to be published at the end of 2022, titled "The Concept of Ecostacking: Techniques and Applications". This book is edited by Jinjun Wang (SWU, China), Huai Liu (SWU, China), Ingeborg Menzler-Hokkanen (UEF, Finland) and Hongbo Jiang (SWU, China).

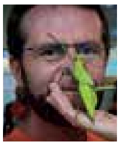
Professor Hokkanen has experience in organizing scientific meetings. He was the Chair of the Organizing Committee for the Society of Invertebrate Pathology Annual Meeting in 2004 in Helsinki. This congress gathered around 350 experts to Helsinki and has been credited as one of the most successful SIP meetings in recent times. Currently he is the President of the Local Organizing Committee for the 26th International Congress of Entomology, to be held in Helsinki in July 2022. In 2012 the International Organization for Biological Control (IOBC-Global) selected Hokkanen as its Honorary Member.

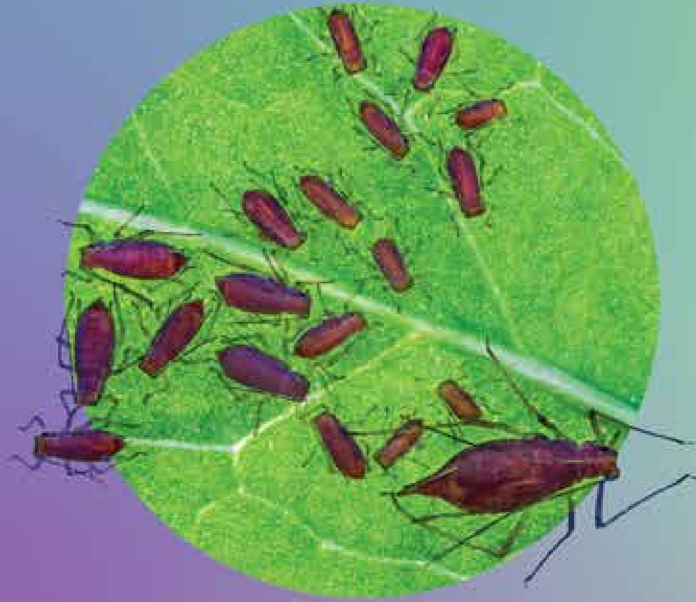
PRELUDE TO THE SCIENTIFIC PROGRAM

The daily program of the ICE2022 Helsinki congress is the result of a core group of international entomologists, who challenged the corona pandemic and other geopolitical situations to make this congress happen. The cover page of the program book lists the ICE congresses during the last over 100 years. More than 100 years of ICE congresses is a tradition which is not broken lightly.

The originally proposed symposia sometimes needed to change the speakers, and often also the symposium organizers during the past two years. After two years of modifications, and the still existing corona and travel restrictions, made it impossible for many symposium organizers to attend the ICE2022 Helsinki. Often colleagues picked up the responsibility of organization, where other scientists had to give up. Please see the current program as a platform to mend traditions after the pandemic, and to facilitate communication and knowledge exchange in-person after two years of lockdown.

The LOC (local organizing committee) had to set deadlines, and according to these deadlines this program has been compiled. The abstracts have been submitted (and peer reviewed) over a long period of time, ranging from 2019 to 2020, 2021 and 2022. Modifications of some of the abstracts submitted in 2019 could be done in time, while other abstracts and presentations are included in the original version. Some delegates, who joined research groups after 2019, might not be listed as authors. Some authors might be still listed, although they left science after 2019. LOC hopes that as delegate to ICE2022 Helsinki you have an understanding about the task which the section organizers, symposium organizers and the scientific advisory council have accomplished. Please forgive us any omissions or mistakes, which are inevitable. This is not the place to hunt for errors - this is the occasion to continue to stimulate entomological research on a global scale.





CODE OF CONDUCT

For congress participants

By attending the ICE2022 event, you agree voluntarily to abide by our ethics policy and the Code of Conduct. A code of conduct is a collection of rules and regulations that include what is and is not acceptable or expected behaviour. The ICE2022 ethics policy applies to speakers, staff, volunteers, and attendees. It defines expected behaviours, definitions of harassment, and reaffirms our support for diversity, equity, and inclusion in the field of entomology and, specifically, at our congress. Congress participants violating these rules may be sanctioned, expelled from the congress, and/or barred from future attendance at ICE events.

Expected Behaviour

- All attendees are to be treated with respect and consideration.
- Public critique should be of ideas rather than individuals.
- Avoid personal attacks directed toward other attendees, participants, ICE2022 organizers, and suppliers/vendors.
- Be mindful of your surroundings and of your fellow participants. Alert ICE2022 organizers if you notice a dangerous situation or someone in distress.
- Respect the rules and policies of the meeting venue, hotels, ICE2022 contracted facility, or any other venue.

Unacceptable Behaviour

- Harassment, intimidation, or discrimination in any form.
- Physical or verbal abuse of any participant.
- Disruption of talks at oral or poster sessions, in the exhibit hall, or at other events organized by ICE2022 at the meeting venue, hotels, or other ICE2022-contracted facilities.

Examples of unacceptable behavior include, but are not limited to, verbal comments related to gender identity, sexual orientation, disability, physical appearance, body size, race, religion, national origin; inappropriate use of nudity and/or sexual images in public spaces or in presentations; exclusion of transgender or intersex individuals; or threatening or stalking any attendee, speaker, volunteer, exhibitor, ICE2022 organizers member, service provider, or other meeting guest. ICE2022 is dedicated to providing a safe, hospitable, and productive environment for everyone attending. It is important to remember that a community where people feel uncomfortable or threatened is neither healthy nor productive. Accordingly, ICE2022 prohibits intimidating, threatening, or harassing conduct during our congress.

Authorship: All authors connected to a presentation and/or abstract must agree on all information contained in the presentation. Failure of an author to agree to the presentation format will lead to the presentation being withdrawn from the congress.

An author who submits a presentation to the congress must have intentions of attending, registering, and presenting at the meeting once the submission is accepted into the program. Repeated or consecutive last-minute cancellations by presenters may result in future submissions being denied.

Capturing, Sharing, and Posting without Permission: Presenters and attendees cannot photograph, screenshot, capture, or otherwise share images or presentation data without a presenter’s expressed written permission. Presenters are encouraged to use share/do not share icons. Presentations without “share” icons should be considered privileged and should not be shared outside the virtual platform.

Code of conduct

COVID-19 Safety: Before, During and After the Meeting

- Follow relevant guidance provided by the Centers for Disease Control and Prevention (CDC), World Health Organization (WHO), or your local health authority.
- Adhere to government issued travel restrictions and guidance issued by the region you will be traveling to and the regions you are traveling through and from.
- Evaluate your own health and that of people you are in close contact with; contact the meeting/event organizers if you have concerns.
- Stay home if you feel sick.

Onsite During the Event

- Abide by the venue's rules and requirements for onsite attendance.
- Assume all risks of attending an in-person event, including the potential risk of becoming infected with COVID-19
- Follow guidance from the local health authority, for everyday preventive actions to help prevent the spread of respiratory viruses, including:
    - Washing hands often with soap and water for at least 20 seconds, or an alcohol-based sanitizer with at least 60% alcohol.
    - Avoiding touching eyes, nose, and mouth with unwashed hands.
    - Covering your nose and mouth when coughing or sneezing. Throw used tissues in the trash.
- Agree to show proof of immunizations if required by ICE2022 or the local venue officials.
- Adhere to social distance protocols put in place by ICE2022 and respect others' personal space.
- Go to the event First Aid office (or equivalent) at any time if you feel unwell or are experiencing flu-like symptoms.
- Stay in your room and contact ICE2022 for further instructions if you wake up not feeling well during the event.

Post-event: Based on current contact tracing advice from many health authorities, if you test positive for COVID-19 up to 14 days after returning home, please contact ICE2022 to advise them.

Want to file a complaint?

Please contact ICE2022 Helsinki registration desk, or write an email to Heikki Hokkanen (heikki.hokkanen@uef.fi).

PLEARY PRESENTATION ABSTRACTS

Complex responses of herbivore insect pests to climate warming

Author: Battisti Andrea, DAFNAE, University of Padua, Italy

Abstract: Although it is well known that insects are sensitive to temperature, how they will be affected by ongoing global warming remains uncertain because these responses are multifaceted and ecologically complex. We reviewed the effects of climate warming on 31 globally important phytophagous (plant-eating) insect pests to determine whether general trends in their responses to warming were detectable. We included four response categories (range expansion, life history, population dynamics, and trophic interactions) in this assessment. For the majority of these species, we identified at least one response to warming that affects the severity of the threat they pose as pests. Among these insect species, 41% showed responses expected to lead to increased pest damage, whereas only 4% exhibited responses consistent with reduced effects; notably, most of these species (55%) demonstrated mixed responses. This means that the severity of a given insect pest may both increase and decrease with ongoing climate warming. Overall, our analysis indicated that anticipating the effects of climate warming on phytophagous insect pests is far from straightforward. Rather, efforts to mitigate the undesirable effects of warming on insect pests must include a better understanding of how individual species will respond, and the complex ecological mechanisms underlying their responses.

In relation to outbreak propensity linked to climate change, four situations are envisaged:

1. The extent of range expansion of non-outbreak insects is virtually unknown; this should come as no surprise because, by definition, these insect species occur at low density. It is quite likely, however, that such expansion has occurred but should be of minor importance from a management point of view, given that the population ecology of these putative species in the new area is similar to that in their core area.
2. A bias exists in the literature with almost all evidence of climate-change effects coming from outbreak species. In the event that outbreaks occur in the expanded range, an important question will then be whether the outbreak dynamics are similar to those in the original distribution range or show new characteristics.
3. Outbreaks in the historical area can be more, or less, frequent under climate change depending on the life history of the insect and how climate affects biotic interactions with host tree, natural enemies, insect pathogens. So far, there are no data to suggest that pest dynamics are significantly different under intensive management.
4. Plant health problems due to non-native insect species will most likely continue to increase in the future. Some non-natives will establish but with dynamics of the low-density type. The distribution of other non-natives will expand, perhaps as a consequence of climate change, and establish in areas where populations increase to outbreak level, becoming thus an invasive.

Changing the paradigm for measuring the impact of insect control interventions

Author: Hemingway Janet, Liverpool School of Tropical Medicine, Liverpool, UK

Abstract: I will describe an embedded cluster-randomised trial using Uganda's 2017-2018 campaign to distribute long-lasting insecticidal nets (LLINs) for malaria control. The largest RCT of this type ever undertaken. Clusters were assigned to PBO LLINs (PermaNet 3·0, Olyset Plus) and conventional LLINs (PermaNet 2·0, Olyset Net) using proportionate randomisation. LLINs were delivered from March 2017 to March 2018. In April–September 2019, 11 cross-sectional surveys were conducted in 50 randomly selected households per cluster; 12 households per cluster were randomly selected for entomology surveys. Due to COVID-19 13 restrictions, only 90 of the 104 clusters were surveyed. The primary outcome was parasite prevalence by microscopy in children aged 2-10 years. In the as-treated analysis, two clusters were excluded (no predominant LLIN received) and four were reassigned; LLINs with piperonyl butoxide (PBO) reduced parasite prevalence more effectively than conventional LLINs for 18 and 24 months. The underlying insect vectors and their resistance status were assessed. WHO have now made an interim recommendation on the use of these nets on the basis of this trial benefiting millions of children in malaria endemic areas.

Innovations in Insect Science for Impact

Author: Kelemu Segenet, International Centre of Insect Physiology and Ecology (icipe), Kenya

Abstract: The International Centre of Insect Physiology and Ecology (icipe) is an African Centre and a regional and global leader in research for development (R4D) through insects and related arthropods and their impacts on food and nutrition security, human health, environmental sustainability, and livelihoods. The year 2020 marked the 50th anniversary of icipe's founding. Since 1970, the Centre's achievements have reached many aspects of rural and urban life in Africa and beyond. icipe has also made a difference in science capability of the region through the significant contribution it has made to building the careers of thousands of staff and students who have worked with the Centre.

Three key elements define icipe's research strategy: (a) a focus on research domains in which insects and related arthropods have critical roles as vectors, pests or are the basis for beneficial uses (such as for food, feed, ecosystem services and value-added products); (b) innovation that can be applied to develop sustainable and safe alternatives to reliance on agri-chemicals; and (c) highly valued R4D Capacity Building and Institutional Development (CBID).

icipe and its partners have delivered science-driven, innovative, and sustainable insect-based technologies that are addressing multidisciplinary developmental challenges through an environmentally benign circular economy approach. In less than a decade, icipe's edible insects programme has generated and disseminated ground-breaking knowledge and innovations on sustainable insect farming/harvesting; recycle bio-waste into nutrient-rich organic fertilizer for improved soil fertility and crop yields; nutritional profiling and safety of insect products; integration of insect proteins in livestock and fish feeds; insect-based feed for improved gut health; and processing of insects into value-added products such as insect oils, sterols, antimicrobial target for novel drug development, chitin, chitosan among others.

icipe is a leading institution in the field of arthropod symbiosis in Africa. Microbiome research is being advanced with the aim of finding strategic entry points to reduce disease transmission. For example, the newly discovered Microsporidia MB in mosquitoes completely blocks plasmodium transmission.

icipe's innovative push-pull technology that can simultaneously address multitude of challenges such as stemborers, the fall armyworm, the parasitic weed Striga, mycotoxins, soil fertility, livestock feed, among others, that affect cereal-livestock farming systems in Africa is now effectively developed for vegetable production system.

Considering the enormous role insects play in food systems, ecosystem health, and many facets of livelihoods, this presentation would highlight and take stock of the R4D efforts in edible insects, arthropod symbiosis, and push-pull technology for vegetables.

On wings and wavelengths, or why moths fly into candle flames

Author: Pierce Naomi, Museum of Comparative Zoology, Harvard University, Cambridge, MA, USA

Abstract: The wings of butterflies are living structures that function as sensitive temperature sensors throughout the lifespan of the insect. To function properly, the wings must be maintained within a window of suitable temperatures, and these are exquisitely regulated by butterflies through multiple structural and behavioral adaptations. Despite the diverse colors and patterns of butterfly wings, regions that contain live cells, such as veins and androconial organs, are always the coolest parts of the wing. An investigation of whether butterflies and moths can also detect long wavelengths reflected by certain wing structures showed that long wavelength opsin duplication coupled with specific mutations in the protein binding pocket can result in spectral tuning shifts that may greatly extend the range of vision. The potential evolutionary significance of these results can be explored through a phylogenetically informed, multispectral survey of museum specimens.

From Me to We: Searching for the Genetic Roots of Social Life with the Honey Bee

Author: Robinson Gene, University of Illinois at Urbana-Champaign, IL, United States

Abstract: One of the most significant developments in the history of this planet has been the evolution of social life. True societies are very rare in biology, but have evolved repeatedly in a group of insects that includes the ants, bees, and wasps, with the honey bee widely considered a paragon of sociality. This lecture uses honey bees to demonstrate how sociogenomics enables researchers to understand social life in molecular terms: how it evolved, how it is governed and how it influences all aspects of genome structure, genome activity, and organismal function. Research will be discussed that illustrates that the relationship between genes and social behavior is 1) close, 2) conserved, and 3) causal.

These three principles are used, respectively, to show that:
1) shifts between cooperative and selfish behavior are subserved, at the whole transcriptome level, by surprisingly fluid and continuous changes in brain gene expression and gene regulation;
2) social behavior likely evolved using genetic toolkits present in solitary ancestors; and
3) evolutionary changes in colony aggression involve changes in brain gene regulatory networks, involving specific transcription factors in specific subsets of brain neurons. These results demonstrate how a research framework that emphasizes both the dynamic and deterministic aspects of the genome leads to new insights on the mechanisms and evolution of social life.

Insect Decline in the Anthropocene: Death by A Thousand Cuts

Author: Wagner David, University of Connecticut, United States

Abstract: The human population has grown to nearly 8 billion and anthropogenic activities are affecting marine, terrestrial and freshwater ecosystems from pole to pole. Nature is under siege. Losses in diversity, abundance, biomass, and range are well-documented for lineages across of the tree of life. Earth's plant and animal life has been plunged into crisis, with insects among the taxa at the forefront of many recent scientific reports and worldwide media attention. Population trends for insects include reports of both increasing and decreasing trends of varying magnitude that are both temporally and spatially complex, with increasing numbers of studies documenting worrisome declines. While many well-documented declines are from regions of high human settlement or activity, some studies report declines from preserves and wildlands free of obvious anthropogenic stressors such as urbanization or pesticide use. My talk will examine etiology of declines as well as studies documenting stable and increasing insect populations, briefly review annual decline rates and how we should look at these, and identify principal stressors. Special emphasis will be placed on the increasing threats of climate change to the biota of wildlands, especially changes in hydrology and climate variability. There remain many important data gaps that require study, e.g., in-situ, cross-taxon studies of pesticides effects; the spatial consequences of light pollution across different spectral bands; how agricultural practices can be changed to better protect biodiversity, locally and globally; and the impacts of tropical forest deforestation, principally for agriculture. The conclusion of the talk will address some ongoing research projects, citizen science efforts, policymaking, and solutions that can slow rates of insect decline.

Sex, conflict and selfish genes

Author: Wedell Nina, University of Exeter, Penryn, CORNWALL, United Kingdom

Abstract: Selfish Genetic Elements (SGEs) are genes, organelles or microorganisms present within the genome or cell of an organism that spread by subverting normal patterns of inheritance to increase their representation in the next generation; hence the term 'selfish'. SGEs such as endosymbionts, transposable elements, and meiotic drive genes are ubiquitous in living organisms and often associated with fitness costs to the bearer. Despite their impact on the reproduction of their host, their potential role in sexual selection and sexual conflict is largely overlooked. I will discuss some recent work examining the impact of a variety of SGEs showing they can affect the behaviour and reproduction of their host, often with sex-specific effects, and argue they are important contributors in shaping sexual selection and sexual conflict.

ENTOMOLOGICAL SOCIETY OF AMERICA
SHARING INSECT SCIENCE GLOBALLY

Explore the Entomological Society of America's Journals:

- **Top-ranked research:** *Insect Systematics and Diversity* received its first impact factor of 4.771.
- **Broad global readership:** The majority of institutional subscribers are outside of North America.
- **Open access options:** Three open access journals and an increasing amount of free content in the subscription journals.
- **Special collections:** Explore hot topics like drones, genetic control of mosquitos, phylogenomics, and the impact of climate change.

Effects of soil microbiome on phyllosphere and aphid microbiome assembly

Authors: Abdelfattah Ahmed[3], Wolfgang Adrian[2], Tack Ayco J.M.[1] and Berg Gabriele[2], [1]Department of Ecology, Environment and Plant Sciences, Stockholm University, [2]Institute of Environmental Biotechnology, Graz University of Technology, [3]Leibniz-Institut für Agrartechnik und Bioökonomie

Abstract: All multicellular organisms are now known to be associated with diverse microbial communities. Identifying the mechanisms by which these communities are assembled is crucial to understanding community dynamics. Here we aimed at identifying the effect of manipulating soil microbiome on the assembly of oak phyllosphere and aphid's microbiomes. We further evaluated the impact of aphid herbivory on the phyllosphere and soil microbiome. We used microcosms, which physically separate above- and below-ground compartments, to grow oak seedlings in three soils with different microbiomes yet the same physiochemical properties. Amplicon sequencing and RT-qPCR were used to characterize and quantify the bacterial and fungal communities in soils, leaves, and aphids. Soil microbial community composition had a significant effect on the fungal and bacterial community compositions of leaf and aphid microbiomes, indicating assembly processes, at least partially, from soil to aphids through plants. Aphid herbivory significantly decreases microbial alpha diversity in leaves. Leaf fungal community composition and soil bacterial community composition shifted upon aphid herbivory.

Efforts to use soft Pesticides for the Control of Insect Pests as contribution towards Green Chemistry

Authors: Abdelgader Hayder, Agricultural Research Corporation, Integrated Agricultural Pests Management Research Center, Sudan

Abstract: In the last decades during the post-war period, the agriculture has developed towards methods that are more intensive. Among these is increased use of agrochemicals. In the Sudan Gezira, as an example, cotton spraying started as early as season 1945/46 when only 1% of the cotton area was sprayed once. By 1978/79 the problem caused by the cotton insect pests, particularly the cotton whitefly (Bemisia tabaci) flared up. The number of sprays per season went up, reaching 9.25 sprays in season 1978/79, which might be attributed partly to the rapid resurgence of insects' pests as a result of the use of non-selective insecticides, which badly affected the natural enemies of these pests. The joint use of natural enemies and selective pesticides might attribute to combat this problem. Studying the side effects of pesticides is of prime importance to save natural population and encourage their role as biological control agents. This paper discuss the various methods which can be used to study the side effects on natural enemies and the results of some studies carried on the side effects of some insecticides on natural enemies both at small and large scale levels in Sudan. The study includes testing the side effects of some insecticides and their impact on bio-safety (Talstar, Polo, Metasystox, Marshal and the mixture Reldan + Endosulfan) on two Predators at small-scale level at the Gezira Research Farm, Wad medani. The Impact of Polo (diafenthiuron) on natural enemies in the cotton-based ecosystem of the Gezira Scheme (Large Scale) was tested in the Study. The results indicated that Polo was relatively safe both at small scale and large-scale level to the natural enemies observed during the study. This study can be considered as a begin of regional testing program in Africa with collaboration of international organization interested on conserving bio-agent.

Integrated Pest Management of Citrus

Authors: Abd-Elgawad Mahfouz, Plant Pathology Department, National Research Centre, Giza, Egypt

Abstract: Citrus group is one of the most popular fruits in tropical regions and elsewhere. Yet, its production has significant instability and decrease since it is usually affected by several biotic and abiotic constraints. The most important abiotic constraints are edaphic factors and bad weather conditions especially during flowering and early fruit set that cause flowers and small fruits to dramatically fall. As for biotic stresses, Citrus tristeza virus, Citrus psorosis virus, Phytophthora, Fusarium and T. semipenetrans rank high in general. Although regional in scope, additional insect pests and the citrus greening disease caused by the bacteria Candidatus Liberibacter spp. should be adequately managed. Given such constraints, integrated pest management (IPM) in citrus for stabilizing high citrus yield and quality by methods that do not degrade the environment should be sought. Phytosanitary measures to prevent further infection or pest/disease transfer should also address weed control, tillage to get rid of infected residue and kill soil-dwelling insect pests, and citrus certification programs. Regulation on certifiable pathogens of citrus-propagating material may include bacteria, fungi, nematodes and graft-transmissible pathogens. Genetic resistance is considered the most desirable method to control many diseases and pests since it is more cost effective and environment friendly than the use of synthetic chemicals. Biological control may emerge as a safe alternative to chemicals, and offers economically viable and ecologically sustainable management but bio-pesticides should be integrated in ways that make them complimentary or superior to such chemicals. This is especially important where bio-pesticides can act synergistically or additively with other horticultural inputs in IPM programs. Developments in IPM of insects, weeds, main disease-causing fungi and bacteria, and nematodes on citrus trees were reviewed. This research is funded in part by Science and Technology Development Fund.

Impact of mosquito coil on the development of pyrethroid resistance in Aedes (Stegomyia) aegypti

Authors: Ablorde Aikins[1], Kudom Andreas[2], Wieser Andreas[1] and Kroidl Inge[1], [1]Ludwig Maximilian University, Munich, [2]University of Cape Coast, Ghana

Abstract: In this study, we assessed the effect of pyrethroid-based mosquito coil on the development of pyrethroid resistance in Aedes aegypti. An established colony of Ae. aegypti originally from Elmina, Ghana was used for the experiment. Six generations of the colony were severally exposed to sub-lethal doses (7 min) of mosquito coil in a Peet-Grady chamber. After the sixth generation, susceptibility levels to Deltamethrin (0.05%) and mosquito coil were evaluated against the experimental colony. The colony was also genotyped for F1534C kdr mutations using an AS-PCR technique. The LT50 (95% CI) resulting from the sub-lethal dose of the coil rose from 7.8 minutes (95% CI; 6.14 – 9.41) at the beginning of the experiment (F0 generation) to 28.3 minutes (95% CI; 23.11 – 33.58) at the 6th generation. The F1534C kdr resistant allele increased from 54% in the unexposed colony (control) to 77% in the experimental colony. The data shows that exposure of Ae. aegypti to a sub-lethal dose of mosquito coil increased the tolerance of the population against the coil as well as selected for the F1534C kdr resistant mutation. This may ultimately result in the development of a pyrethroid-resistant population driven by the homozygous genotype.

A successful method of cold storing brown marmorated stink bug egg masses for the rearing of its parasitoid, Trissolcus japonicus

Authors: Abram Paul[1], Oscienny Angela[2], Sherwood Jade[3] and Walz Matt[2], [1]Agriculture and Agri-Food Canada, Canada, [2]The University of the Fraser Valley, Canada

Abstract: Trissolcus japonicus (Ashmead) is a candidate biological control agent that is an egg parasitoid of the brown marmorated stink bug (Halyomorpha halys Stål), a worldwide pest. As the mass rearing of T. japonicus is predicated on the availability of its host egg masses, the methods of producing and storing large quantities of H. halys egg masses is essential for future release programs. Currently, the two options for storing H. halys eggs are cold storage or freezing. However, it has been demonstrated that frozen egg masses can reduce parasitism rate by 35 - 44%. Our study demonstrates that emergence rates of T. japonicus can remain above 85% when host eggs are exposed to 8 degrees celsius storage for up to two months. T. japonicus fitness proxies such as emergence time, fecundity, activity, weight, and longevity are largely unaffected when host eggs were stored in 8 degrees celsius for 14 days.

Intraspecific variation in traits determining benefits and risks of egg parasitoids: a case study with Trissolcus japonicus

Authors: Abram Paul[3], Haye Tim[5], Moffat Chandra[4], Thiessen Jason[2] and Tuttle Sasha[1], [1]Agriculture and Agri-Food Canada, Agassiz Research and Development Centre, Agassiz, British Columbia; University of the Fraser Valley, Abbotsford, British Columbia, [2]Agriculture and Agri-Food Canada, Agassiz Research and Development Centre, Agassiz, British Columbia, Canada, [3]Agriculture and Agri-Food Canada, Canada, [4]Agriculture and Agri-Food Canada, Summerland Research and Development Centre, Summerland, British Columbia, Canada, [5]CABI, Delémont, Switzerland

Abstract: Egg parasitoids introduced for classical biological control have both benefits and risks that are inevitably difficult to predict. To complicate matters further, there may be intraspecific variation in egg parasitoid traits that are associated with both their potential biocontrol efficacy, and their non-target risk. Thus, the risks and benefits of an egg parasitoid introduction may depend on what strain is selected, and/or what adventively established strains are already present in introduced areas. Here, we propose using an invasion biology framework to select traits that may determine the relative efficacy and non-target risk of different strains of egg parasitoids. We use the samurai wasp (Trissolcus japonicus), a parasitoid of the brown marmorated stink bug, Halyomorpha halys, as a case study to demonstrate that there is significant intraspecific variation in egg parasitoid traits, including behaviours, symbiont infection, and life history, that are predicted to determine the risks and benefits of their introduction and spread in new geographic areas.

Non-reproductive effects of Insect Parasitoids on their hosts

Authors: Abram Paul[1], Tena Alejandro[2], [1]Agriculture and Agri-Food Canada, Canada, [2]Instituto Valenciano de Investigaciones Agrarias, Spain

Abstract: Parasitic wasps are important components of natural communities and are used to control insect pests in biological control programs worldwide, in addition to being fruitful models in theoretical ecology. As biological control agents, their main modes of action are considered to be killing their hosts with egg laying followed by offspring development (reproductive mortality), and feeding on them directly (host feeding). However, parasitoids can also negatively affect their hosts in ways that do not contribute to current or future parasitoid reproduction (non-reproductive effects). Outcomes of non-reproductive effects for hosts can include death, altered behavior, altered reproduction, and altered development. Based on these outcomes and the variety of associated mechanisms we will first categorize non-reproductive effects into: (i) non-consumptive effects; (ii) mutilation; (iii) pseudoparasitism; (iv) immune defense costs; and (v) aborted parasitism. Since these effects are widespread in the wild, we will present some of the most representative cases of non-reproductive effects of parasitic wasps on their hosts and their implications in biological control and community ecology.

UV light environment influences host location and exploitation in egg parasitoids

Authors: Abram Paul[1], Gaudreau Mathilde[2], Souza Mikaela[3] and Brodeur Jacques[2], [1]Agriculture and Agri-Food Canada, [2]Department of Biological Sciences, University of Montreal, Canada, [3]Luiz de Queiroz College of Agriculture, University of São Paulo, Brazil

Abstract: Parasitoids respond to a variety of biotic and abiotic factors to successfully interact with their hosts in highly variable natural settings. To that effect, the influence of light environment on parasitoid behaviour and fitness could be underestimated compared to better-studied olfactory cues. Because hymenopteran parasitoids can see the ultraviolet (UV) light that can harm both their mature and immature life stages, behavioral strategies involving UV vision could not only help find hosts, but also minimise negative effects of UV exposure to both mother and progeny. To investigate if or how this type of colour vision could be involved in assessing host and microhabitat quality, we conducted a series of laboratory experiments on stink bug egg parasitoids placed under different UV intensities using UV-visible fluorescent lights as well as UV-blocking and UV-transmitting filters. First, we examined whether foraging females tend to seek or avoid UV wavelengths by evaluating the walking activity of Telenomus podisi and Trissolcus cosmopeplae (Hymenoptera: Scelionidae) in absence of hosts. Wasps spent more time in areas exposed to UV light, while individuals and species varied in the intensity of this behavioral response. We then tested the implications of this apparent attraction to UV wavelengths on patch finding ability and maternal investment intensity (i.e. oviposition and brood guarding duration), by releasing individual T. podisi parasitoids in laboratory mesocosms containing a single egg mass on top of a soybean plant under similar UV treatments and recorded it for 24 h. Results will be discussed in the context of light environment control in protected agriculture.

Creepy crawlies or beauty queens? The effect of type of insect on the evaluation of foods containing insects

Authors: Adamczyk Dominika[1], Modlińska Klaudia[2], Maison Dominika[1], Goncikowska Katarzyna[2], Ekström Sebastian[1] and Pisula Wojciech[2], [1]Faculty of Psychology, University of Warsaw, [2]Institute of Psychology, Polish Academy of Sciences

Abstract: Rich in digestible protein, insects are more and more widely considered to be “the food of the future” and a good substitute for meat. However, the willingness to ingest them depends largely on the consumers’ perception of insects. To understand the specificity of insects among other animals, their characteristics as a potential food source, and to examine what makes some insects more acceptable as food than others, we conducted two complementary studies (qualitative and experimental). The qualitative study (18 IDIs) allowed us to identify the dimensions that determine the perception of insects as potentially edible and inedible.

In the experimental study (n=437), we examined the potential of three different types of insects (larvae, ants, crickets) as food ingredients. Pictures of four versions of the same product (Bolognese sauce) were presented to the respondents – three containing insects and one without insects (control condition). The results showed that foods containing insects scored lower on each dimension. Furthermore, we observed a different impact of various insects on product evaluation: products containing crickets were evaluated higher than those with larvae. In addition, we noted some individual differences in acceptance of insects as food. Respondents with a higher level of food neophobia and a lower level of variety-seeking tendency assessed products containing insects more negatively than participants with higher levels of the latter trait.

Of insects and men - analysis of visual characteristics and labeling of a food product containing insects on its acceptance as a meal

Authors: Adamczyk Dominika[1], Goncikowska Katarzyna[1], Maison Dominika[1], Modlinska Klaudia[2] and Pisula Wojciech[2], [1]Faculty of Psychology, University of Warsaw, Poland, [2]Institute of Psychology, Polish Academy of Sciences, Poland

Abstract: Studies suggest that the appropriateness of food is more important than its sensory characteristics, such as taste. Inappropriate of insects as food seems to be linked to their appearance and texture. An image of the whole animal elicits strong objection and negative emotions to the food offered i.e. people are reluctant to eat animal heads, entire limbs, etc. Perhaps in the case of insects, the fact that they are often served whole elicits similar reactions. In addition, adding entire insects or their recognizable parts to meals may convey the impression that the food is polluted or dirty. Insects in the form of flour should reduce this strong negative response. However, data on that matter are inconclusive. Therefore, we propose a study analyzing the effects of the form of insects added to food and a description of a meal on people’s assessment of the sensory properties of food.

In our study, every participant was offered a set of three food products (a cookie, a cupcake, and a date ball). None of the dishes contain insects. However, the respondents from the two experimental groups were informed that the products contained edible insects (in the form of flour or pieces). Also, half of the products presented in the study contain an ingredient that may look like traces of added insects. Every food set had a label informing that the food contains insects in the form of flour or pieces or contains other common ingredients. For each product, the respondent was asked to fill in a short questionnaire to evaluate its taste, appearance, smell, etc. Additionally, we asked participants to fill in a set of questionnaires measuring psychological variables (such as food neophobia, disgust, sensation-seeking, etc.).

We assume that a food label indicating the insect content will lower scores for sensory properties of food. What is more, we hypothesize that meals with ingredients in the form of insects’ pieces will be scored lower than that described as containing insects’ flour. The results of the study will be presented at the conference.

No silver bullet: Multiple mechanisms are used by the wasp Cotesia congregata on its host the caterpillar Manduca sexta

Authors: Adamo Shelley[1], Miles Carol[2], Miller Dylan[1] and McMillan Laura[1], [1]Dept Psychology and Neuroscience, Dalhousie University, Canada, [2]SUNY Binghamton, United States

Abstract: The parasitic wasp, Cotesia congregata, uses a multi-pronged approach to control behaviour in its host Manduca sexta. During emergence from the host, the area around the exit wound is numbed by the exiting wasps. This numbness prevents the host from disturbing the wasps as they leave the host. The host also exhibits extreme quiescence. The host regains some mobility after wasp emergence. However, host feeding behaviour is suppressed. The suppression appears to be due to changes in the central brain. Both motor and chemosensory systems are normal. For example, cutting the connective to the part of the brain that controls chewing (subesophageal), restarts chewing in parasitized caterpillars. A proteomics study demonstrated a number of protein changes in the central brain that correlate with the change in host behaviour.

A proposed hypothesis of a “natural”; phylogenetic-classification for the world Blastobasidae (Lepidoptera: Gelechioidea) based on macromorphological features of the adult.

Authors: Adamski David[2], Frandsen Paul[1], [1]Department of Plant and Wildlife Sciences, Brigham Young Univ., Provo, UT, United States, [2]Dept of Entomology, Smithsonian Institution, Washington, DC, United States

Abstract: Previous intuitive classifications of world Blastobasidae made minimal contributions in providing a natural phylogenetic-classification for the Blastobasidae. In our study, two analyses were conducted. In the first analysis, four different phylogenetic simulations were used to hypothesize relationships between and among clades for the family. These simulations included TNT Parsimony Analysis (PA), TNT Parsimony with Bootstraps (PBA), Bayesian Analysis (BA), and Maximum Likelihood Analysis (MLA). All four simulations show high congruence in separate tree topologies at the family and subfamilial levels within the world Blastobasidae. Although PA and PBA simulations recognize different monophyletic solutions within Holcocerinae, BA and MLA recognize cause for reexamination between the cladistic relationships between Inbioxa and Hera with other Holcocerinae genera. For the Blastobasinae both PA and PBA tree topologies are nearly identical. Tree topology generated by (BA) for Blastobasinae is most similar to the tree generated by (MLA). Both show strong support at the family level. Additionally, both BA and MLA mirror values with the greatest support at the Blastobasinae node and significantly less support at the Holcocerinae node. In summary, all four simulations show high congruence in separate tree topologies at the family and subfamilial levels within the world Blastobasidae. In the Blastobasinae clade, all four simulations show high congruence levels for support of the clade containing Doscostoma, Lateantenna, Neoblastobasis + Sirindhorn. Similarly, all four simulations show strong congruence in support of the clade uniting the two sister genera Blastobasis + Hypatopa that is rooted to the clade of Pheos, Hallicis, and Barbaloba. In addition, Koleps and Pseudokoleps are also recognized in all four simulations as a clade with high support values. The cladistic relationships for the sister genera, Pigritia + Mastema remains uncertain, however, the significantly higher support value in MLA may indicate a more confident relationship with Blastobasis + Hypatopa.

In the second analysis coded data were taken from all primary types and/or authoritatively identified specimens representing species in the analysis. This approach shows that the “exemplar approach” for underestimates homoplasy within the in-group and overlooks new combinations at the generic and species levels. Contrastingly, an “all-inclusive approach” finds unrecognized genera represented from type specimens not previously dissected. Once stability is achieved in the later analysis the evolution of hosts preferences and zoographical hypotheses can be attempted for the family.

Morphological Phylogenetics of World Blastobasidae (Lepidoptera: Gelechioidea): A Comparative Approach Using Exemplar and Super-Saturated Sampling

Authors: Adamski David[2], Frandsen Paul[1], [1]Department of Plant and Wildlife Sciences, Brigham Young Univ., Provo, UT, United States, [2]Dept of Entomology, Smithsonian Institution, Washington, DC, United States

Abstract: Morphological characters and character states were taken from exemplar and super-saturated samples to construct matrices in order to generate phylogenetic trees from simulations based on cladistic methodology for the world Blastobasidae (Lepidoptera: Gelechioidea). Phylogenies generated from an exemplar data matrix using maximum parsimony analyses did not show direct evidence when taxa shared cladistic characters as part of a transformation series. Bayesian and maximum likelihood analyses were limited in diagnosing transformation series among these taxa by arranging them in unresolved polytomies. Only when a super-saturated sampling of taxa was used to construct a character matrix, and analyzed using maximum parsimony with bootstraping were these transformation series detected and arranged into fully resolved clades. Moreover, this highly resolved tree simulation, based on dense taxon sampling, shows significant advantages in detecting paraphyly at various categorical levels resulting in many nomenclatural changes at the species and generic levels, and a more “natural” phylogenetic-classification compared to those previously published.

Criticisms and recommendations on the current situation of response to invasion of the fall armyworm in Asia and Africa

Authors: Adati Taro[1], Sato Yoshiki[1], [1]Tokyo University of Agriculture, Japan

Abstract: In recent years, the fall armyworm (FAW), Spodoptera frugiperda from the Americas has invaded Africa and Asia. However, so far, there have been no reports of catastrophic crop damage due to outbreaks of the FAW in the invaded areas. In these areas, there are indigenous FAW-related species, as well as other pest species that have invaded and established themselves in the past. Whether the new invasive species will cause significantly more damage than these indigenous pests remains a matter of speculation. In fact, FAW population density in forage corn fields in south-central Kyushu, Japan, is dependent on crop height and other factors, and is not necessarily dominant in some fields among several pests, including indigenous species. In response to the invasion of the FAW into Africa and Asia, there have been calls for increased application of synthetic insecticides and the introduction of GM crops. However, the effectiveness of such measures that were implemented in the original habitat of the species is questionable due to the emergence of strains resistant to insecticide components and Bt toxin. Such measures risk increasing dependence on foreign sources of commercial crop seeds and pest control agents and fundamentally altering indigenous agricultural systems that have adapted to local environments. Therefore, from the perspective of sustainable pest management strategy and comprehensive food security, recommendations for appropriate responses to the invasion of the FAW are required.

Understanding the multi-pathway spread of agricultural pests; challenges, network models and results

Authors: Adiga Abhijin, University of Virginia, United States

Abstract: Movement of humans and their goods is widely accepted as the primary driver of invasive species invasions. But rigorous methods that account for the multiple pathways of spread are few and far between. Epidemiological models based on network dynamics can simulate the spatiotemporal spread of the pest and thereby help policy makers make informed decisions in monitoring, prevention and mitigation efforts. Unlike pest risk maps based primarily on ecological suitability, these models can provide causal explanations to the observed spread and enable counterfactual analysis. However, modelers face a number of challenges in realizing such systems: data scarcity, complexity of the phenomenon, and need for multi-domain expertise, to name a few. We have developed robust data-driven models to study the role of natural and anthropogenic drivers of invasive species spread, with application to T. absoluta. This talk will present our recent work demonstrating the role of this new modeling approach in analyzing the spread, the role of tomato trade, various intervention measures and economic impact.

Does Müllerian mimicry structure pollinators communities over time? A case study for bees and wasps in Bonifacio (France)

Authors: Adrien Perrard[1], Chatelain Paul[5], Cornuel-Willermoz Alexandre[7], Villemant Claire[6], Fontaine Colin[2], Dajoz Isabelle[4], Elias Marianne[3] and Andrei-Ruiz Marie-Cécile[7], [1]1) Sorbonne Université, CNRS, INRA, IRD, UPEC, Institut d'écologie et des sciences de l'environnement, IEES, Paris, France 2) Université de Paris, IEES, France, [2]Centre d'Ecologie et des Sciences de la Conservation (CESCO), Muséum national d'Histoire naturelle, Centre National de la Recherche Scientifique, Sorbonne Unive, [3]Institut de Systématique, Evolution, Biodiversité (UMR 7205) Muséum national d'Histoire naturelle, France, [4]Institute of Ecology and Environmental Sciences, iEES-Paris, France, [5]Institute of Ecology and Environmental Sciences, iEES-Paris, France, [6]Muséum National d'Histoire naturelle, Institute of Systematics, Evolution, Biodiversity (ISYEB UMR 7205), France, [7]Office de l'Environnement de la Corse, Observatoire Conservatoire des Insectes de Corse, France

Abstract: Many stinging bees and non-parasitoid wasps (Hymenoptera, Aculeata) exhibit contrasted colour patterns, which constitute an aposematic signal. Such aposematic signal enables predators to recognize and to avoid the painful experience of the sting of these potential preys. Because the efficacy of a given aposematic signal increases with its own abundance, predation pressures induce Müllerian mimicry: the convergence in aposematic colour patterns among co-occuring stinging species. Although Müllerian mimicry has already been reported for some Hymenoptera groups, to date no study has investigated this mimicry at the level of an entire community of stinging Hymenoptera. Our purpose here is to evaluate the prevalence of co-mimic species within an aculeate community sampled at a same site (Bonifacio, South Corsica) after more than a century. The mimicry rings are identified for the whole community by quantifying aposematic colour patterns using image analysis of collection specimens. Here we will show that a community of aculeates tend to be partitioned in different mimicry rings. We will also discuss how these rings are related to the size of the different species and how changes in community composition through time can affect the aposematic landscape. These data contribute to a better understanding of mimicry and its importance within pollinators communities and may help to evaluate the actual impact of predation on local extinctions and ecosystem services.

IDmyBee, a free, collaborative tool to face the current taxonomic impediment for European wild bees

Authors: Adrien Perrard[1], Straka Jakub[4], Polaszek Andrew[6], Schatz Bertrand[3], Michez Denis[8], Mario Saliba Elie[7], Le Divelec Romain[2] and Radchenko Vladimir[5], [1]1) Sorbonne Université, CNRS, INRA, IRD, UPEC, Institut d'écologie et des sciences de l'environnement, IEES, Paris, France 2) Université de Paris, IEES, France, [2]Agence Française de la Biodiversité, Paris, France, [3]Centre d'Ecologie Fonctionnelle et Evolutive, CNRS, Montpellier, France, [4]Department of Zoology, Faculty of Science, Charles University, Czech Republic, [5]Institute for Evolutionary Ecology of the National Academy of Sciences of Ukraine, Kiev, Ukraine., Ukraine, [6]Natural History Museum, United Kingdom, [7]Sorbonne Université, France, [8]Université de Mons, UMONS, Belgique, Belgium

Abstract: There are more than 2000 wild bee species recorded in Europe, many of which require an expert's eye for identification due to the lack of proper identification keys. In many parts of Europe, studies and monitoring projects about wild bees rely therefore on a handful of taxonomists to identify the specimens. However, in the current state of low funding for taxonomic work, wild bee taxonomists cannot answer the high demand for bee identification, clarify taxonomic problems, educate a new generation of taxonomists, develop clear identification tools and keep them up to date, all at the same time. As a result, many pollination scientists focus on a few species, or work at a coarse taxonomic scale, which leads to under-exploitation of available pollinator diversity data. The project IDmyBee, which started in 2019, aims at developing collaborative identification tools to facilitate wild bee identification, to promote education about wild bee diversity and to centralize our knowledge on European wild bee taxonomy. Using the online platform Xper3, we are developing a set of identification tools that act as biodiversity database for the different bee genera and species. These tools have several advantages over the current identification keys: they are available freely, online, so that scientists and conservation actors can easily access this knowledge. They can be built collaboratively, so that the tedious work of key creation and improvement can be shared among taxonomists and with other actors depending on their availability. These tools can be easily updated to follow the changes in the taxonomy, so they offer an up to date vision of wild bee diversity. They are based on a matrix of characters instead of the classical dichotomic key, so they are more versatile for the user. Finally, they are not limited in terms of space or illustration. Illustrations are crucial since access to reference collections is time-consuming and difficult to many people. Despite these advantages, these tools are not aimed at replacing the taxonomic expertise. They will help identify which species require an expert's help and which can be identify by non-specialists. They will also help taxonomists to build and to keep a clear taxonomic framework that can be used by the different environment actors interested in wild bees. In the end, this project should stimulate the taxonomic work on wild bees by reducing the workload of taxonomists due to specimen identification and by providing them with a way to highlight their work through the publications linked to these tools. Once in place, this knowledge database could be linked to other identification methods such as barcoding or image analysis to facilitate wild bee identification even further.

Development of a Novel Biopesticide using an RNA Interference Approach Targeting Potassium and Fibroblast Growth Factor in Helicoverpa armigera.

Authors: Afifi Feras, Newcastle University

Abstract: This project has two main aims first, Development of a novel and sustainable form of pest control based on an RNAi approach targeting potassium ion channel and fibroblast growth factor in Helicoverpa armigera. Second, evaluation of the biosafety of the use of dsRNA on non-targeted organisms such as honeybees. The results were observed the knockdown of both target genes (potassium ion channel and fibroblast growth factor) via silencing of the expression by qPCR and measuring mortality rate after delivered dsRNA through injection and feeding. Biosafety studies will be perform by using adult honeybee to observed that there are no significant different of gene expression and mortality rate.

Current knowledge of Anagonia cf. lasiophthalma, a promising biological control agent of Gonipterus platensis

Authors: Afonso Catarina[1], Martins Cátia[3], Gonçalves Catarina[3], Valente Carlos[3] and Branco Manuela[2], [1]Forest Research Centre (CEF), ISA, University of Lisbon & RAIZ, Aveiro, Portugal, [2]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [3]RAIZ Forest and Paper Research Institute, Eixo, Aveiro, Portugal

Abstract: The Tasmanian eucalyptus snout beetle Gonipterus platensis (Marelli) is the most widely distributed Eucalyptus weevil in the world. In Portugal, this pest has been managed by classical biological control programs using the egg parasitoids Anaphes nitens (Girault) and Anaphes inexpectatus Huber & Prinsloo (Hymenoptera: Mymaridae). However, economically relevant attacks in eucalypt plantations still occur in many areas. Supplementary natural enemies of this insect pest, namely parasitoids targeting other host life stages, such as larvae, may boost the overall control of the pest.

Field surveys undertaken in Tasmania in 2017 followed by the import of Gonipterus spp. larvae allowed the establishment of larval parasitoid populations from genus Anagonia (Diptera: Tachinidae) under quarantine conditions in Portugal. Since then, a stable population of Anagonia cf. lasiophthalma is being reared and studied at RAIZ facilities.

Before A. cf. lasiophthalma can be released in the field, several aspects of its bioecology must be resolved. Furthermore, its potential efficacy as a biological control agent and the likelihood of environmental undesirable outcomes must be assessed. Here, we present the available results of the studies conducted so far on the identification, basic life cycle traits, and parasitism behaviour of A. cf. lasiophthalma.

Challenges to the use and exchange of classical biological control agents: the case of Cleruchoides noackae

Authors: Afonso Catarina[4], Seehausen Lukas[2], Mendel Zvi[3], Hurley Brett[6], Martinez Gonzalo[7], Wilcken Carlos[8], Barbosa Leonardo[1] and Branco Manuela[5], [1]Brazilian Agricultural Corporation (Embrapa), Colombo, Paraná, Brazil, [2]Centre for Agriculture and Bioscience International (CABI) Delémont, Switzerland, [3]Department of Entomology, Volcani Center, ARO, Bet Dagan, Israel, [4]Forest Research Centre (CEF), ISA, University of Lisbon & RAIZ, Aveiro, Portugal, [5]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [6]Forestry and Agricultural Biotechnology Institute (FABI), Pretoria, South Africa, [7]National Institute of Agricultural Research of Uruguay, Montevideo, Uruguay, [8]School of Agricultural Sciences, UNESP Botucatu, São Paulo, Brazil

Abstract: The eucalypt bronze bug, Thaumastocoris peregrinus (Hemiptera: Thaumastocoridae) is a small sap-feeding insect native to Australia. Since the first report of this species as a pest, in 2001, it has spread and established on non-native eucalypts in many countries in the world, causing major economic losses. This insect is effectively managed by means of classical biological control using the egg parasitoid Cleruchoides noackae (Hymenoptera: Mymaridae). The first country to use C. noackae against the eucalyptus bronze bug was Chile, in 2010. Since then, Brazil, Uruguay, Argentina, South Africa, Israel, and Portugal have imported and released it in the field. All these countries are contracting parties of the IPPC and have adopted the procedures established in the ISPM3 for import and release of biological control agents. All are also members of regional plant protection organizations. However, the import and release of this biological control agent involved a variety of approaches, even between members of the same regional platform. These different approaches stemmed from particularities of each country in their national regulations or from the lack of specific legislation regarding the introduction of biological control agents. Some countries were able to introduce the parasitoid without any host-specificity tests. Other countries required results from host-specificity tests and to be included in an application for release, but even here the extent of information required differed between countries. The disparities in regulations and procedures adopted by the different countries influenced the agent's introduction promptness.

Adapt or bust? Predicting insect adaptation to new dietary challenges

Authors: Agashe Deepa[1], Buddh Shyamsunder[1] and Ravi Kumar Vrinda[1], [1]National Centre for Biological Sciences, Bangalore, India

Abstract: Insects are incredibly adept at using diverse diets. Yet, it remains challenging to predict their survival and dynamics in new habitats. Which populations can adapt to sudden dietary change, and what information do we need to predict this? Among other factors, theory suggests the importance of evolutionary history and ancestral trait variation, and the position of the ancestor along the generalist-specialist continuum. We tested our ability to predict long-term adaptive dynamics in laboratory populations of a generalist pest, the red flour beetle Tribolium castaneum. We founded replicate lines using beetles collected from 10 locations in India, and allowed them to adapt to new diets for over 50 generations. Resource identity had a strong impact on population dynamics: despite substantial trait divergence across source populations, all lines adapting to the same resource showed surprisingly parallel dynamics. Although the same source populations adapted most successfully to different diets, these best-adapted populations did not always have the most "generalist" ancestors. Indeed, adaptation to each resource was associated with different ancestral traits. Thus, we suggest that predicting insect dietary shifts requires detailed understanding of ancestral trait variation, tailored to the new diet.

Influence of multifunctional flower margins on the improvement of biodiversity and production of Pisum sativum L.

Authors: Aguado Martin Luis Oscar[1], Peris-Felipo Francisco Javier[3], Miranda-Barroso Luis[3], Rad Carlos[4], Sacristán Pérez-Minayo Gonzalo[4], Núñez Seoane Eva[2] and Vasileios Vasileiadis, [1]Andrena Iniciativas y Estudios Medioambientales, [2]Centro Investigación y Tecnología Agroalimentaria de Aragón, [3]Syngenta Crop Protection, [4]Universidad de Burgos

Abstract: Conventional agriculture faces three complex challenges because of climate change, high loss of biodiversity and increase demand of sustainable food production by society and markets.

As an approach to enhance pollinator biodiversity in agricultural landscapes, Syngenta had proactively introduced Operation Pollinator (OP) programme in agricultural areas which objective is to improve pollinator biodiversity in crops by mixture of flower margins.

In this presentation, we focus our experiment in three pea fields from Spain. This crop is considered as an "improvement crop" due to the ability to fix atmospheric nitrogen thanks to the bacterium Rhizobium leguminosarum, associated with its roots and the important role it plays in crop rotations. Its agronomic qualities make it a key crop in the European Common Agricultural Policy (PAC) where it is given a premium as "Area of Ecological Interest", restricting the application of phytosanitary products, so enhancing the presence of beneficial insects and pollinators can contribute to improving the profitability of the crop.

In each field a multifunctional margin was sown, and insects were sampling following a gradient of distance by sweeping net and yellow traps. The results of the pollinator biodiversity and pollinator-production correlation on pea fields are going to be presented.

Local depressions play a key role in the maintenance of ant diversity in a forested mountain landscape

Authors: Aguilon Dianne Joy[4], Lorinczi Gábor[3], Módra Gábor[2], Elek Maák István[3], Juhász Orsolya[1] and Bátori Zoltán[3], [1]Department of Ecology, University of Szeged Doctoral School of Biology, University of Szeged, Hungary, [2]Department of Ecology, University of Szeged Doctoral School of Environmental Sciences, University of Szeged, Hungary, [3]Department of Ecology, University of Szeged, Hungary, [4]University of the Philippines Los Baños, Department of Forest Biological Sciencesences, University of Szeged Department of Forest Biological Sciences, College of, Philippines

Abstract: Sinkholes (or dolines) are bowl-shaped depressions in karst surfaces. They provide a diversity of environmental factors (e.g., humidity, nutrient, soil, temperature, and water), thereby facilitating the persistence of various functional groups of species, and hence could function as local biodiversity hotspots. Here, we investigated the potential of dolines to function as safe havens by studying the distribution patterns of ants in forested and non-forested (i.e., grassland) microhabitats inside (south-facing slopes, bottoms and north-facing slopes) and outside of dolines (i.e., plateau) in the Bükk Mountains, north Hungary. We used only non-destructive sampling methods (such as baiting and hand collecting) to assess the species diversity and relative abundance of ants. We found that the fine-scale distributions of the functional groups of ants correspond to the different microhabitats and vegetation cover. The north-facing slopes and bottoms of dolines provided key habitats for ants associated with cooler and/or moister conditions (e.g., Myrmica ruginodis), while the south-facing slopes provided key habitats for ants associated with warmer and/or drier conditions (e.g., Myrmica sabuleti). The occurrence of species on the surrounding plateau indicated intermediate conditions. In addition, non-forested microhabitats had more ant species than forested ones. To our knowledge, this is the first study to illustrate that the fine-scale topography of dolines may provide microhabitats for diverse ant assemblages. We can conclude that in forested landscapes the maintenance of semi-natural grasslands may be especially important to preserve high biodiversity.

Barley varieties Stoneham and Sydney exhibit mild antibiosis and antixenosis resistance to the wheat curl mite, Aceria tosichella

Authors: Aguirre Rojas Lina[1], Michael Smith C[1] and Khalaf Luaay[2], [1]Department of Entomology, Kansas State University, United States, [23]Department of Plant Protection, University of Baghdad, Iraq

Abstract: The wheat curl mite, Aceria tosichella (Keifer), devastates cereal crops worldwide by direct feeding damage and transmission of several deadly viruses. Cereal crop varieties resistant to A. tosichella are fundamental for the integrated pest management of this pest. Barley varieties resistant to A. tosichella are not known to exist. Non-choice and choice experiments were conducted to determine if A. tosichella resistance exists in the barley varieties Sydney and Stoneham which are resistant to the Russian wheat aphid, Diuraphis noxia (Kurjumov). Sydney barley displayed mild resistance to A. tosichella biotype 1 and 2, while Stoneham barley exhibited only mild resistance to biotype 2.

Mexican Research Experiences with Genetically Modified Corn

Authors: Aguirre U Luis Alberto[1], Hernandez J Agustin[1], Flores D Mariano[1], Cerna CH Ernesto[1], Frias T Gustavo[1] and Ochoa Yisa[1], [1]Universidad Autónoma Agraria Antonio Narro, Mexico

Abstract: Genetically modified organisms (GM) is a controversial issue worldwide. In Mexico, debate is greater being the center of origin of corn. Mexico approved controlled planting in 2009-2013 for research purposes allowing testing of hybrids AgrisureTM 3000 GT, Agrisure® VipteraTM 3110 y Agrisure® VipteraTM 3111 with Bacillus thuringiensis (BT) genes which codify Cry1Ab, Vip3Aa20 and mCry3A proteins resistant to Lepidoptera and Coleoptera in the State of Sinaloa. Resistance of hybrids to foliar damage by armyworm Spodoptera frugiperda, cob damage by corn earworm Helicoverpa zea and the sugarcane borer Diatraea saccharalis and compared with their respective isohybrids and an insecticide treatment. Results proved that hybrids containing Bt genes were resistant to foliar and cob damage from above-mentioned pests. Low incidence of sugarcane borer was observed; however, damage was lower on the GM hybrid when compared with conventional hybrids. Corn pests evaluated using GM hybrids could be a strategy to be incorporated in an insect pest management system. This technology may contribute to preserve agroecosystem biodiversity compared with other management options avoiding the use of chemical insecticides if their use is approved. Evaluations in other Mexican areas are needed to better understand this technology and support regulatory decisions in the matter.

Development of a PCR-based method to discriminate between dead and living insect pest present in stored rice

Authors: Agusti Nuria[1], del Arco Lidia[2], Riudavets Jordi[2], [1]IRTA, Spain, [2]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain

Abstract: Most of the current methods to detect the presence of insects in stored cereals are not sensitive enough to detect low pest levels or some immature stages, like the visual inspection of the grain after sieving. Once the pest is detected in the grain, the only method to determine if it is dead or alive is the grain incubation until completing the developmental period, which can last up to 40-50 days. Alternative tools to discriminate between live or dead individuals present in the grain in a shorter period are needed.

We have developed a PCR-based method to discriminate between dead and living insect pests present in stored rice by using primers that amplify long DNA fragments. Our hypothesis was that short DNA fragments are detected in both living and dead individuals, whereas long DNA fragments are only detected in living specimens, due to the degradation process after the death of the organism. For this, degenerated primers that amplify long DNA fragments have been designed within the mitochondrial regions Cytochrome Oxidase I and II. Results on some Coleoptera and Lepidoptera species that are pests in stored rice are shown and discussed depending on the time elapsed after death.

Understanding food webs in agroecosystems: the use of a universal arthropod and plant multi-primer NGS approach

Authors: Agusti Nuria[2] and Alomar Oscar[1], [1]IRTA, [2]IRTA, Spain

Abstract: The use of DNA metabarcoding is becoming an important tool to study biological control of pests in agroecosystems by revealing unknown details of the food webs. In this study, we have developed a multi-primer NGS approach to analyze the gut content of predatory arthropods present in a peach crop. This multi-primer system, which allows identifying the ingested arthropods and plants, is composed by two pairs of universal arthropod primers and two pairs of universal plant primers. The use of both arthropod universal primers was compared when used together or separately regarding the number of prey species obtained after the analysis. The resolution of both plant primers was studied to determine the assignment level to the plant resources detected. Obtained results showed that the analysed predators ingested arthropod and plant resources, including peach, other crops, and other plants present around the peach orchard. Within the arthropod resources, it was possible to detect peach pests, as well as other preys present in the peach crop and in the surrounding vegetation. This molecular tool could also be used to reveal the most important arthropod and plant resources consumed by omnivorous predators in other agroecosystems.

The diversity and spatiotemporal distribution of microbiota associated with Macrosteles leafhoppers (Hemiptera: Cicadellidae)

Authors: Ahlen Mulio Sandra[1], Lukasik Piotr[1] and Michalik Anna[1], [1]Jagiellonian University, Poland

Abstract: Microbial symbionts play important roles in insect biology, but their diversity, distribution, and dynamics over time across host populations is poorly understood.

We surveyed the spatio-temporal distribution of bacterial symbionts in several species of the broadly distributed, diverse, and economically significant leafhopper genus Macrosteles, with emphasis on Macrosteles laevis. Amplicon sequencing of the Cytochrome oxidase I (COI) gene allowed us to distinguish species, revealed lack of strong genetic differentiation across M. laevis populations combined with significant levels of heteroplasmy, and multiple cases of parasitoid infections. 16S rRNA amplicon sequencing data confirmed the omnipresence of the ancient nutritional endosymbionts Sulcia and Nasuia and a high, but variable prevalence of Arsenophonus, previously shown to colonise Sulcia cells. Other abundant symbionts included Rickettsia, Wolbachia and a previously unreported symbiont in Auchenorrhyncha, Ca. Lariskella. Further, we detected the known plant pathogen phytoplasma in 31 specimens, or 8.5% of samples. However, there was no discernable patterns in the symbiont prevalence among M. laevis populations, or associations between the presence of different symbionts. Combined, our data show how the simultaneous characterization of host and symbiont marker gene amplicons in large insect collections can reveal patterns critical for the understanding of their significance.

Influence of Macronutrients Induced Biochemical Changes in Plant as Mediator of Insect Pest Population in Okra (Abelmoschus esculentus (L.) Moench)

Authors: Ahmad Shahbaz[1], Azam Ayesha[2], Ijaz Butt Hira[2], Mahmood Rashid[2], [1]Institute of Agricultural Sciences University of the Punjab, Pakistan, [2]Institute of Agricultural Sciences, Pakistan

Abstract: Okra is highly nutritious crop with the production rate of 303.16 tons per year from the area 232.05 ha in Pakistan with the growing contribution of 2% in the world. Insect pests of okra are one of the key factor in reducing or effecting its yield and esthetic value. Nutrition of a plant plays an important role in regulating the insect pest population and the rate of infestation. The nutrients in the plant induces the biochemical changes which act as a mediator of insects of okra. The research was conducted in the greenhouse of Institute of Agricultural Sciences during the summer season 2018-19 to evaluate that upto what extent different levels of nitrogen, phosphorus and potassium modulates the insect pest population on okra. Three levels of nitrogen and phosphorus were prepared (315, 210, 105 ppm) with two levels of potassium (117 and 234 ppm). The number of insects were counted after every 7 days of interval. The encountered sucking insects of okra include whitefly, aphid, jassid and mealybug. The results of this study were assessed through RSM (response surface methodology) which shows that the high level of nitrogen increase the rate of leaf production (RLP), and total yield of okra in contrast to nitrogen at the high level of potassium the rate of soluble sugars are reduced which suppresses the insect pest population. Conclusion from results depict that nitrogen along phosphorus enhance the primary growth of plant and soluble sugar content and potassium turns it into secondary growth. Through RSM the maximum optimum rate of yield and minimum optimum rate of insects were predicted at different recommended concentration of nutrient solution of NPK.

Assessing biodiversity value of linear farm habitats across different levels of farming intensity in agricultural grassland using Diptera as bioindicators

Authors: Ahmed Karzan D.[2], O Hanlon Aidan[2], Volpato Alessio[2], White Blanaid[3], Williams Christopher[6], Mulkeen Collette[2], Ó hUallacháin Daire[8], Moran James[4], Stout Jane[7], Carey John[5], Day Michael[2], Gormally Mike[1], Rotchés Ribalta Roser[8] and Ruas Sara[4], [1]Applied Ecology Unit National University of Ireland Galway, Ireland, [2]Applied Ecology Unit, National University of Galway, Ireland; Ryan Institute, National University of Ireland Galway, Ireland, [3]DCU Water Institute, School of Chemical Sciences, Dublin City University, Glasnevin, Dublin 9, Ireland, [4]Department of Natural Sciences; Galway Mayo Institute of Technology, Galway Campus, Galway, Ireland, [5]National Parks and Wildlife Service, Agri Ecology Unit, Food St Galway, Ireland, [6]School of Natural Sciences and Psychology, Liverpool John Moores University, United Kingdom, [7]School of Natural Sciences, Trinity College Dublin, Dublin, Ireland, [8]Teagasc Environment, Soils and Land use Department, Johnstown Castle, Co Wexford, Ireland

Abstract: Agricultural intensification is known as one of the primary causes of rapid decline in farmland biodiversity, particularly insects. While the incorporation of linear farm habitats to counteract biodiversity decline have been proposed, much remains unknown about the specific impacts on insect diversity of different types or combinations of linear farm habitats, particularly on farmlands of different intensities. With this in mind, we investigated the value of different linear farm habitats for invertebrates using adult species of two dipteran families (Sciomyzidae and Syrphidae) as bioindicators, at three levels of land use intensity. The study was conducted on grassland farms (in the north-west of Ireland) which were grazed by sheep/cattle and categorised into extensive, intermediate and intensive farms based on stocking rates and proportional area of semi-natural vegetation/linear feature density (High Nature Value index). Five categories of linear farm habitats were selected within each farming intensity: a) Dense hedgerow; b) Open hedgerow; c) Dense hedgerow adjacent to a watercourse; d) Open hedgerow adjacent to a watercourse; and e) Watercourse only. Insect sampling was conducted from May-September 2018 using bi-directional Malaise traps which separated catches originating in the linear habitat and field respectively. In addition, the quality of the habitats was assessed using a rapid assessment method developed for both fields and linear habitat types. Our results show that hedges associated with watercourses within extensive farming systems support important habitats for the selected indicator taxa. Syrphidae species richness was significantly greater in dense hedges associated with watercourses than either open hedges or watercourses only. On the other hand, Sciomyzidae species richness was significantly greater in water courses with or without hedges than either dense or open hedges only. NMS analysis showed that the community composition of both insect families was significantly affected by habitat quality of linear habitats in intermediate and intensive farms, while in extensive farms, community structure was significantly affected by habitat quality of grasslands, soil moisture and/or organic matter. While the abundances of Syrphidae/Sciomyzidae captured were consistently greater on the linear feature side of the malaise traps across all faming intensities, proportionally more were captured on the linear feature side in intensive farms. Moreover, indicator species analysis revealed significant Sciomyzidae and Syrphidae indicators of linear farm habitats and farming intensification. Our study indicates that not only are linear farm habitat type and quality important for biodiversity but the context in which these are found i.e. farming intensity also plays a role. This needs to be taken into consideration when developing or designing new agri-environment schemes to improve biodiversity associated with linear farm habitats.

Skeletomuscular transformations in the mesosoma of ants to support forward leaping

Authors: Aibekova Lazzat[1] and Economo Evan[1], [1]Okinawa Institute of Science and Technology

Abstract: Ants, one of the most successful groups on the planet, play an essential role in almost all terrestrial ecosystems. They evolved different locomotion patterns to be able to move on different surfaces, to exploit different habitats, and also to cope with adverse conditions. Some ants are specialized in running, such as desert ants, some are specialized for gliding, swimming, and many other locomotion types. One rare specialization in the evolution of worker ant locomotion is the ability to jump. Jumping is one of the fastest terrestrial mode of locomotion. It is used to get away from predators, to move from one place to another, and for hunting prey. Forward jumping in ants convergently evolved in three subfamilies. Although, kinematics of jumping was thoroughly studied in previous contributions, no research has been done on the anatomical modifications in jumping ants. Evolution of jumping behavior often involves a combination of structural transformations, e.g., muscular volumes, skeletal elements, energy storage, and tendon. In this study, we will focus on the gross anatomy and the muscle architecture of the leg apparatus, to understand the underlying cause of the jumping ability in ants.

Developing Strategies to Use Zoophytophagus Mirid Predators to Control Pests in Open Field Tomato Crops: Preparation for the Potential Incursion of Tuta absoluta in Southern U.S.A.

Authors: Ajlan Aziz[3], Roda Amy[1], Kostyk Barry[2] and Castillo Jose[2], [1]United States Department of Agriculture, Animal and Plant Health Inspection Service, Plant Protection and Quarantine, Science and Technology, United States, [2]University of Florida, Institute of Food and Agricultural Sciences, Southwest Florida Research and Education Center, United States, [3]King Faisal University, Saudi Arabia

Abstract: The tomato leafminer, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) is expanding in the greater Caribbean region and threatens U.S. tomato production. To prepare for the potential incursion of the pest, we investigated the ability of plant-feeding mirid predators to control established leafminer (Keiferia lycopersicella Busck) (Lepidoptera: Gelechiidae) and whitefly (Bemisia tabaci) tomato pests. In cage studies, one exotic, Nesidiocoris tenuis (Reuter) (Hemiptera: Miridae), and one native, Macrolophus praeclarus (Distant) (Hemiptera: Miridae), Florida mirid species were found to significantly reduce the number of leafminers and whiteflies on tomatoes compared to tomato plants without mirids. We also investigated the ability of N. tenuis and M. praeclarus to control B. tabaci on tomato in seven open field tomato trials conducted in South Florida, U.S.A. Fewer whitefly eggs and nymphs were seen in the mirid and pesticide treatments compared to the no treatment controls. Nesidiocoris tenuis was found to establish, while M. praeclarus was observed only during the first weeks of the studies. Field trials that included sesame plants with tomato plants increased the numbers of N. tenuis when prey was scarce and allowed sustained whitefly control. U.S. native and fortuitously established mirids may prove to be immediately available biological agents for the management of Tuta absoluta should the pest reach U.S. shores.

Development of a Precision Guided SIT technology to control wild populations of D. suzukii

Authors: Akbari Omar, UCSD, United States

Abstract: Drosophila suzukii has caused significant worldwide economic losses including significant damage in the berry- and cherry-growing industries of western North America. Achieving effective control of D. suzukii has been difficult in a number of crop systems including cherries, and control measures have largely relied on prophylactic application of expensive broad spectrum insecticides, which have been expensive and problematic. Alternative, highly promising approaches that could complement existing control methods are urgently needed. To fill this void, here I will describe the development of a novel CRISPR based approach termed Precision Guided SIT technology (pgSIT) that can be used to control and eliminate wild populations of D. suzukii.

Insecticidal potential of cardamom and clove extracts on adult red palmweevilRhynchophorus ferrugineus

Authors: Al Dawsari Mona, Prince Sattam bin Abdel Aziz university, Saudi Arabia

Abstract: Toxicity of cardamom and clove seed powder and extracted compounds against the red palm weevil,Rhynchophorus ferrugineus(Coleoptera: Dryophthoridae), was assessed in laboratory exposure experi-ments. The treatments comprised different amounts of seed powder of cardamom (0.8, 1, 3, and 5 mg)and clove (1, 3, 5, 7 mg), and extract concentrations (0.2, 0.4, 0.5, 0.6, 0.7, and 0.8) for both plants usingether petroleum or chloroform. Data showed that 5 mg of cardamom powdered seed resulted in 93% mor-tality after one day and 100% mortality after two days. Whereas after two days, lower amounts (0.8, 1,and 3 mg) resulted in 26%, 40%, 46%, respectively. A similar result was obtained for clove seed powder,where 7 mg caused 53% mortality after one day and 100% mortality after three days, other amounts(1, 3, and 5 mg) resulted in 33%, 73%, and 80%, mortality respectively, after three days. We found thatall amounts of extract of both plants resulted in 100% mortality after three days. GC-MS analysis of thecardamom and clove extracts revealed the presence of a large number of terpenes of particular notewas eugenol and two novel compounds Hydroxy-alpha-Terpenyl Acetate and Labda -8(17),13(E)-Diene- 15. The current work aims at the possibility of benefiting from natural plants pesticides as beingsafer as well as on the separation of volatile oils, which was known to be important in the control pests.Ó2019 Production and hosting by Elsevier B.V. on behalf of King Saud University. The API-Tree project: Developing Apple Pest control strategies through an Integrated Agro-ecosystem approach

Authors: Alaphilippe Aude, French National Institute of Agricultural Research Experimental Unit Gotheron, France

Abstract: Apple trees account for 35% of the European orchards and apple production is questioned since it relies on a heavy use of pesticides. The objective of the API-tree project is to design and assess the efficiency and sustainability of combinations of practices alternative to chemicals to control apple pests. In this project, the whole apple pest complex has been considered, with a focus on aphids, for which chemical control solutions are missing due to regulatory pesticide withdrawal. The novelty of this project is the integrated approach that takes into account agroecosystems management, orchard design and practices, as well as economic constraints.

A range of geographic and climatic conditions is covered by API-tree thanks to the consortium, which comprises countries from Northern to Mediterranean Europe. This also permits to share various experiences and knowledge to propose innovative context-adapted solutions. API-tree will permit to design and assess new orchard systems in collaboration with end-users (mainly growers), who will participate in co-design activities and test some proposed strategies in their commercial orchards. Targeted practices will aim at building consistent and resilient systems that reduce both pest attacks and damage to attacked plants. Those practices are related to the enhancement of plant diversity (additional cultivars, cover crops, introduction of companion plants…), to soil and tree management (cultural practices) and to the design of agroecological infrastructures (e.g. habitat management to provide pest natural enemies with food resources and shelters, push-pull plant assemblages etc.).

In this presentation we will introduce a framework to combine all the levers and methods we have been working on to reach the zero insecticide in apple orchard and give an overview of the different tested levers. Following presentations will give more details on the tested levers and outcomes.

The Evolution of the Sternopriscina (Coleoptera: Dytiscidae, Hydroporinae) larval forms

Authors: Alarie Yves, Department of Biology, Laurentian University, Sudbury, Ontario, Canada P3E 2C6, Canada

Abstract: All Australian Hydroporini (Coleoptera: Dytiscidae, Hydroporiniae) have been historically regarded as strongly monophyletic and therefore put into the subtribe Sternopriscina, one of the four putative lineages within the tribe. As different expressions of the same genotype, larval characters help to complement adult characters that have been traditionally the primary basis for Holometabola classification. The fact that all Sternopriscina genera were historically regarded as strongly monophyletic raises an interesting question: what larval phylogeny tells us about the evolution of the Sternopriscina larval forms? This paper aims at comparing in a phylogenetic context the larvae of the recently described genera Chostonectes Sharp, Antiporus Sharp, 1882, Barretthydrus Lea, 1927, Megaporus Brinck, 1943, Paroster Sharp, 1882, Sternopriscus Sharp, 1880, and Necterosoma MacLeay, 187. In this provisional phylogenetic framework Paroster stands out as sister to all the other Sternopriscina studied, which are characterized by well-developed frontoclypeal lateral branches as well as by the presence of elongate natatory setae on femora, tibiae and tarsi. Such character states coupled with variably elongate urogomphi with numerous secondary setae are probably adaptations to improve the swimming ability of their larvae.

Behavioral responses of Drosophila suzukii females to odors of blackberry and bramble

Authors: Alawamleh Amani[5], Anfora Gianfranco[2], Wackers Felix[1], De Cristofaro Antonio[4], Maqsood Hashmi Maaz[3], Giovanna Di Stefano Maria[4] and Ganassi Sonia[4], [1]Biobest Group NV, Belgium, [2]Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy, [3]Institute for Research in Terrestrial Ecosystems National Research Council of Italy, Italy, [4]University of Molise, Department of Agricultural, Environmental and Food Sciences, Italy, [5]University of Molise, Department of Agricultural, Environmental and Food Sciences, Italy; Biobest Group NV, Belgium

Abstract: Drosophila suzukii Matsumura (Diptera: Drosophilidae), an invasive fruit fly originated from Eastern Asia, has a wide range of crop and non-crop host plants. It infests the most valuable crops in Europe including soft fruits such as strawberries and cherries, and several non-crop plants. Similarly to polyphagous fruit pests, D. suzukii utilizes different odor cues for feeding and oviposition behaviors, involving odors emitted by host fruits and their associated microorganisms. However, D. suzukii behavioral response towards crop host fruits has been evaluated enormously, but has been rarely investigated towards non-crop host fruits. Thus, we conducted this study to assess the behavioral responses of female D. suzukii towards odors emitted by crop and non-crop host fruits of same host species. We designed a laboratory experiment using naive flies and ripen fruits of blackberry crop Rubus fruticosus along with wild blackberry fruits, commonly known as bramble. Fruits were individually treated with chemical sterilization and no sterilization then tested using dual-choice bioassays with Y-tube olfactometer. The flies showed a significant preference for non-sterilized fruits of blackberry and bramble over the sterilized fruits. Blackberry fruits showed higher attractiveness towards non-sterilized fruits more than bramble fruits. Moreover, the overall flight activity was significantly increased when both fruits were tested in sterilized treatment. The highest activity of flies was recorded in bramble fruits. Our data indicates that flies attraction can be related to volatile compounds emitted by ripen fruits and microorganisms associated with fruits' surface. The low flies' attraction towards sterilized fruits indicates that the fruits lack the active microorganisms that may attract the flies. However, crop host fruits were more attractive than non-crop host fruits due to different volatile profiles and microbial communities. These results highlight the importance of selection of key volatile compounds emitted by both crop and non-crop host fruits and their associated microorganisms to increase attractiveness of current attractive lures. Our findings present the first report of behavioral responses of D. suzukii to sterilized and non-sterilized fruits of crop and non-crop hosts, providing promising prospects for developing a new trapping system for D. suzukii management. Such system can be based on the exploitation of volatiles emission from host fruits and microbes in a selective attractant lure which enables efficient trapping of flies during the fruiting season of both crop and non-crop hosts.

Hedgehog regulation

Authors: Alenius Mattias, Department of Molecular Biology Umeå University, Sweden

Abstract: Metabolic status regulates olfaction and taste responses in insects. During starvation many insects change food preference and response to odors. Even if we start to understand the coding principles behind olfaction and taste in insects are the molecular mechanisms that connect metabolic state and chemo sensation poorly understood.

We have previously identified that Hedgehog, a key development regulator that control segmentation in most insects, is reused after development in Drosophila to regulate the olfactory sensory neurons odor response. The results revealed a non-canonical Hedgehog signaling pathway that regulate odorant receptor transport to the cilium. Our results further showed that the system is conserved in large detail from Drosophila to humans.

Here, I will present our novel results that reveal Hedgehog to be an endocrine signal. Interestingly, the endocrine signal uses a specific receptor and suppress the olfactory sensory neuron odor response. Our results show that food composition determines the level of Hedgehog in the circulation and like that link metabolic state with food detection. Finally, I will disclose how Hedgehog skews some of the odor responses and possibly change the odor perception in Drosophila.

Measuring the evolutionary potential of a diapause-avoiding parasitic wasp to climate change

Authors: Alford Lucy[2], van Baaren Joan[1], Louâpre Philippe[3] and Mougel Florence[4], [1]UMR-CNRS 6553 ECOBIO, Univ Rennes 1, France, [2]University of Bristol, United Kingdom, [3]University of Burgundy UMR CNRS 6282 Biogéosciences, France, [4]University Paris-Sud, France

Abstract: The earth is currently experiencing rapid changes in climate. In addition to warming temperatures, an increase in the incidence of unpredictable thermal events such as heat / cold waves is also forecast. Species are differently affected by these climatic changes depending on their ability to buffer from and/or to respond to stressful thermal conditions. In areas with mild winters, an increasing number of ectothermic species have lost their diapause strategy, thus remaining active all year. As a consequence, such species are increasingly vulnerable to unpredictable cold stress events. The current study aimed to better understand the evolutionary potential of one such species by estimating heritability of cold tolerance. Using a parental half-sibling breeding design, cold tolerance, morphology and longevity of the parasitoid wasp Aphidius avenae, which has lost its diapause strategy in western France, was investigated and heritability estimates obtained. If the low heritability estimates obtained are indicative of the evolutionary potential of A. avenae cold tolerance, A. avenae may be increasingly reliant on behavioural responses and adaptive phenotypic plasticity to persist in a changing climate, with potential implications for the biological control function they provide.

Neuroendocrine control of environmental stress responses

Authors: Alford Lucy[2], Davies Shireen[1], Dornan Anthony[1], Dow Julian[1], Cabrero Pablo[1], Marley Richard[1], Terhzaz Selim[1], [1]Institute of Molecular, Cell and Systems Biology, College of Medical, Veterinary and Life Sciences, University of Glasgow, United Kingdom, [2]University of Bristol, United Kingdom

Abstract: Insects are exposed to a continuous multiple stressors across a range of environments. Desiccation tolerance and survival is dependent on fluid homeostasis by fluid transporting epithelia including the Malpighian tubules. Fluid transport by insect Malpighian tubules is modulated by diuretic neuropeptides which have also recently been shown to affect desiccation and cold tolerance in e.g. Drosophila melanogaster and D. suzukii.
Evidence suggests that at least three diuretic neuropeptides (capa, DH44, kinin) perform functions in environmental stress tolerance via the Malpighian tubules. Thus, Malpighian tubule function, and diuretic neuropeptides, have much wider implications for physiology and behaviour beyond osmoregulation.

Population dynamics of microbial symbionts from the common bed bug Cimex lectularius

Authors: Alhasdi Dina[1] and Welkinson Tom[1], [1]UCD School of Biology and Environmental Science, University College Dublin, Belfield, Dublin, Ireland

Abstract: The common bed bug Cimex lectularius harbours multiple symbiotic partners, at least one of which has been implicated in the supplementation of the vitamin-deficient blood diet. However, the integration of these multiple partners into the development of the insect has not been investigated in detail. In this study we monitor the population density of two cohabiting bacterial symbionts (Wolbachia and BLS) from egg to adulthood, and assess how insect gender, reproduction and availability of food impacts the bacterial populations.

Determination of Resistance Improving Potential of Cotton Whitefly Bemisia tabaci (Genn.) (Hemiptera: Aleyrodidae) Biotypes Against Cyantraniliprole

Authors: Ali Isse Hassan[1] And Yükselbaba Utku[1], [1]Akdeniz University, Turkey

Abstract: In this research, the resistance development potential of MEAM1 and MED genetic groups of cotton whitefly Bemisia tabaci to Cyantraniliprole was investigated. In addition, it was also determined the development of multiple resistances to different insecticides (pyriproxyfen, Spirotetramat and acetamiprid) in each biotype of B.tabaci. The obtained data will be a useful reference for future monitoring and management of insecticide resistance.

Field evaluation of natural pest control services at rice landscape

Authors: Ali MP, Entomology Division, Bangladesh Rice Research Institute (BRRI), Gazipur, Bangladesh

Abstract: Climate change induces salinity intrusion into soil and crop production land (terrestrial ecosystem) and the rate of salinity growth increases in terrestrial agricultural production landscape yearly. The impact of salinity on crop production, environment, social and food security is widely studied. However, the impact of elevated salinity on a natural pest control service system (where plant, pest and pest control providers live together) remains elusive. We tested the impact of elevated salinity on pest control service in coastal sites of Bangladesh using artificial inoculation approaches where insect pests and its eggs were released into rice field. Two gravid brown planthoppers were introduced in each place where six rice hills were covered with nylon mesh net. Three places were covered by nylon mesh net and three were exposed to natural enemies. Three locations of salinity elevated area and three locations of non-saline areas were selected for this experiment. Brown planthoppers (only 0.55) were not observed in exposed area where eggs and adult BPH were released at the mid stage of rice growth in field. On the other hand, where BPH introduced area was covered by nylon mesh cage showed significant higher number of populations developed (180.89) and feed rice plant ($P < 0.001$). Statistically similar development trends were found in three locations as saline area ($P > 0.05$). Number of natural enemies in exposed and non-exposed area were also recorded. Among the natural enemies, lady bird beetle, staphylinid beetle, carabid beetle and spiders were largely found both in exposed and non-exposed areas. These indicate that natural enemies are available to destroy insect pests in rice field. Significant number of lady bird beetles (21), spiders (13), and staphylinid beetle (30) were recorded outside the cage in rice field. Higher number of lady bird beetle (31), spiders (18) and staphylinid beetle (46) were recorded in pest exposed area. Similarly, natural enemies were observed in non-saline area both in exposed and non-exposed pest area. Significant number of lady bird beetles (12), spiders (10), and staphylinid beetle (20) were recorded outside the cage in rice field. Higher number of lady bird beetle (18), spiders (14) and staphylinid beetle (26) were recorded in pest exposed area. In non-exposed pest area, natural enemies including lady bird beetle, spiders and staphylinid beetles densely prevail closed to cage where pest remained throughout the experimental period. More importantly, we quantified the yield reduction due to pest introduced in cage. Significant lower amount of rice yield observed in non-exposed area (total 9 hills/ cage, area: 0.36 m2). Non-exposed area showed 206.52 g rice yield where as exposed area showed 238.52 g yield. This result indicates that brown planthopper can reduce 13.41% rice yield if natural enemies are absent in the field.

Establishing next generation pest control service in rice landscapes

Authors: Ali MP[1], Bari MN[2] and Haque SS[1], [1]Entomology Division, Bangladesh Rice Research Institute (BRRI), Bangladesh

Abstract: Pesticides are commonly used in food crop production systems to control crop pests and diseases and ensure maximum yield with high market value. However, the accumulation of these chemical inputs in crop fields increases risks to biodiversity and human health. In addition, people are increasingly seeking foods in which pesticide residues are low or absent and that have been produced in a sustainable fashion. More than half of the world's human population is dependent on rice as a staple food and chemical pesticides to control pests is the dominant paradigm in rice production. In contrast, the use of natural enemies to suppress crop pests has the potential to reduce chemical pesticide inputs in rice production systems. Currently, predators and parasitoids often do not persist in rice production landscapes due to the absence of shelter or nutritional sources. In this study, we modified the existing rice landscape through an eco-engineering technique that aims to increase natural biocontrol agents for crop protection. In this system, planting nectar-rich flowering plants on rice bunds provides food and shelter to enhance biocontrol agent activity and reduce pest numbers, while maintaining grain yield. The abundance of predators and parasitoids and parasitism rates increased significantly in the eco-engineering plots compared to the insecticide-treated and control plots. Moreover, a significantly lower number of principal insect pests and damage symptoms were found in treatments where flowering plants were grown on bunds than in plots where such plants were not grown. This study indicates that manipulating habitat for natural enemies in rice landscapes enhances pest suppression and maintains equal yields while reducing the need for insecticide use in crop fields.

Host sex discrimination by egg parasitoids of stink bugs

Authors: Alinc Tugcan[3], Arif Mokhtar Abdulsattar [1], Guarino Salvatore [2], Colazza Stefano[3], Cusumano Antonino[3] and Peri Ezio[3], [1]Ministry of Agriculture, Baghdad, Iraq, [2]National Research Council of Italy (CNR), Palermo, Italy, [3]University of Palermo, Italy

Abstract: Chemical traces deposited by herbivores walking over the plant surface may act as contact kairomones for their associated insect parasitoids during the host location process. In the several stink bug-egg parasitoid systems, these indirect host-related cues do not only provide information about the potential presence of the stink bug host in the surrounding areas but also provide information on the host sex. Particularly, egg parasitoids spend more time on the traces left by female bugs, which would normally be of higher hierarchical value, showing the fact that such female wasps have evolved strategy based on host sex discrimination to arrive in the vicinity of freshly laid host eggs. Here, we provide a comprehensive overview of host sex discrimination ability in egg parasitoids of stink bugs and discuss the role of cuticular hydrocarbons as key compounds mediating the discrimination behavior.

Release of earwigs (Forficula auricularia Linnaeus (Dermaptera: Forficulidae)) to control woolly apple aphid (Eriosoma lanigerum Hausmann (Hemiptera: Aphididae))

Authors: Alins Georgina[1], Lordan Jaume[1] and Rodríguez-Gasol Neus[1], [1]IRTA Fruitcentre, PCiTAL, Park of Gardeny, Fruitcentre Building, Lleida, Spain

Abstract: Woolly apple aphid affects apple trees and causes damage to branches, trunks and roots. Previous studies indicate that earwigs can play an important role in the control of this pest; however, even though earwigs are naturally present in apple orchards, they do not prevent outbreaks. For this reason, a trial was carried out to evaluate the effect of earwig release on the biological control of woolly apple aphid. This trial was carried out in 2017, 2018 and 2019 in an organic apple orchard located in Catalonia (NE-Spain). In 2017 and 2018 earwigs were released in June, while in 2019 they were released in May. Two treatments were evaluated: release (by means of a shelter with 30 earwigs) and control. The experimental design was completely randomized with 10 replicates. Each replicate was constituted by a tree in which an infested bud of woolly apple aphid was selected to evaluate the growth of the colony. The release carried out the first year (2017) did not affect the presence of the woolly apple aphid. However, the releases that were performed in 2018 and 2019 caused a decrease in colony size. Our results show the potential of earwigs' releases in the biological control of woolly apple aphid.

Perspectives on the potential applications of Antimicrobial Peptides

Authors: AlJabr Ahmed M[1], Hussain Abid[1] and Al-Ayedh Hassan[2], [1]Laboratory of Bio-Control and Molecular Biology, Department of Arid Land Agriculture, College of Agricultural and Food Sciences, King Faisal University, Hofuf 3, [2]Life Science and Environment Research Institute, King Abdulaziz City for Science and Technology, Kingdom of Saudi Arabia

Abstract: Antimicrobial peptides (AMPs) are small evolutionarily conserved biologically active molecules widespread in nature. These naturally occurring AMPs are considered essential protective component, thereby imparting the first-line of defense against pathogens. Currently, more than 2900 AMPs from six life Kingdoms including bacteria (335), fungi (16), archaea (4), protists (8), plants (343) and animals (2219) have been reported. Multidimensional biological characteristics such as antimicrobial, immune modulator, least toxicity and decreased resistance development make APMs versatile promising future drug candidate in pharmaceutical industries. They are mainly involved in their defense mechanism in order to protect them against invading infections agents including fungi, bacteria, yeast and viruses. In addition to antifungal, antiviral and antibacterial response through diverse mechanisms, AMPs provide the avenues for the development of novel therapeutic alternative due to their anticancer response against cancer cell lines. This presentation intents to highlight how short antimicrobial peptides can become novel therapeutic tool to tackle future resistance development challenges.

Monitoring Elaterid Beetles on Sweet Potato in the Mississippi Delta

Authors: Allen Clint[1], Johnson Chris[1] and Reddy Gadi[1], [1]USDA-ARS, United States

Abstract: Wireworms, the larvae of click beetles, are insect pests with a wide host range consisting of vegetables, grains and other crops such as peanuts, strawberries and tobacco. They are capable of inflicting economic damage to the roots and tubers during their long-life cycles. They are difficult to control due to their protected habitat below ground. In Mississippi and in the southeastern U.S. Conoderus spp are major wireworm pests. The cryptic life cycle of wireworms renders chemical control efforts unsuccessful and estimation of pest numbers difficult. The primary objective of this research was to determine the damage potential and distribution of wireworms/click beetles. The Noronha Elaterid Light Trap, or "NELT", is made with three pieces — a small solar-powered spotlight, a plastic white cup and a piece of screening. The light is set close to the ground to attract the source of the wireworms, the female click beetles that emerge from the ground in April and May. These traps will be installed at several sweet potato fields in the Mississippi Delta. The proposed survey work will help us to determine the distribution of click beetles in the Mississippi Delta and the potential need for preventative control of this important insect group.

Australian Eadya (Braconidae) as larval endoparasitoids for classical biocontrol of globally invasive paropsine leaf beetles

Authors: Allen Geoff[2], Pugh Andrew[1], Sharanowski Barb[3], Ridenbaugh Ryan[4], Quarrell Stephen[2] and Withers Toni[1], [1]Scion, New Zealand, [2]Tasmanian Institute of Agriculture, University of Tasmania, Australia, [3]University of Central Florida, Department of Biology, Orlando, FL, United States of America, United States

Abstract: A number of countries using Eucalyptus in plantations have been the recipient of a number of invasive paropsines (Col.: Chrysomelidae: Chrysomelinae) from Australia. All species are significant defoliating pests. In a departure from the reliance upon egg parasitoids, further investigations into larval endoparasitoids began as a result of interest in locating host specific classical biological control agents. A collaboration between the University of Tasmania and Scion in New Zealand and the University of Central Florida over the last eight years has resulted in the description of four new species discovered in the field and confirmed with molecular identifications, as well as a revised key for the genus of Eadya. Eadya which are striking black and orange wasps, were found to be larval parasitoids of nine differing paropsine species, and one species studied in most detail suggest all attack any of the four larval instars during spring/early summer when they are feeding either clustered or singly on Eucalyptus leaves.
Paropsis charybdis is New Zealand's arguably most damaging eucalyptus pest, Eadya daenerys which attacks P. charybdis has now been approved for release there. The most common field host of this parasitoid in Tasmania is Paropsisterna agricola. Paropsisterna variicollis is also a pest causing concern in New Zealand and spreading rapidly. Field and laboratory host range data suggest Eadya annleckieae specialises on Pst. variicollis and Pst. selmani. With Pst. selmani being a pest of Eucalyptus plantations in Ireland, this species could become a promising biocontrol agent in both New Zealand and Ireland.

Invasive ants and virus dispersal

Authors: Allen Margaret, U.S. Department of Agriculture, Agricultural Research Service, United States

Abstract: Ants are highly effective invasive species. I have scrutinized RNA viruses in Mississippi USA populations of red imported fire ants, and have identified evidence of six viruses. Each virus present has unique implications and potential applications.

The Role of Chemical Ecology in the Management of Forest Insect Pests

Authors: Allison Jeremy, Great Lakes Forestry Centre, Canadian Forest Service, Canada

Abstract: The study of the chemistry, biochemistry and function of natural products (chemical ecology), has immense potential to inform our understanding of the biotic world. It also has the potential to provide biorational tools for integrated pest management (IPM) and the promise of this potential has been the primary impetus for the development of the discipline of chemical ecology. Examples of pest management tools based on the chemical ecology of target pests are now common but remain far more numerous for agricultural than forestry pests. In part this is a product of a larger research investment into agricultural than forest pests. It is also a reflection of the reality that trying to develop IPM for forest insect pests has challenges unique to forest settings. Primary among these are: 1) rotation periods that can mean that decades pass before a return on the investment in IPM can be realized; and 2) spatial scales and associated limited infrastructure that can make implementation of IPM difficult. While the area of planted forests is increasing globally and compartments of planted forests can be large, plantation forests are typically characterized by intensive management and consequently good infrastructure and accessibility, as well as short rotation periods. As a result, the temporal and spatial constraints that limit the application of chemical ecology to the IPM of insect pests in natural forests may be attenuated in plantation forests. This presentation will provide an overview of current applications of chemical ecology to the management of forest insect pests and discuss potential areas for increased contributions to the development of IPM tactics for insect pests in plantation forests.

Sugar feeding increases immunity in the gut and protects the female mosquito Aedes aegypti against arboviruses

Authors: Almire Floriane[1], Kohl Alain[1], Pondeville Emilie[1], McFarlane Melanie[1] and Terry Sandra[1], [1]MRC-University of Glasgow Centre for Virus Research, Glasgow, Scotland, United Kingdom

Abstract: Female mosquitoes usually drink sugars from plants and flowers for their own energy but also require a blood meal to reproduce. Due to this last strategy, they are vectors of arthropod-borne viruses (arboviruses) such as Zika (ZIKV) or chikungunya (CHIKV) viruses. Sugar sources can be rare in some arboviral endemic regions, forcing female mosquitoes to feed exclusively on blood to use it as a nutrient source and therefore, leading to a higher risk of arbovirus transmission. Mosquito immunity is an important factor influencing vector competence. The gut is the first barrier to be overcome by an arbovirus after blood meal and is the major determinant of arbovirus infection. We demonstrate that the gut immunity in females is enhanced and maintained through regular sucrose solution feeding. Our data show that sucrose, glucose and fructose (sugars naturally present in plant and flower nectar) can all maintain gut immunity in females. We next investigated the role of the intestinal microbiota in sugar-induced immunity. Antibiotic-treated mosquitoes showed a stronger sugar-induced immunity than non-treated mosquitoes. Therefore, sugars increase gut immunity independently of the microbiota. Moreover, microbiota decreases immunity, either by directly competing with the mosquito host for sugars, either by directly inhibiting immunity. Also, we found that females that fed on sucrose few hours before the intake of an arbovirus-infected blood meal are less susceptible to the virus than non-sugar-fed females. Altogether, these results showed the extreme importance of sugar on the gut immunity and on arbovirus infection in the female mosquito Aedes aegypti.

Pea leaf weevil and broad bean weevil control time in broad bean (Vicia faba)

Authors: Almogdad Mohammad[2], Semaškiene Roma[1], [1]Department of Plant Pathology and Protection, Institute of Agriculture, Lithuanian Research Centre for Agriculture and Forestry, Lithuania, [2]Lithuanian Research Centre for Agriculture and Forestry, Lithuania

Abstract: Pea leaf weevil (Sitona lineatus) and broad bean weevil (Bruchus rufimanus) are destructive insect pests on broad bean (Vicia faba) worldwide. The best control time under natural field conditions of these two pests was investigated at the Institute of Agriculture, Lithuanian Research Centre for Agriculture and Forestry during 2018-2020. Contact and systemic insecticides were used. The abundance of S. lineatus and B. rufimanus was monitored from germination till full ripening. For S. lineatus, several application times were tested (at growth stage BBCH 08; when the first weevil adult was caught in the yellow water trap; when the daily air temperature for three days exceeds that of threshold for adult activity; at the local threshold (5–10 beetles m-2); at the growth stage BBCH 10–11). For B. rufimanus, several application times were tested (when the first weevil adult was caught in the yellow water trap; when the daily temperature for three days exceeds that of threshold for adult activity; at the end of flowering (BBCH 69); spray three times beginning at growth stage BBCH 69 with a one-week interval).

At low density of S. lineatus adults (3.5 beetles m-2) at early growth stages, application of insecticides according to the tested spray regimes did not show significant effect on leaf damage (notches). At high density of S. lineatus adults (18 beetles m-2), application according to the local threshold gave significantly the lowest number of notches on leaves compared to the early spray at BBCH 08 growth stage. The abundance peak of B. rufimanus adults corresponded with the full flowering stage (BBCH 65). The best control of B. rufimanus was achieved when insecticide application was done three times beginning at the end of flowering (BBCH 69) with a one-week interval. This spray regime decreased the damaged seeds by 57.7% compared to the untreated control and resulted in 38.9% yield increase.

Recent trends in stream macroinvertebrates: warm-adapted and pesticide-tolerant taxa increase in richness

Authors: Altermatt Florian[1], Obrist Martin K.[2], Siber Rosi[1], Bollmann Kurt[2] and Schuwirth Nele[1], [1]Eawag: Swiss Federal Institute of Aquatic Science and Technology, [2]Swiss Federal Institute for Forest, Snow and Landscape Research WSL

Abstract: In recent years, massive declines in insect biodiversity have been reported from many European countries.

We analysed nationwide, systematic monitoring data on aquatic insect diversity collected at 438 sites in Switzerland from 2010 to 2019. In addition to taxonomic richness, we considered functional traits such as temperature preferences and feeding guilds. Furthermore, we explored the sensitivity of aquatic insects towards pesticides. We found that insect species richness increased in the time period considered. Warm-adapted species showed the strongest increase with time while cold-adapted species richness remained stable. Generalists such as collector-gatherers displayed the highest gain in species richness, and pesticide-insensitive taxa increased most with time. Moreover, we developed a predictive model of aquatic insect richness by considering both in-stream conditions such as temperature and catchment-level factors such as land use and found that the importance of predictors depended on the functional group under consideration.

Our results suggest that recent developments in insect species richness are context-dependent and affect functional groups differently. Longer investigations are needed to confirm the positive trend and to reveal if the increase in temperature and pesticide tolerant species could lead to a decrease in specialised species and a homogenisation of biotic communities in the long term.

Effect of landscape complexity and Bt technology on phytophagous stink bugs and predatory arthropods abundance in soybean

Authors: Altier Nora[1], Silva Horacio[4], Bentancur Oscar[3], Abbate Silvana[2] and Pons Xavier[5], [1]Instituto Nacional de Investigación Agropecuaria. INIA. Uruguay, Uruguay, [2]Universidad de la República. CENUR Litoral Norte. Uruguay, [3]Universidad de la República. Facultad de Agronomía, EEMAC, Biometría y Estadística. Paysandú, Uruguay, [4]Universidad de la República. Facultad de Agronomía, EEMAC, Departamento de Protección Vegetal. Paysandú, Uruguay, [5]Universidad de Lleida. Departamento de Producción Vegetal y Ciencia Forestal. Lleida, Cataluña, Spain

Abstract: In Uruguay, as in the rest of South America, agroecosystems underwent two major changes: agricultural intensification and the inclusion of Bt crops. The removal of natural habitats caused by landscape simplification and the high adoption of transgenic cultivars resistant to defoliating lepidoptera could generate side effects on phytophagous and beneficial arthropods. This research aimed to evaluate the effect of landscape complexity (percent of landscape in agriculture) and the technology used at the local scale (RR or RRBt) on the abundance of phytophagous stink bugs and predominant predatory arthropods in soybean. Sampling was completed in 32 fields (16 RR and 16 RRBt) located in the Northwest of Uruguay throughout the whole cycle of the crop during 2017-18 season. Arthropod abundance was estimated every three weeks using sweep netting conducted inside the fields and in field edges. Landscape complexity was measured as the proportion of agriculture-land use within 1km radius circle. The average values obtained in the six sampling moments were accumulated and analyzed fitting generalized linear models ($p\text{-value}<0.05$). Piezodorus guildinii was the predominant stink bug species in all sampled fields, while spiders, predatory bugs and ladybugs were the most abundant predators. Soybean fields surrounded by landscapes with more than 75% of agriculture had higher number of stink bugs, but reduced landscape complexity did not affect any group of predators. Abundance of stink bugs or predators was not significantly different between RRBt and RR soybean fields. Spontaneous vegetation at the edges of the field had a greater abundance of spiders than the crop area, while stink bugs, predatory bugs and ladybugs were more abundant inside the crop. Understanding the relative importance of agricultural practices at different scales and the interaction with stink bugs and predators dynamics will facilitate recommendations on the sustainable management of soybean pests at the local and landscape scales.

Effect of landscape composition and Bt technology on phytophagous stink bugs and predatory arthropods abundance in soybean

Authors: Altier Nora[1], Abbate Silvana[3], Madeira Filipe[2] and Pons Xavier[4], [1]Instituto Nacional de Investigación Agropecuaria. INIA. Uruguay, Uruguay, [2]Mountains of Research Collaborative Laboratory. Portugal, [3]Universidad de la República. CENUR Litoral Norte. Uruguay, [4]Universidad de Lleida. España

Abstract: South America agroecosystems underwent two major changes: agricultural intensification and the inclusion of Bt crops. The landscape simplification and the adoption of transgenic cultivars resistant to defoliating lepidoptera could generate side effects on phytophagous and beneficial arthropods. We evaluated the effect of landscape composition (1km radius) and the technology used (RR or RRBt) on the abundance of phytophagous stink bugs and arthropods predators in soybean. Over two-year, sampling was completed in 60 soybean fields in the Northwest of Uruguay. Arthropod abundance was estimated using a sweep and a beating sheet. Piezodorus guildinii was the predominant stink bug, while spiders, predatory bugs and ladybugs were the most abundant predators. The abundance of stink bugs and predators in soybean was affected by the type of vegetation cover and did not differ between RRBt and RR soybean fields. Spontaneous vegetation at margin's fields had a greater abundance of spiders than the crop area, while stink bugs, predatory bugs and ladybugs were more abundant inside the crop. Abundance of many predators in soybean was positively associated with their abundance in the margins. Our results contribute to understand the relative importance of agricultural practices at different scales towards the sustainable management of these pests.

Priming of Beauveria bassiana spores to enhance biocontrol of the red-banded stink bug Piezodorus guildinii

Authors: Altier Nora[3], Sessa Lucía[2], Abreo Eduardo[2] and Pedrini Nicolás[1], [1]INIBIOLP, Universidad Nacional de La Plata. Argentina, [2]Instituto Nacional de Investigación Agropecuaria. INIA. Uruguay, [3]Instituto Nacional de Investigación Agropecuaria. INIA. Uruguay, Uruguay

Abstract: The hydrocarbon layer of the insect epicuticle represents the first barrier to infection by entomopathogenic fungi such as Beauveria bassiana. The aim of the present research was to study the effect of hydrocarbon nutrition on virulence and gene expression of two B. bassiana strains (ILB308-high and ILB299-low virulence) towards Piezodorus guildinii, a hemipteran highly resistant to infection. Strains were grown on minimal media (MM) with n-pentadecane as sole carbon source (HC15); Piezodorus guildinii insects were inoculated by immersion and mortality was recorded daily for 12 days. The expression of genes involved in either spore viability and osmolarity, spore adhesion, hydrocarbon assimilation or oxidative stress was evaluated by qRT-PCR. Strain ILB308 showed an increase on its virulence towards P. guildinii as well as early over-expression of mostly all evaluated genes. The low virulence strain -ILB299- also showed an increase on its virulence when grown on HC15, but the overexpression of genes relevant to infection and HC degradation metabolism was low and delayed in time. In conclusion, gene induction patterns (identity, time, and level of induction) are different in both strains and correlate well with the different virulence enhancement patterns exhibited on P. guildinii.

Insect-specific virus-arbovirus interactions in mosquitoes

Authors: Altinli Mine[5], Agboli Eric[2], Schnettler Esther[4], Schulze Jonny[7], Hermanns Kyra[1], Leggewie Mayke[3] and Junglen Sandra[6], [1]1- Institute of Virology, Charité – Universitätsmedizin Berlin, corporate member of Free University Berlin, Humboldt-University Berlin, and Berlin Institute of, [2]1-Molecular Entomology, Molecular Biology and Immunology Department, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany; 2-Department of Epidemiology and Biostatistics, School of Public Health, University of Health and Allied Sciences, Ghana, [3]1-Molecular Entomology, Molecular Biology and Immunology Department, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany; 2- German Centre for Infection research (DZIF), partner site Hamburg-Lübeck-Borstel-Riems, Hamburg, Germany, [4]Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany German Centre for Infection research, partner side Hamburg-Lübeck-Borstel-Riems, Germany, [5]Bernhard Nocht Institute for Tropical Medicine; German Centre for Infection research, partner side Hamburg-Lübeck-Borstel-Riems, Germany, [6]Charité Universitätsmedizin Berlin, Germany, [7]Molecular Entomology, Molecular Biology and Immunology Department, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany

Abstract: Virus discovery has long depended on outbreaks, and the research to understand their pathogenicity depended on their isolation and culture. Due to the persistent nature of their infections, the ubiquity and diversity of insect-specific viruses of mosquitoes have been only discovered following the recent advances in sequencing technologies. While the interactions of these viruses with arboviruses raised scientific interest in insect-specific viruses, these interactions are usually studied in acute infections and not in persistently infected hosts. In this study, we focus on a recently isolated insect-specific virus Agua-Salud Alphavirus (ASALV, Togaviridae). We studied the interactions of ASALV with different arboviruses and have observed differences in the interference capacity of ASALV with arboviruses depending on its infection status (acute versus persistent). ASALV was able to interfere with the replication of two different arboviruses, but only in the case of ASALV persistent infection. No difference in arbovirus replication was observed in the case of simultaneous co-infection of ASALV and the arboviruses. Further research is needed to understand the mechanisms behind these interactions.

The RNAi response in vector mosquitoes against mosquito-specific viruses versus arboviruses

Authors: Altinli Mine[3], Schnettler Esther[3], Kohl Alain[5], Hermanns Kyra[1], Varjak Margus[5], Badusche Marlis[3], Leggewie Mayke[2], Junglen Sandra[4] and B. Sreenu Vattipally[5], [1]1- Institute of Virology, Charité – Universitätsmedizin Berlin, corporate member of Free University Berlin, Humboldt-University Berlin, and Berlin Institute of, [2]1-Molecular Entomology, Molecular Biology and Immunology Department, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany; 2- German Centre for Infection research (DZIF), partner site Hamburg-Lübeck-Borstel-Riems, Hamburg, Germany, [3]Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany German Centre for Infection research, partner side Hamburg-Lübeck-Borstel-Riems, Germany, [4]Charité Universitätsmedizin Berlin, Germany, [5]MRC-University of Glasgow Centre for Virus Research, Glasgow, Scotland, United Kingdom

Abstract: Mosquito-specific viruses (MSVs) often share several similarities with arboviruses, but are, in contrast to arboviruses, restricted to their mosquito host. All findings support a worldwide distribution of MSVs in a variety of mosquito species, including important arbovirus vector mosquitoes.

RNA interference has been shown to be one, if not the most important antiviral response in mosquitoes against arboviruses and linked to vector competence. Although, for some MSVs it was shown that they also induce and interfere with the RNAi response, little is known about this interaction for most MSVs, especially the ones sharing strong similarities to arboviruses. Besides, it is unclear whether the interaction between MSVs and the mosquito vector could in turn have an effect on a potential co-infection with an arbovirus. Comparing the interaction of an arbovirus and a MSV, belonging to the same virus genus, with the mosquito RNAi response is important to understand potential effects on vector competence of mosquitoes for arboviruses.

Knockdown experiments of key proteins of the different RNAi pathways (siRNA, miRNA and piRNAs) in Ae. aegypti derived cells are performed followed by infection with the mosquito specific Agua Salud Alphavirus (ASALV). Effects on ASALV infection are compared to results of arbo-alphaviruses (e.g. Chikungunya virus and Semliki Forest virus). Moreover, production of virus specific small RNAs in infected cells is investigated.

Similar to arbovirus infection, the siRNA pathway is triggered by ASALV infection and has antiviral activity. Surprisingly, an antiviral effect was also observed for the miRNA pathway in case of ASALV, not seen for the arbovirus infections. Results regarding the piRNA pathway, showed an antiviral activity for Piwi4 for MSV and arboviruses; however, no ASALV-specific piRNAs could be detected.

Taken together, these results highlight important differences between the interactions of the mosquito with MSVs versus arboviruses.

Field-evolved resistance to Bt Crops in Latin America

Authors: Alves Analiza, Corteva Agriscience

Abstract: Fall armyworm, Spodoptera frugiperda (J.E. Smith) is one of the most destructive maize pests in the tropical zone of the American Continent, causing significant yield losses under moderate-high infestations. Historical S. frugiperda management in South America relied on plant protection with synthetic insecticides, ranging from 1-10 applications per crop cycle, depending on pest pressure and crop system management. More recently, genetically modified maize plants expressing insecticidal Bt proteins gained significant role in managing this pest in the region due to its effectiveness. Nonetheless, local environment, landscape, and agricultural practices can create intense selection pressure favoring resistance development to chemistries and biotech traits, representing a significant challenge to effective long-term control of this pest. Short term financial and food security goals driving maximization of land productivity in large monoculture agricultural systems with potential extraction of two to three crops per year impose strong selection pressure through an environment biologically accelerated. Understanding regional landscape, pest ecology, insect-crop/trait interactions, and genetic variability is fundamental for deployment of effective, locally adapted practices. The utilization of a variety of control tactics is key for sustainable management and cropping systems. The biggest challenge is balancing economic, environmental, and social aspects of sustainability at the local level.

Crop pollination by nocturnal bees

Authors: Alves dos Santos Isabel[4], Inês Silva Claudia[4], Schlindwein Clemens[2], Krug Cristiane[1], Duran Cordeiro Guaraci[3], Oliveira Reisla[2], Mateus Sidnei[4] and Dötterl Stefan[3], [1]Embrapa, Manaus, Brazil, [2]University of Minas Gerais (UFMG), Brazil, [3]University of Salzburg, Austria, [4]University of São Paulo, Brazil

Abstract: Most bees are active during the day. However, approximately 1% of the bee species are nocturnal and forage in search for flowers during the low light intensities of the night, between sunset and sunrise. They account for about 250 species and are distributed among the families: Andrenidae, Apidae, Colletidae and Halictidae. We evaluate the role of nocturnal bees in the pollination of “cambuci”, Campomanesia phaea, Myrtaceae, and “guarana”, Paullinia cupana, Sapindaceae, both economically highly important plants of the Brazilian Atlantic Rainforest and Amazon, respectively. Furthermore we collected floral volatile from the host plants using dynamic headspace method and tested if these compounds were capable of attracting nocturnal bees in the field. Synthetic scent mixtures that contained various of the identified floral scent components, successfully attracted nocturnal bee pollinators. Our data show that cambuci and guarana attract their nocturnal bees by strong floral scents and suggest that the chemical communication between these plant and their pollinators is a key step in crop production of these economically important plant species.

Insect role in transmitting Dickeya dianthicola among potato plants

Authors: Alyokhin Andrei[1], Hao Jianjun[2] and Insinga Jonas[1], [1]School of Biology and Ecology, University of Maine, United States, [2]School of Food and Agriculture, University of Maine, United States

Abstract: The blackleg bacterium Dickeya dianthicola Samson is an important pathogen of potato, Solanum tuberosum, in North America and Europe. Previous work has suggested that insects, particularly aphids, may be able to vector bacteria in this genus between plants. However, no empirical work was conducted to evaluate their epidemiological role in transmitting this disease on commercial potato fields. We tested vector potential of the two potato pests most common in most temperate growing areas: the Colorado potato beetle (Leptinotarsa decimlineata Say) and the green peach aphids (Myzus persicae Sulzer).

Olfactometry and recruitment experiments evaluated if either insect discriminates between infected and uninfected foliage. Infection was determined using visual symptoms and genus-level PCR primers for Dickeya. In the laboratory, beetles and aphids were fed infected plants and then transferred to uninfected plants to determine if bacteria would be transmitted between plants. In the field, insect densities were manipulated to correlate them with the incidence of the disease.

Neither Colorado potato beetles nor green peach aphids were attracted to infected foliage in either olfactometry or recruitment experiments. To the contrary, presence of butanediol, which is product of Dickeya fermentation, significantly reduced beetle attraction to the odor of potato foliage. Green peach aphids preferred uninfected foliage, but only when conspecifics were present. Neither Colorado potato beetles nor green peach aphids acquired and transmitted D. dianthicola through feeding on infected plants in the laboratory. In the field, neither insect’s abundance correlated significantly with the spread of this disease. Therefore, controlling these pests is unlikely to prevent blackleg outbreaks in potato fields. Instead, the efforts to limit spread of this disease should focus on sanitation, water management, and seed screening.

Endogenous insect resources for a more sustainable aquaculture

Authors: Ameixa Olga[5], Duarte Pedro[2], Lillebø Ana[1], Maciel Elisabete[3], Pinho Marisa[1], Calado Ricardo[1] and Domingues Rosário[4], [1]Department of Biology & CESAM & ECOMARE, University of Aveiro, Portugal, [2]Department of Biology & CESAM, University of Aveirol, Portugal, [3]Department of Chemistry & CESAM, University of Aveiro, Portugal, [4]Department of Chemistry & CESAM, University of Aveiro; Mass Spectrometry Center, Department of Chemistry, University of Aveiro, Portugal, [5]University of Aveiro, Portugal

Abstract: The future and the ability of the world food system to ensure food security for a growing world population are closely tied to improve the protection of natural resources, and in the delivery of alternative sustainable protein sources. The need for more sustainable feedstuffs in the aquaculture sector has determined the use of alternative food sources, and in this context, insects have been investigated as potential ingredients. However, nutritional profiles of commonly studied insects lack important nutrients for marine organisms. Here, we show how endemic costal insect species may contribute to overcome this gap and contribute to improve the nutrition of aquaculture marine species.

Hermetia illucens egg volatile signalling and its relevance for mass-scale production

Authors: Ameixa Olga[2], Rodrigues Daniela[1] and Calado Ricardo[1], [1]Department of Biology & CESAM & ECOMARE, University of Aveiro, Portugal, [2]University of Aveiro, Portugal

Abstract: Available data on oviposition behaviour of H. illucens, one of the most important insect species reared for food and feed, is scarce and highlights the variability associated with oviposition in this species reinforcing the need to gain additional knowledge on this topic to achieve economically feasible mass-scale production. Here we provide a first screening of the volatile organic fraction of H. illucens eggs from oviposition to hatching, shedding light over the temporal evolution of semiochemicals composition, a knowledge which can contribute to advance the state of the art on H. illucens mass-scale production.

Can insect pests be controlled using antifungal lipopeptides?

Authors: Ameline Arnaud[5], DENOIRJEAN Thomas[2], Hance Thierry[1], Cherqui Anas[4], Coutte François[3] and Doury Géraldine[4], [1]UCLouvain, Belgium, [2]UMR CNRS 7058 EDYSAN, Université de Picardie Jules Verne, France, [3]University of Lille, INRA, ISA, University of Artois, University Littoral Côte d'Opale - Charles Viollette Institute, France, [4]University of Picardie Jules Verne - UMR CNRS 7058 EDYSAN (Écologie et Dynamique des Systèmes Anthropisés), France, [5]University of Picardie Jules Verne - UMR CNRS 7058 EDYSAN (Écologie et Dynamique des Systèmes Anthropisés), France

Abstract: The development of organic agriculture and the increasing restriction on pesticide use have impulsed a growing interest to develop new strategies of weeds, pathogens and pests control. Bacteria are well identified sources of biocontrol molecules, among which lipopeptides exhibit interesting properties such as broad spectrum of activities (Ongena and Jacques, 2008) and biodegradability. Although lipopeptides produced by Bacillus subtilis show well-documented anti-bacterial and anti-fungal properties, the number of studies on their putative insecticidal effects remain scarce (Guo et al., 2015) despite a growing interest to develop ecofriendly alternatives for plants protection. Aphids are major pests causing great damages to vegetable crops and orchards either because of their direct action by sap sucking, or indirectly by the transmission of viruses. We compared the effects of three different lipopeptides families (fengycin, mycosubtilin and surfactin) produced by B. subtilis strains, on Myzus persicae (a polyphagous aphid) and Dysaphis plantaginea, the major aphid pest of apple trees. Two modes of exposure were used, either by topical application or by ingestion using artificial diet with different lipopeptide concentrations. The effects of each lipopeptide were assessed on aphid survival and fertility. The results are discussed in the context of versatile molecules combining both pests and pathogens biocontrol properties in a management program.

Companion planting involving Amaryllidaceae (ex. Alliaceae): a strategy for aphid pest control?

Authors: Ameline Arnaud[5], Couty Aude[1], Doury Géraldine[5], Lateur Marc[2], van Havermaet Robin[4], Baudry Xavier[3] and van Begin Xavier[6], [1]CNRS / University Picardie Jules Verne, France, [2]CRA-W. Walloon Agricultural Research Center. Gembloux, Belgium, [3]Edysan, Ecology and Dynamics of Human-influenced Systems, UMR CNRS 7058 University of Picardy Jules Verne., France, [4]Research station for vegetable production, Sint-Katelijne-Waver, Belgium, [5]University of Picardie Jules Verne - UMR CNRS 7058 EDYSAN (Écologie et Dynamique des Systèmes Anthropisés), France, [6]Xavagri, Belgium

Abstract: “Companion planting” is one specific type of polyculture, under which two plant species are planted together that are known, or believed, to synergistically improve one another’s growth trait. This kind of plant association can help to control insect pests either directly, by disturbing pest settling and/or indirectly, by attracting natural enemies. Some plants belonging to the Alliaceae family (chives, garlic, onion, leek) release Volatile Organic Compounds (VOC) with strong repellent potentialities. The aim of this work was to investigate the disturbance of aphid pest colonization behavior when submitted to putative repellent plant or essential oil extracts. Plants selected in our experiments belong to species conventionally grown in the field or in greenhouses in the Hauts de France Region and Belgium. The companion plants belong to Alliaceae, whereas pepper was the target plants. The positive control consists of submitting volatils from Alliaceae extract to the pest – plant target system. EPG technique and Clip cage experiments were used to assess the effects of companion plant vs essential oil extract VOC on the feeding behavior and demographic parameters of aphids when feeding on the target plants. Results are discussed in the context of environmentally friendly and sustainable pest management strategies.

Insect decline – an issue in forensic entomology?

Authors: Amendt Jens, Institute of Legal Medicine, Goethe-University am Frankfurt, Germany

Abstract: At the end of 2017, a study showed a significant decline in insect populations within the last 27 years in German nature reserves. This was a scientific validation of what many had long since subjectively perceived: a widespread reduction in insect abundance. Insects play a key role in terrestrial ecosystems and perform important ecosystem functions and services such as pollination, the formation of important linkages in food webs or the disposal and recycling of dead organisms. The latter builds the bridge to forensic entomology (FE) and its use of necrophagous insects, degrading the dead organic matter, here: human bodies. Statements in the media give the impression that insect decline threatens FE. However, no reliable data on this exist at this time. Numerous factors of insect decline are discussed, such as the intensification of agriculture with increased pesticide consumption and the establishment of large monocultures, are of questionable relevance for necrophagous insects. In addition, the main application of FE is mainly based on the analysis of an insect complex that can be described as “species-poor”, focusing on a few polyvoltin species with an extremely high reproductive potential. In accordance with these assumptions, our own studies over the last 20 years at the institute of legal medicine in Frankfurt/Germany show no significant changes in the diversity and abundance of these species on human bodies and in the field. However, it cannot be ruled out that this will change in the coming years, not least because of the challenges associated with climate change such as e.g. prolonged heat waves or the dispersal of invasive species. This could lead to a shift in phenology patterns and abundances of forensically relevant taxa.

50 shades of green – a case-based introduction to the insect infestation of the living and the dead

Authors: Amendt Jens[2], Lutz Lena[1], [1]Goethe-University, Germany, [2]Institute of Legal Medicine, Goethe-University am Frankfurt, Germany

Abstract: Forensic entomology uses insects to draw conclusions on legal matters. The main emphasis is on estimating the minimum post-mortem interval (PMImin) by determining the age of the juvenile insect stages developing on a corpse. It is highly useful when human remains are found more than 72 hours after death, at a point when forensic pathological approaches are no longer appropriate to determine the time of death. Forensic entomology can also help in the detection of neglect, where living people are infested with insects. Such infestation of live vertebrates (humans and/or animals) with dipterous larvae, which feed at least for a certain period of time on the host's dead or living tissue is defined as myiasis. Since 2001 the Institute of Legal Medicine Frankfurt am Main analyses insect infested bodies and research on necrophagous taxa, supports death investigations at the crime scene and during autopsies, and delivers entomological reports to answer questions of legal interests. To proof the importance of forensic entomology we evaluated insect associated cases from 2001 to 2019 (n = 852). Sex and age of the deceased, date of autopsy and discovery, place of finding (indoor or outdoor), supposed post mortem interval (PMI) (based on the time last seen or other hints such as newspapers, letters or neighbors' statements), and the cause of death were noted. Overall more dead bodies were found indoor (82 %) than outdoor (18 %) regardless of year and month and the majority were male (70 %) and in the age of 60 – 70 years. From June to August, i.e. summer months and typical blow fly season the most bodies were found, while in winter December to March only a few bodies were colonized. In more than 70 % of all cases the PMI ranged from one day to three weeks, so that in these cases it would have been possible to estimate the PMImin to the day on the basis of entomological findings. In about half of the cases the person died of natural causes (e.g. cardiac failure) but in many cases a clear cause of death was not visible due to external and internal decay of the body. Detailed information on insect species and diversity was available for about 25% cases. There were over 20 frequent insect taxa, of which the blow flies Lucilia sericata and Calliphora vicina were the most dominant species. There was a seasonal trend in the occurrence of the two species, with L. sericata being active in the summer months and C. vicina colonizing carcasses mainly in spring, autumn and winter, i.e. during the colder period of a year.

When it comes to the infestation of the living, most cases have been neglect in a domestic environment where people were overstrained with the care of their relatives. The relevant species differed according to where the living or meanwhile deceased person was found. While blowflies and here Lucilia sericata dominated the outdoor cases, mainly Muscidae colonized the bodies indoors. Musca domestica was the most common species here.

Intercepted Mosquitoes at New Zealand's Ports of Entry, 2001 to 2018: Current Status and Future Concerns

Authors: Ammar Sherif[5], Derraik José[2], Kasper Julia[3], McIntyre Mary[4], Baker Michael[4], Hales Simom[4] and Swan Tom[1], [1]Australian Institute of Tropical Health and Medicine, James Cook University, Queensland, Australia, [2]Liggins Institute, University of Auckland, Auckland, New Zealand, [3]Museum of New Zealand, Te Papa Tongarewa, Wellington, New Zealand, [4]University of Otago, New Zealand, [5]University of Otago, New Zealand

Abstract: Mosquito vectors are extending their range via international travel and trade. Climate change makes New Zealand an increasingly suitable environment for less tropically adapted exotic mosquito vectors to become established. This shift will add a multiplier effect to existing risks of both the establishment of new species and of resident exotic species extending into new areas. We describe trends in the border interceptions of exotic mosquitoes and evaluate the role of imported goods as a pathway for these introductions. Ae. aegypti and Ae. albopictus, the two most commonly intercepted species, were only intercepted in Auckland. Used tyres and machinery were the main mode of entry for both species. The majority of Ae. albopictus were transported as larvae by sea, while most Ae. aegypti were transported as adults by air. Continuing introductions of these mosquitoes, mainly arriving via Japan or Australia, increase the risk of the local transmission of mosquito-borne diseases in New Zealand in general and in the Auckland region in particular. These findings reinforce the need for a high performing and adequately resourced national biosecurity system, particularly port surveillance and inspection. Recommended biosecurity improvements are described.

Invasions old and new: reconstructing the spread of winter moth (Operopthera brumata) in Europe and North America

Authors: Andersen Jeremy[1], Elkinton Joseph[2], Caccone Adalgisa[4] and P. Havill Nathan[3], [1]Department of Environmental Conservation, University of Massachusetts Amherst, United States, [2]Department of Environmental Conservation, University of Massachusetts, Amherst, United States, [3]Northern Research Station, USDA Forest Service, Hamden, CT, United States, [4]Yale University, United States

Abstract: Native to Europe, outbreaks of the invasive geometrid Operophtera brumata (winter moth) have in recent times been reported in geographically isolated populations including Northern Scandinavia (1900s), Nova Scotia (1930s), Oregon (1950s), the Pacific Northwest (1970s), Northern Africa (1970s), and New England (1990s). Using a combination of phylogenetic and population genetic techniques, we explore the evolutionary history of winter moth populations across four continents to unravel 1) the ancestral origins of this species; 2) the use of glacial refugia in Europe and Africa during the Last Glacial Maximum (LGM); and 3) the contemporary origins of invasive winter moth populations. Using coalescent species tree analyses based on DNA sequences from three nuclear loci (28S, EF1?, and Wingless) and one mitochondrial locus (COI) we find that winter moth is more closely related to Asian species in the genus Operophtera than to European or North American species, and that it likely diverged from species found in Japan and Eastern Russian between 400,000 and 1.4 million years ago suggesting that winter moth is a relatively new addition to the European ecological community. To explore the use of glacial refugia during the LGM as well as the contemporary origins of invasive species in Northern Africa, Northern Scandinavia, and North America, we amplified 24 polymorphic microsatellite loci and conducted Approximate Bayesian Computation (ABC) simulations. These simulations indicate that 1) the invasive population in Northern Africa is native to the region, and likely established in the North African refugium during the LGM; 2) that outbreaks in Northern Scandinavia are caused by a population that likely migrated along the coast of Norway from the British Isles following the retreat of glacial ice sheets after the LGM, and 3) that invasive populations in North America are the result of at least three separate introductions from geographically distinct source populations.

Real-time witness to formation of a hybrid zone between non-native winter moth and native Bruce spanworm

Authors: Andersen Jeremy[1], Elkinton Joseph[2], Havill Nathan[3], Caccone Adalgisa[4], [1]Department of Environmental Conservation, University of Massachusetts Amherst, United States, [2]Department of Environmental Conservation, University of Massachusetts, Amherst, United States, [3]USDA Forest Service, Northern Research Station, United States, [4]Yale University, United States

Abstract: The European winter moth, Operophtera brumata (Lepidoptera: Geometridae), is an invasive species in North America which is known to hybridize with a related native species, Bruce spanworm, O. bruceata. We genotyped thousands of moths across a hybrid zone in New England using polymorphic microsatellite loci from 2007-2018. This period captured the time when the hybrid zone was settling on the landscape. This study is a unique glimpse at hybrid zone formation in nature and may provide insight into the impacts of hybridization between native and non-native species on biological invasions.

Functional characterization of odorant receptors in the spruce bark beetle Ips typographus and prediction of their ligand binding site

Authors: Andersson Martin[1], Löfstedt Christer[1], K. Yuvaraj Jothi[1], Roberts Rebecca E.[1], Johanson Urban[1], Hou Xiaoqing[1] and Sonntag Yonathan[1], [1]Lund University, Sweden

Abstract: The European spruce bark beetle (Ips typographus L.) causes severe destruction of spruce (Picea abies) forests across large parts of Europe. Improved pest management is urgently needed, and one avenue towards this aim could be to target the odorant receptors (ORs), which are used by the beetles to find mates and hosts. Hence, we sequenced an antennal transcriptome, and identified 73 ORs of which 52 ORs were present as full-length sequences. Functional characterization of two of these ORs in HEK293 cells and Xenopus oocytes revealed highly selective responses to pheromone compounds that are used by several bark beetle species in chemical communication. Homology modelling and ligand docking simulations were performed to predict the ligand binding sites of these ORs. Site-directed mutagenesis targeting two of the amino acid residues that were predicted to be central for the binding, abolished the response to pheromone, demonstrating a key functional role of these residues. The characterization of the two ORs and their putative ligand binding sites is an important first step towards OR-targeted control of bark beetles because these ORs can be screened for better agonists or antagonists, or be employed in biosensors for early detection of bark beetle infestations.

Food webs associated with epigeal predators in an integrated crop-livestock-forestry system in Brazil

Authors: Andow David[2] and Pires Paula Debora[1], [1]Embrapa-Cenargen, United States, [2]University of Minnesota

Abstract: We conducted a large-scale experiment manipulating vegetational diversity and evaluate the effects on the epigeal natural enemy community. We used molecular gut content analysis to determine what the most common predator species were consuming to determine how these predators might contribute to pest suppression. We tested four hypotheses: (1) the vegetationally diverse production system has higher predator species richness at higher abundance than the other systems; (2) the predator community composition of the diverse system will overlap the community composition of all of the other production systems; (3) the predators in the diverse system will have more prey and more herbivore prey than in the other systems; (4) the prey consumed in the diverse system will overlap the prey consumed in all of the other production systems. In addition, we describe a food web associated with 15 common predators in this study. We will discuss the implications of our findings.

Integrating adverse effect analysis into environmental risk assessment for exotic generalist arthropod biological control agents: a three-tiered framework

Authors: Andow David[3], Pires Paula Debora[1], van Lenteren Joop[5], Barratt Barbara[2] and Pfannenstiel Robert[4], [1]Embrapa-Cenargen, United States, [2]Resilient Agriculture, [3]University of Minnesota, [4]USDA-APHIS-PPQ, [5]Wageningen University, Netherlands

Abstract: Environmental risk assessments (ERAs) are required before utilizing exotic arthropods for biological control (BC). Generalist arthropod BCAs (GABCAs) have been considered inherently risky and less used in classical biological control. To safely consider exotic GABCAs, an ERA must include methods for the analysis of potential effects. A panel of 47 experts from 14 countries discussed, in six online forums over 12 months, scientific criteria for an ERA for exotic GABCAs. Using four case studies, a three-tiered ERA comprising Scoping, Screening and Definitive Assessments was developed. In the Scoping Assessment, likelihood of establishment (for augmentative BC), and potential effect(s) are qualitatively assessed. If risks are identified, the Screening Assessment is conducted, in which 19 categories of effects (adverse and beneficial) are quantified. If a risk exceeds the proposed risk threshold in any of these categories, the analysis moves to the Definitive Assessment to identify potential non-target species in the respective category(ies). When at least one potential non-target species is at significant risk, long-term and indirect ecosystem risks must be quantified with actual data or the petition for release can be dismissed or withdrawn. The proposed ERA should contribute to the development of safe pathways for the use of low risk GABCAs.

A study case of invasion of Aleurocanthus camelliae cryptic species in Japan: Identification, symbionts infection, and wasp parasitism

Authors: Andrianto Eko[2] and Kasai Atsushi[1], [1]Shizuoka University, [2]UGSAS Gifu University, Japan

Abstract: Aleurocanthus camelliae (Camellia spiny whitefly) is an invasive whitefly pest of tea and is considered a cryptic species due to its similarity with Citrus spiny whitefly, A. spiniferus. Both species originated from China and were intercepted in Japan in 2004 and the early 1920s, respectively, and they were separated by host preference. Recently, A. camelliae which is predominantly parasitized Theaceae plants has been also detected in Netherland (2018), Italy (2020), and Indonesia (2020). This cryptic species is divided at least into 3 morphospecies, i.e., A. camelliae, consisting of 3 haplotypes; A. spiniferus, consisting of 2 haplogroups; and A. woglumi. Due to morphologically indistinctive, we then characterized the detection of cryptic species by the symbionts infection. This study revealed the novel cryptic species of Japan on Eurya japonica (Theaceae) which harbor different strains of Portiera, the primary symbiont of whiteflies. Moreover, unlike A. camelliae which is highly Wolbachia infected whiteflies, whiteflies belonging to A. spiniferus morphospecies tend to be Wolbachia uninfected populations. In addition, a new record of Eretmocerus wasp in A. camelliae has been discovered. Using a multiplex PCR, the existence of parasitism was confirmed in January 2020. The bacterial symbiont-based detection of A. camelliae cryptic species and new potential parasitoid wasp are discussed.

Role of ovipositor and sensory cues in short-range host selection by Drosophila suzukii

Authors: Anfora Gianfranco, Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy

Abstract: Drosophila suzukii is an invasive pest native to Eastern Asia able to lay eggs on undamaged ripening fruits, rather than in fermenting substrates like most other Drosophila species. This ability is due to the exploitation of visual, olfactory, and tactile cues for the location of the best oviposition site and to the presence of an enlarged and serrated ovipositor. In a series of studies, we explored the sensory system of the ovipositor of D. suzukii, comparing it to that of closely related species, and elucidated some behavioral and chemical aspects of short-range site selection of this species. We first sequenced the ovipositor transcriptome in D. suzukii and in three Drosophila species characterised by progressive changes in oviposition behaviour and revealed a set of gustatory and ionotropic receptors conserved among the four Drosophila species. We therefore tested the occurrence of chemosensory neurons in D. suzukii ovipositor using an anti-horseradish peroxidase antibody to target presence and shape of neuronal structures: results indicate that neurons associated with D. suzukii ovipositor spines have mechanosensory function. Further analysis of morphology and ultrastructure support the hypothesis that these structures are involved in mechanoreception and are likely used to test the stiffness of substrates. We also demonstrated that D. suzukii preferred to lay eggs on already egg-infested fruits instead of artificially-pierced or intact ones. Video recordings of ovipositional behaviour evidenced the release of an anal secretion over the fruit surface near the oviposition site. Choice and non-choice tests indicated oviposition preference towards egg-infested fruits, suggesting a role of the released liquid as a marking pheromone attracting multiple ovipositions. The knowledge gained with these studies may accelerate establishment of control strategies based on the interference and disruption of the processes involved in D. suzukii egg-laying site selection.

Multifaceted sublethal effects of insecticide microdoses on the orientation of the spotted wing Drosophila

Authors: Anfora Gianfranco[1], Biondi Antonio[2], Cavallaro Carmelo[2], P Strano Cinzia[2], Lisi Fabrizio[4], Zappalà Lucia[2], Scala Marica[4], Ricupero Michele[2] and Desneux Nicolas[3], [1]Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy, [2]Department of Agriculture, Food and Environment, University of Catania, Italy [3]INRAE, France

Abstract: Exposure to sublethal doses of insecticides can result in various physiological and behavioral traits of the exposed organisms. Insect pests have evolved fine mechanisms for host detection and among these the orientation towards host-borne volatiles are of paramount importance for pest reproduction and thus for yield losses. The spotted wing drosophila (SWD), Drosophila suzukii (Matsumura) (Diptera: Drosophilidae), is a devastating invasive pest of soft-skinned fruits. In this context, we first characterized the baseline toxicity of four neurotoxic insecticides through ingestion during larval development and via adult residual exposure. Then, the estimated lethal doses 10% (LD10) for the four chemicals were used to carry out a multilevel analysis of their sublethal effects on orientation behavior. Olfactometer, electroantennographic (EAG) and olfaction gene expression experiments were carried out on insects survived to the exposure. The resulting LD10s proved to be extremely lower than insecticide label doses and, more interestingly, the exposure to these microdoses strongly impaired the host location capacity in exposed flies. The results strongly support the need to comprehensively study the potential sublethal effects of agrochemicals, even at very low doses, on key biological traits.

Exploitation of population dynamics and chemical communication for integrated management of Drosophila suzukii

Authors: Anfora Gianfranco[1], Tait Gabriella[4], Grassi Alberto[3], Cabianca Alessandro[3], Crava Cristina[6], Pfab Ferdinand[7], Ometto Lino[5], Valerio Rossi-Stacconi Marco[4], Mermer Serhan[4] and Walton Vaughn[2], [1]Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy, [2]Department of Horticulture, Oregon State University, Agriculture and Life Sciences Building, Corvallis, Oregon, United States, [3]Edmund Mach Foundation, Italy, [4]Oregon State University, United States, [5]Pavia University, Italy, [6]Universitat de València, Spain, [7]University of California, United States

Abstract: Drosophila suzukii (Matsumura), also known as Spotted Wing Drosophila (SWD), is a vinegar fly belonging to the Diptera order and Drosophilidae family. It is native to South East Asia and it has recently invaded western countries, affecting fruit production. Because of its rapid spread, the economic impact has been huge in most of the invaded countries. SWD infestations generate direct and indirect economic impacts, through yield losses, shorter shelf life of infested fruits, extra labour and costs for monitoring, field sanitation and post-harvest handling. For all these reasons, deeper information about the biology, ecology, chemical-ecology, genetics and behavior are necessary to better manage the species. In the last four years a lot of work was developed by us to contribute towards a better understanding of these topics, in order to find a scientifically supported and effective solution. In particular, our work focused on three aspects: 1) understand the spread and therefore the capacity of movement of SWD in large and small scale, 2) study the chemical aspects of short-range ovipositional site selection within the context of D. suzukii reproductive biology and 3) manipulate the egg-laying behavior thanks to an innovative technology, which is able to attract and arrest flies on alternative substrate by therefore, reducing the egg-infestation level in the crop. Understanding seasonal and daily migrations SWD populations is fundamental, since it could help farmers and industries decide where to apply specific management techniques. We found that abiotic factors, such as temperature and humidity, as the food availability, play a fundamental role in the environmental distribution of the species. The finding of a consistent seasonal and daily movement from the crop to the surrounding vegetation and towards areas with different altitude, recorded by our works, may lead to use treatments, especially chemical, in precise periods of the year and in defined zones on the border of the crop. The dispersal movement of SWD is also highly dependent and affected by the odors emitted by conspecific individuals, by other insect species and by plants. By performing a study on the anal secretions release after oviposition by SWD females, we were able to identify some specific volatiles which attract, arrest SWD flies and stimulate the release of eggs to the already egg-infested berries. Using these knowledges, we identify specific plants which produce the same volatiles. By mixing these plant extracts with more ingredients, we developed a new technology able to arrest SWD flies on an alternative matrix substrate and reduce the infestation level on berries. This promising approach was tested in laboratory and open field condition on blueberry, cherry, strawberry, cranberry and grapes. Taken together, the results contribute to enhance our understanding of SWD biology, ecology and chemical and to expand integrated pest management options.

Innovation in solitary bees is driven by exploration, shyness and activity levels

Authors: Ángel Collado Miguel[2], Sol Daniel[1], Bartomeus Ignasi[3] and Menzel Randolf[4], [1]CREAF - Research Center of Ecology and Forestal Resources, Spain, [2]EBD - Doñana Biological Station CREAF - Research Center of Ecology and Forestal Resources, Spain, [3]EBD - Doñana Biological Station, Spain, [4]FU Berlin - Free University of Berlin, Germany

Abstract: Behavioural innovation is widely considered an important mechanism by which animals respond to novel environmental challenges, including those induced by human activities. Despite its functional and ecological relevance, much of our current understanding of the innovation process comes from studies in vertebrates. Understanding innovation processes in insects has lagged behind partly because they are not perceived to have the cognitive machinery required to innovate. This perception is however challenged by recent evidence demonstrating sophisticated cognitive capabilities in insects despite their small brains. Here, we study the innovation capacity of a solitary bee (Osmia cornuta) in the laboratory by exposing naïve individuals to an obstacle removal task. We also studied the underlying cognitive and non-cognitive mechanisms through a battery of experimental tests designed to measure learning, exploration, shyness and activity levels. We found that solitary bees can innovate, with 11 of 29 individuals (38%) being able to solve a new task consisting in lifting a lid to reach a reward. The propensity to innovate was uncorrelated with learning capacities, but increased with exploration, boldness and activity. These results provide solid evidence that non-social insects can innovate, and highlight the importance of interpreting innovation in the light of non-cognitive processes.

The clades of the Palaearctic Hydrobius fuscipes species group – chromosomes and morphology

Authors: Angus Robert[3], Bilton David[4], van Berge Henegouwen Arno[1] and Jia Fenglong[2], [1]Museon, The Hague, Netherlands, [2]Museum of Biology, Sun Yat-sen University, Guangzhou, Guangdong, China, [3]Scientific Associate, Insects Division, Life Sciences Department, Natural History Museum, London, United Kingdom, [4]University of Plymouth, United Kingdom

Abstract: DNA analysis of Hydrobius fuscipes (L.). sensu lato by Fossen et al. (2016) has demonstrated the existence of at least nine distinct clades, some of which have already been given names as separate species.
Chromosomally Hydrobius clades are all very similar, but with some useful distinctions. Clade 1 has a distinctly longer X chromosome than the others, Clade 3 has distinct centromeric C-bands, and H. subrotundus and Clade 7 have interstitial satellite C-bands. Hydrobius chromosomes are difficult to work with, with demonstration of the C-bands tricky. The related Limnoxenus niger has strong centromeric C-bands, but Limnohydrobius convexus has delicate C-bands like Hydrobius but an X-chromosome even longer than that of Clade 1.
Morphologically the Hydrobius taxa divide into a H. arcticus-rottenbergii group in which the aedeagus has the parameres relatively shorter and distinctly incurved apically, and the others in which the parameres are more attenuate and less incurved. Members of this group, with the exception of H. arcticus and the Chinese H. pui, usually have the large trichobothria-bearing punctures on elytral interstices 3 and 5 placed in striae 3 and 5 in the basal sections of the interstices but, as has been pointed out, this character can vary. The H. arcticus-rottenbergii group are all placed in the same (large) section of Fossen et al.'s cladograms, but the others are scattered round the edge. Apart from the aedeagal differences, there are indications that the form of the mentum, especially in males, may be helpful in recognising various clades, and the arrangement of the elytral striae apically also appears promising.
Work led by D. T. Bilton suggests that H. fuscipes and H. subrotundus have very different thermal tolerance ranges. This work proceeds slowly as it is dependant on accurately named (by DNA or in some cases chromosomes) material.

Effects of tree richness, structural variation and leaf traits on herbivory and predation in different local scales in a subtropical BEF-experiment

Authors: Anttonen Perttu[2] and Schuldt Andreas[1], [1]Georg-August-University Göttingen, [2]Martin Luther University Halle-Wittenberg; iDiv institute, Germany

Abstract: Biodiversity loss is one of the most urgent challenges in the world affecting ecosystem functions and ecosystem services. BEF-China is the world's largest BEF (Biodiversity-Ecosystem Functioning) experiment, located in subtropical China. As part of the research consortium TreeDi "Tree Diversity Interactions: The role of tree-tree interactions in local neighborhoods in Chinese subtropical forests", we focused on how tree richness, plant nutritional quality and tree structure affect the herbivory and predation pressure in different spatial-scales in close neighborhoods, going from tree with its immediate neighbors to plot level (~26 x 26 m). Understanding how forest structure and leaf quality affect trophic interactions in relation to tree diversity is important as higher trophic level interactions can strongly affect the structuring and functioning of species-rich forest ecosystems. Our results showed that forest structure and leaf quality affected herbivory and predation, but the effects varied between spatial scales and tree richness levels. Scale dependence of forest structure affected the responses between predator groups (arthropods, birds and mammals). Furthermore, the predator group responses varied in response to tree apparency and vegetation density. The results offer insight into how biodiversity loss of producers affects higher trophic levels in relation to other main features of forest stands.

Cattle intensification as a potential driver of dung beetle diversity and ecosystem services loss: a global experiment

Authors: Ari Noriega Jorge, Department of Biogeography and Global Change, Museo de Ciencias Naturales (MNCN-CSIC), Madrid, Spain

Abstract: Biodiversity provides ecosystem services that sustain human life. However, anthropic disturbance is affecting negatively the diversity, functioning and provisioning of these ecosystem services. One of the main drivers of this effect is land-use intensification, which is an important factor in pastures used for livestock breeding. Dung beetles are important in removing waste on these ecosystems and contributing to the cycling of nutrients. However, their action could be hampered by land-use intensification, impacting negatively their diversity, functional structure, ecosystem services they provide and causing potential local extinctions. In this study we conducted a global multi-site experiment in 24 countries to understand the effect of cattle density on dung beetle diversity and dung removal. For each sampling site selected an area with extensive and another with intensive cattle use, and in each of them we quantified dung removal through an experimental approach, sampled dung beetle's diversity, and quantified functional diversity (FD). Pairwise comparisons were used to evaluate differences in diversity and dung removal of intensive and extensive areas. Structural equation models (SEM) were performed for disentangling the relative importance of cattle intensification, climate, and diversity on dung removal rates. Cattle intensification has an overall negative effect on species richness but not on abundance, evenness, FD, and dung removal. A SEM model, using cow density as a proxy of cattle intensification, shows a direct negative effect of intensification on dung diversity and dung removal. However, in the SEM models built separately for extensive and intensive sites, the main drivers are different; for extensive sites richness and climate affects dung removal, while for intensive sites only abundance drives dung removal. These results highlight the negative impact of land-use intensification on biodiversity and ecosystem services, and the potential loss of biodiversity in a global perspective.

Evolution of diapause across space and time in the invasive mosquito, Aedes albopictus

Authors: Armbruster Peter[1], Mushegian Alexandra[1] and Batz Zachary[1], [1]Georgetown University, United States

Abstract: Invasive species that spread rapidly across broad geographic ranges represent an outstanding opportunity to investigate the temporal dynamics and selective targets of rapid climatic adaptation. The invasive and medically important mosquito, Aedes albopictus, invaded the US in 1985 and rapidly spread across ca. 15 degrees of latitude. Comparison of critical photoperiod (CPP) among populations across latitudinal gradients in both the native (Japan) and invasive (US) ranges has been conducted across 30 years at three time points (3, 23 and 33 years post-invasion). These data are provide a unique spatial and temporal record to investigate the dynamics of rapid adaptive evolution and responses to ongoing global climate change. Additional traits related to climatic adaptation in North American Ae. albopictus, including traits expressed during diapause and traits presumably unrelated to diapause (chill coma recovery), have also been evaluated. Taken together, the results of these experiments demonstrate multiple components of rapid adaptation to climatic variation across the invasive North American range of Ae. albopictus. Mechanistic studies are being performed to determine the underlying molecular and physiological basis of these adaptive changes.

Biological Control of Tuta absoluta from a Mediterranean Prespective

Authors: Arnó Judit[1], Riudavets Jordi[3] and Gabarra Rosa[2], [1]IRTA (Institute of Agrifood Research and Technology), Cabrils (Barcelona), Spain, [3]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain, [2]IRTA, Spain

Abstract: The South American tomato moth, Tuta absoluta (Meyrick) (Lepidoptera:Gelechiidae) is a pest native to South America that produces significant damage to tomato crops and was first detected in Europe in late 2006 in the Mediterranean coastal area of Spain. Soon after the invasion, the Integrated Pest Management (IPM) programs based on biological control shown to be useful for the control of this pest. These programs were based either in the conservation or in augmentative releases of the zoophytophagous predatory mirid bugs Macrolophus pygmaeus (Rambur) and Nesidiocoris tenuis Reuter (Hemiptera: Miridae). They are voracious T. absoluta egg predators, but have low efficacy feeding on larvae. Currently, their use is a cornerstone in the IPM programs, both in greenhouse and open field crops.

More than 50 species of T. absoluta parasitoid wasps have been identified to date attacking T. absoluta in the Mediterranean basin, being by far the largest group the wasps that attack larvae followed by the ones that attack eggs. Among larval parasitoids, only few were considered as effective potential biocontrol agents. The most extensively studied has been Necremnus tutae Ribes & Bernardo (Hymenoptera: Eulophidae), first identified as N. nr. artynes (Walker). Although currently it is not commercially available, natural populations of this parasitoid effectively contribute to control T. absoluta on tomatoes crops in Spain and other Mediterranean countries. On the contrary, egg parasitoids are scarce, and only Trichogramma achaeae (Nagaraja & Nagarkatti) (Hymenoptera: Trichogrammatidae) has been considered for inoculations in greenhouse crops as a complementary tool for T. absoluta control.

In Mediterranean conditions, conservation of natural enemies seem to play an important role in T. absoluta control. Laboratory and field studies have demonstrated the positive influence of some selected insectary plants to improve the fitness of T. absoluta natural enemies and to boost their populations on the crops. Therefore, the use of ecological infrastructures such as flower margins with selected plants has been considered as a strategy to enhance predators and parasitoid populations near tomato crops.

Diversity of aphid parasitoids in East Africa and the implications for biological control

Authors: Arnold Sarah[1], Woolley Victoria[8], Obanyi Janet[2], Ogendo Joshua[2], Baltazar Ndakidemi[5], Ndakidemi Patrick[5], Stevenson Philip[7], Mkenda Prisila[6], Belmain Steven[4] and Tembo Yolice[3], [1]1. Natural Resources Institute, University of Greenwich 2. The Nelson Mandela African Institution of Science and Technology, United Kingdom, [2]Egerton University, Kenya, [3]Lilongwe University of Agriculture and Natural Resources, [4]Natural Resources Institute, University of Greenwich, [5]Nelson Mandela African Institution of Science and Technology, [6]Sokoine University of Agriculture, [7]University of Greenwich Royal Botanic Gardens, Kew, United Kingdom, [8]University of Greenwich, United Kingdom

Abstract: Aphids, particularly Aphis fabae, are a major pest of common bean (Phaseolus vulgaris) which is an important food crop and dietary protein source among East Africa smallholders. We investigated the potential of natural enemies, particularly parasitoids, to control this pest and identified interventions that could be used to conserve or augment populations of these natural enemies. Parasitoids of A. fabae were monitored using sentinel plants, sweep netting and sticky traps at small holder bean farms in Kenya, Tanzania and Malawi. They were identified using DNA barcoding and the most common primary parasitoids were selected for further study. There were found to be differences in the identity of primary and secondary parasitoids between the three countries investigated, with the most common primary parasitoids being Aphidius colemani and Lysiphlebus testaceipes, but the latter being found primarily in Malawi. Additionally, the most abundant secondary parasitoid was a Pachyneuron sp., which was primarily found in Tanzania. Fields with high plant-diversity margins yielded higher numbers of parasitoids compared to plant-depauperate margins. These results suggest that there is potential to augment the population of primary parasitoids on smallholder bean farms by encouraging plant species-rich field margins containing floral resource plants; however, management needs to be tailored to favor the key primary parasitoids in each region without disproportionately benefitting pest insects or secondary parasitoids.

Not just more plants, but the right ones: supporting ecosystem services on African smallholder farms

Authors: Arnold Sarah[2], Mkenda Prisila[5], Tembo Yolice[1], Ndakidemi Patrick[3], Elisante Filemon[6], Belmain Steven[2] and Stevenson Philip[4], [1]Lilongwe University of Agriculture and Natural Resources, [2]Natural Resources Institute, University of Greenwich, [3]Nelson Mandela African Institution of Science and Technology, [4]Royal Botanic Gardens, Kew, [5]Sokoine University of Agriculture, [6]University of Dodoma

Abstract: Plant-diverse field margins are commonly promoted in temperate countries to support beneficial insect communities for pollination and natural pest regulation. The benefits on tropical smallholder farms are less clear. Here we report the results of biodiversity surveys from smallholder bean farms, and the relationship between field margin richness, natural enemy abundance, pollinator activity, and ultimately, yield. Botanical surveys, pan-trapping and walked transects were carried out in Tanzania and Malawi on smallholder bean farms.

A range of natural enemies are present on smallholder farms in both countries, using various native- and non-native plant species in margins. While botanical richness was linked to beneficial insect activity, this related to particular types of plants - including trees and native species. Many plants showing high interaction rates with natural enemies had other benefits to farms, such as sources of medicines or pesticides, livestock fodder, firewood or vegetables. Fields with plant- and tree-rich margins showed significant higher yields than fields without. The findings indicate that non-crop botanical diversity can confer multiple benefits and is a valid component of an ecological intensification system for these farms.

Perspectives for using RNA interfering approach to control the invasive pest of beehives Aethina tumida

Authors: Arpaia Salvatore[3], Bonina Valeria[5], Iovieno Paolo[2], Smagghe Guy[4] and Federico Giovanni[1], [1]Istituto Zooprofilattico Sperimentale per il Mezzogiorno, Italy, [2]CNR National Research Council, Institute of Bioscience and Bioresources, Italy, [3]ENEA - Italian National Agency for new technologies, energy and sustainable econ, Italy, [4]Ghent University, Belgium, [5]Università di Napoli “Federico II”, Italy

Abstract: The small hive beetle (SHB) Aethina tumida is a parasitic beetle of Apis mellifera, native to South Africa which damages preferably commercial apiaries. Its presence impairs the production of honey and wax and undermines the integrity of the colony. This pest was included in the OIE list of bee pathogens with the goal of preventing its further spread. SHB is also among the diseases of interest of the EU (Regulation EC 2016/429) since it was found in 2014 in Calabria region (southern Italy) where it continues to be present. The RNA-interfering (RNAi) technique exploits a natural mechanism present in eukariotic organisms to lead to the loss of functionality of a gene. A first attempt to use RNAi to control SHB was made by Powell et al. (2016, doi.org/10.1002/ps.4365) who found that oral delivery of dsRNA against V-ATPase subunit A in solutions resulted in 50% larval mortality, however gene suppression could not be verified. We tested v-ATPase and ribosomial protein 13 dsRNA designed to silence essential genes of A. tumida. We amplified regions of four target genes with primers containing the T7 promoter, using PCR products for in vitro transcription. In vitro bioassays were setup to evaluate their potential as biological insecticides.

An autonomous system for the detection and counting of the malaria mosquitoes larvae in natural populations

Authors: Artemov Gleb[2], Khozhanov Alexandr[1], Bondarenko Semen[1] and Dirko Vladimir[1], [1]Laboratory of ecology, genetics and environment protection, Tomsk State University, Tomsk, Russia, [2]Tomsk State University, Russia

Abstract: Malaria is the cause of death for about half of the million people every year and Anopheles mosquitoes are the exclusive vectors of the malaria parasite. Monitoring of the natural populations of Anopheles mosquitoes provides essential data for effective malaria control. The density of malaria mosquitoes larvae is an important indicator of the possible outbreaks of diseases and the effectiveness of insecticide treatment. All traditional methods of mosquitoes density estimation are time and effort consuming, thus new autonomous and remote approaches became more attractive.

In our work, we present an autonomous system for the detection and counting of malaria mosquito larvae in natural populations. The system consists of two major components: 1) a device (Figure 1), which scans the surface of the natural water reservoir and sends the image to the remote drive and 2) a software, which recognizes larvae on the images and estimates the number of the larvae. The device is based on a 64-bit mini-computer Raspberry Pi 3b with a Raspberry v2.0 camera module. The images with 2592x1954 pixels resolution are transmitted by a high-speed modem according to UMTS-2100 (3G) standard. The resolution of the images is high enough to identify a small object within a few millimeters in size. Li-ion batteries and solar modules provide up to 2800 hours of autonomous work of this device at above zero degrees. The modules were mounted on the upper part of the aluminum framework in a truncated pyramidal shape. Cylindrical polystyrene floats were installed on the corners of the device's base to keep the device on the water. A white screen was mounted on the underwater part of the device in order to provide a contrasting background for the living objects.

The Anopheles larvae have distinguishable among the other objects patterns of swimming on the water surface, which is a useful feature for neural network training. Faster R-CNN with ResNet feature was used as a pre-trained model for malaria mosquitoes larvae differentiation. Before the model training, the images were annotated by LabelImg. TFrecord file was used as an input file for the neural network training. The model trained with Intel Core i5 9400 OEM, until the logarithmic loss became to be 0.0002. The current model recognizes mosquito larvae with 82% accuracy.

The presented system is necessary for the monitoring of mosquito populations in the remote and poorly accessible for people regions. The area of monitoring is restricted only by 3G-net coverage. The depth of the study (the number of images per time unit) can be adjusted depending on the aim. Therefore the distributed network of the devices presented here will be useful for real-time, remote and simultaneous evaluating of the mosquito population density in multiple locations where malaria control required.

Management of Popillia japonica in Japan

Authors: Asano Shin-ichiro, Applied Molecular Entomology Lab. Research Faculty of Agriculture Hokkaido University, Japan

Abstract: Japanese beetle (Popillia japonica) is a serious pest of turf and ornamental plants in Japan. Japanese beetle larvae were collected in Hokkaido to discover insect pathogenic bacteria which were effective for beetle control. We isolated and identified novel Paenibacillus popilliae (Pp)strain from Japanese beetle larvae (Matsuki et al., 1997). The cry43Aa gene cloned from the isolated P. popilliae hime strain had insecticidal activity against Japanese beetle larvae. Also, we want to determine the whole genome sequence of P. popilliae strain (Iiyama et al., 2013). As a result, it was revealed that P. popilliae had no catalase gene, and that artificial culture could be performed by adding its activity. From Bacillus thuringiensis (Bt) collections in our laboratory, two Bt strains (SDS-502, BBT2-5) with insecticidal activity against Japanese beetle larvae and adults were found (Asano et al., 2003; Yamaguchi et al., 2008). The cry8Da gene has been cloned, and its insecticidal activity mechanism has been studied (Yamaguchi et al., 2013). We are promoting the development and commercialization of Bt and Pp strains as beetle pest control agents, and have developed a scarab-resistant turf grass by introducing the cry8Da gene.

An insect specific system for terrestrialization: eco-evo perspective on the occurrence of insects

Authors: Asano Tsunaki[1] and Hashimoto Kosei[2], [1]Department of Biological Sciences, Tokyo Metropolitan University, Japan, [2]Faculty of Economics, Takasaki City University of Economics, Japan

Abstract: Previously, we proposed a new hypothesis on the mechanisms by which insects adapted to terrestrial environments during their evolutionary history. This hypothesis is based on presence of a unique system for cuticle formation that is catalyzed by an insect-specific enzyme, laccase. The main function of laccase is the oxidation of catecholamines, the products of which are highly reactive and possibly mediate cross-linking between cuticular components (proteins and chitin fibers). The laccase-mediated system does not require high amounts of calcium ions, in contrast to the cuticle-hardening system of crustaceans, the closest relatives of insects. Crustaceans are dominant animals in marine environments and known to be morphologically the most diverse among any taxa. This diversity is often compared with that of insects, and both insects and crustaceans can be characterized by their high potential to adapt to various environments by diversification, although their main habitats are terrestrial and marine environments, respectively. Our idea is that the systems for cuticle hardening are one of the most important factors affecting their distributions in these habitats. In contrast to the abundance of calcium ions in sea water, calcium ion content is restricted on land or in fresh water. Such a situation can be exemplified by the behavior of crustaceans: formation of gastroliths with calcium ions from the old cuticles before molting of crayfishes, or consumption of exuviae for recycling of calcium ions in the old cuticles by isopods. Alternatively, by evolving the laccase-mediated system, insects can harden their cuticles without the high requirement of calcium ions. In the process of terrestrialization, insects may have extended their distributions far from the seashores to inland areas more freely than that by crustaceans. Noteworthy, the laccase-mediated system can be an adaptive trait to utilize molecular oxygen from the atmosphere, since this system utilizes molecular oxygen as the electron acceptor from substrates. The content of molecular oxygen in air is much higher (30 fold) than that in water due to its low solubility, and this level in the evolutionary era had already reached the current value. Cuticles that are hardened without biomineralization are less rigid although they are light-weight, which may be a contributing factor towards insects becoming the first to fly in the kingdom Animalia. With the ability of flight and the high diversification potential, insects may have extended their distributions by creating new and open niches that other animals could not easily access. Currently, insects are one of the most successful organisms with their large biomass and high impacts on eco-systems. However, it seems difficult for them to re-adapt completely to marine environments where the insect-specific cuticles are not necessarily advantageous.

The functions of a chitin-binding protein in flight and jumping of insects

Authors: Asano Tsunaki[1], Hagiwara Miyuna[1] and Aigaki Toshiro[1], [1]Department of Biological Sciences, Tokyo Metropolitan University, Japan

Abstract: Insects have evolved various styles of locomotions such as jumping and flying, both of which are rapid and efficient. With regard to the mechanical properties of body structures enabling insects to jump and fly, previous studies have suggested the involvement of an insect specific protein, Resilin. Resilin is a chitin-binding protein that was originally found as a component of elastic matrices in wing hinges of dragonflies or in the leg joints of grasshoppers. Resilin is composed of three regions from the N-terminus; 1) repeats of elastic motifs ((PxxxYGAP)s), 2) chitin binding motif, and 3) repeats of another elastic motifs ((GYxSGxPG)s). With the elastic and resilient properties, Resilin-matrices may adsorb mechanical resistance from high frequency of wing flapping, or may storage mechanical energy for jumping like spring. Resilin molecule has high content of tyrosine residues that are used for polymerization of Resilin molecules through formation of inter-molecular cross-links mediated by di-tyrosines or tri-tyrosines. Since the first finding, there have been many studies on Resilin. However, many of the researches were based on approaches of material science for application of Resilin molecules to produce new biomaterials. Correlations between mechanical properties of Resilin-matrices and their localizations in joint parts of insect bodies have been well explained, but in vivo functions of Resilin gene or molecular process of resilin polymerization have not yet been well examined in biological contexts. Here, we focus on the functions of the gene for Resilin in the fruit fly, Drosophila melanogaster, as an ideal model for the genetic research of Resilin. The gene (DmResilin) is expressed throughout the developmental stages, but in late pupal stages the expression is very strong, indicating that the protein is mainly used for making adult body. DmResilin knocked-down flies cannot move their wings at all and therefore they cannot fly. In addition, the jumping performance (distance and velocity) of the KD flies is worse than that of the controls. DmResilin mutant flies that were generated by CRISPR-Cas9 system show the same phenotypes as KD flies. These results indicate that DmResilin have indispensable roles in both jumping and flying, possibly with the elastic-resilient properties of matrices produced from the gene products. We also checked the sites of DmResilin expressions by reporter gene expression using Resilin promoter-Gal4 line. The GFP signals can be seen in the wing hinges at the late pupal stage, which is consistent with the previous observations of other insect species. In western analyses, the protein signal is gradually weakened after eclosion to adults, suggesting that in adult stages Resilin molecules become insoluble after polymerization via formation of di-tyrosines or tri-tyrosines.

Potential role of blood microRNAs in mosquito-virus interactions

Authors: Asgari Sassan[2], Perdomo Hugo[1] and Parry Rhys[1], [1]School of Biological Sciences, University of Queensland, Brisbane, Queensland, Australia, [2]The University of Queensland, Brisbane, Australia

Abstract: microRNAs (miRNAs) are small non-coding RNAs of about 22 nt in length. They play important roles in regulation of gene expression at the post-transcriptional level in various biological processes. Blood feeding is a major event in the life cycle of mosquitoes essential for mosquitoes' egg development and reproduction with profound effects on their physiology and gene expression. Intake of blood concurrently exposes mosquitoes to a range of vertebrate-derived blood factors such as hemoglobin, complement, insulin, and pathogen-derived factors, which have roles in modifying mosquito physiology and immune responses. Studies have shown that miRNAs are present in large numbers in animal host bloods. In a recent study, we have been investigating the potential role of human miRNAs that are abundantly found in the blood meal taken by Aedes aegypti mosquitoes on replication of dengue virus. Our data analyses and experimental results suggest miRNAs present in vertebrate bloods are stable post-blood feeding, pass through the midgut barrier, and disseminate to mosquito tissues. Preliminary results also suggest that they may potentially target mosquito genes that are involved in immunity and development.

Towards the use of Wolbachia in area-wide control programs for Haematobia spp

Authors: Asgari Sassan[3], James Peter[3], Brown Geoff[1], Morgan Jess[2] and Madhav Mukund[3], [1]Department of Agriculture and Fisheries, Queensland, Australia, [2]Department of Agriculture and Fisheries, Brisbane, Queensland, Australia, [3]The University Of Queensland, Brisbane, Australia

Abstract: Haematobia spp. are obligate haematophagous flies and major economic pests of cattle that have proven to be strongly invasive in both the northern and southern hemispheres. Horn flies (Haematobia irritans) were introduced from Europe and spread through North America in the late 1800s and more recently through most of the major cattle producing areas in South America. Buffalo flies (Haematobia exigua), very closely related to horn flies, spread from South East Asia to Oceania and are continuing to expand their range in Australia. Regulated cattle movements and compulsory chemical treatments have proven unsuccessful in preventing the spread of these flies. We are investigating the feasibility of area-wide control of H. exigua, utilising the intracellular maternally transmitted bacterium Wolbachia. We have successfully infected H. irritans cell lines with the wMel, wMelPop and wAlbB strains of Wolbachia and passaged them through more than 50 generations to adapt them to the intracellular environment of Haematobia. Investigation of different microinjection techniques indicated that pupal or adult injection is more suitable for transinfection of Haematobia spp. than more commonly used embryonic microinjection. When injected into H. exigua pupae or female flies all three strains of cell line-adapted Wolbachia established widespread somatic infections, with transmission to F1 generations in a number of instances. Wolbachia infection was associated with fitness effects including reduced adult lifespan, decreased and delayed eclosion from pupae and reduced fecundity. These outcomes suggest significant potential for the use of Wolbachia in control programs for H. exigua, which are not naturally infected with Wolbachia, as well as for H. irritans where natural infection is with a strain of Wolbachia that is genetically distinct from the strains used in our studies.

Age-stage, two-sex life history and parasitism rate of Diadegma insulare against Plutella xylostella reared on different cruciferous hosts

Authors: Asif Aziz Muhammad[1], MOHSIN ATA-UL[1], Ahmad Hafiz Ishfaq[2] and Khaliq Sobia[1], [1]Department of Entomology Faculty of Food Crop and Food sciences PMAS-AAUR, Pakistan, [2]Department of Horticulture Faculty of Food Crop and Food sciences PMAS-AAUR, Pakistan

Abstract: Diamondback moth, Plutella xylostella, is a serious pest of cruciferous crop in Pakistan. This study is carried out to get better knowledge related to predator-prey relationship and compare predation rates of parasitoid, Diadegma insulare on different brassica genotypes. The life history data and predation rate data of D. insulare, fed on P. xylostella reared on different brassica crop genotypes were collected at 25 °C in the laboratory. The data were analyzed based on age-stage, two-sex life table theory to take both sexes and different developmental stage into consideration. The intrinsic rate of increase for D. insulare fed on P. xylostella reared on cauliflower, broccoli, canola, cabbage, chinese cabbage and Pakchoi was 0.1971 d-1, 0.2189 d-1, 0.1868 d-1, 0.1631 d-1, 0.2024 d-1 and 0.1959 d-1, respectively. The highest net reproductive rate was observed on broccoli as 22.35 offspring while highest mean generation time for D. insulare was observed on P. xylostella reared on pak choi as 14.526 d. The net parasitism rate for D. insulare was highest on broccoli as 22.35, followed by 17.23, 16.51, 13.53, 12.42 and 9.22 P. xylostella reared on, pak choi, chinese cabbage, cauliflower, canola and cabbage, respectively. Finite predation rate was comparatively higher (0.2814) on broccoli, while it was the lowest (0.2114) on cabbage. Due to age-stage, two-sex life table studies and incorporation of finite parasitism rate, we were able to explore that although D. insulare successfully completed life cycle on P. xylostella reared on all cruciferous crops, however the parasitoid showed better fitness on the herbivore consuming broccoli leaves which is very important cash vegetable in Punjab, Pakistan.

Age-stage, two-sex life history and predation rate of Diadegma insulare fed on Plutella xylostella reared on different brassica genotypes

Authors: Asif Aziz Muhammad[1], -ul-Mohsin Ata[2], Ahmad Hafiz Ishfaq[1] and Khaliq Sobia[1], [1]Department of Entomology Faculty of Food Crop and Food sciences PMAS-AAUR, Pakistan, [2]Professor Department of Entomology Pir Mehr Ali Shah Arid Agriculture University Rawalpindi, Pakistan

Abstract: Diamondback moth, Plutella xylostella, is a serious pest of cruciferous crop in Pakistan. This study is carried out to get better knowledge related to predator-prey relationship and compare predation rates of parasitoid, Diadegma insulare on different brassica genotypes. The life history data and predation rate data of D. insulare, fed on P. xylostella reared on different brassica crop genotypes were collected at 25 °C in the laboratory. The data were analyzed based on age-stage, two-sex life table theory to take both sexes and different developmental stage into consideration. The intrinsic rate of increase for D. insulare fed on P. xylostella reared on cauliflower, broccoli, canola, cabbage, chinese cabbage and Pakchoi was 0.1792 d-1, 0.1970 d-1, 0.1698 d-1, 0.14711 d-1, 0.1864 d-1 and 0.1796 d-1, respectively. The highest net reproductive rate was observed on broccoli as 19.83 offspring while highest mean generation time for D. insulare was observed on P. xylostella reared on Pakchoi as 15.83 d. The net predation rate for D. insulare was highest on broccoli as 22.35 offsprings, followed by 17.23, 16.51, 13.53, 12.42 and 9.22 offsprings of P. xylostella reared on, pakchoi, chinese cabbage, cauliflower, canola and cabbage respectively. Finite predation rate was highest (0.2814) on broccoli, while it was lowest (0.2114) on cabbage. The results show D. insulare to be the potential biological control agent of P. xylostella in integrated pest management and the life history parameters of D. insulare can be used to predict its biological potential and develop models for the population dynamics of D. insulare.

Saving the wine one parasitoid at a time: analysis of Goniozus jacintae as a potential biocontrol agent for the light brown apple moth (Epiphyas postvittana)

Authors: Aspin Emma[2] and Hardy Ian[1], [1]Uni. Helsinki, Finland, [2]University of Nottingham and University of Adelaide, United Kingdom

Abstract: Before releasing a biocontrol agent into the field, we should first understand how it interacts with its target and other environmental components, including competitors.

We conducted an array of experiments to explore the behavioural ecology of the parasitoid wasp Goniozus jacintae Farrugia (Hymenoptera: Bethylidae), to develop the understanding of the parasitoid as a potential biocontrol agent for the light brown apple moth (LBAM), Epiphyas postvittana (Walker) (Lepidoptera: Tortricidae), a pest of grapevine, Vitis vinifera L. (Vitaceae), and other crops in Australia.

How does the parasitoid find a host? A wind tunnel experiment found host-stage dependent foraging behaviour in G. jacintae: timing, frequency, and duration of foraging behaviours of G. jacintae varied among host instars.

How does the parasitoid select its host when faced with competition? We tested the host discrimination ability of G. jacintae when presented with hosts of varying quality: unparasitised or parasitised by an allospecific. Discrimination ability of G. jacintae was influenced by both the order in which different hosts types were presented and time since parasitisation.

How does the parasitoid utilise selected hosts? We observed the egg laying behaviour of G. jacintae when presented with different sized hosts. Average clutch size increased with bigger host instars.

Evaluation of a Greek diatomaceous earth and a zeolite for stored-product insect control and techniques that maximize their insecticidal efficacy

Authors: Athanassiou Christos, University of Thessaly, Greece

Abstract: In the present study, seven series of laboratory bioassays were conducted to evaluate the insecticidal efficacy and the abiotic factors that can alter the efficacy of one diatomaceous earth (DE) and one zeolite, originating from natural deposits of Greece. The DE rocks were treated in different ways (differences in grinding, sieving, diatom enrichment, powder granulometry), leading to five DE types, with different technical characteristics. In the first series, bioassays were conducted to evaluate the insecticidal efficacy of all DE types and the zeolite, when applied in organic soft wheat at different doses, against major stored-product insects, i.e. Tribolium castaneum, Tribolium confusum, Sitophilus oryzae, Rhyzopertha dominica, Cryptolestes ferrugineus and Oryzaephilus surinamensis. Then, bioassays were performed to evaluate the insecticidal properties of the DE formulations and zeolite for T. confusum, S. oryzae and R. dominica in different cereals. At the same time, the zeolite was tested also in legumes that were infested with the beetle Callosobruchus maculatus. For the two most effective DE types, the effect of temperature and relative humidity were evaluated in a third series of experiments. Separate bioassays were made in all combinations of two temperature levels and two levels of relative humidity, for S. oryzae and R. dominica. Bioassays on cement and steel surfaces also took place for these two DE types and for the zeolite, in order to evaluate their residual insecticidal activity. Finally, we examined the effect of all formulations to the bulk density of soft and durum wheat, rice and maize. Based on our results, there were significant differences in the insecticidal efficacy of the various DE types tested when applied on wheat. We consider that these differences are due to the different mechanical treatment of the DE, resulting in the presence of broken diatoms in the two most efficient DE types, as opposed to the whole diatoms found in the rest of the DE types, as well as the smaller size of the powder granules. Also, there were noticeable variations among different grains. None of the DE or zeolite formulations showed any significant insecticidal effects on maize, rice and barley compared to wheat. The increase of the relative humidity adversely affected the effectiveness of the DE formulations. On the contrary, zeolite appears to be unaffected by relative humidity fluctuations. DE formulations and zeolite appeared to be very effective for their use as insecticides on cement and steel surfaces. Surprisingly, small doses of some DE types, increased the bulk density of all the tested cereals, while the higher doses did not have any effect in it. In contrast, the most effective types of DE show an increase in bulk density with increasing dose. Overall, our data clearly indicate that these specific Greek deposits of both DE and zeolite, have considerable insecticidal properties, especially when specific techniques applied in them.

Susceptibility of insect meals to insect infestations during storage: The case of Tenebrio molitor and Alphitobius diaperinus larvae meal

Authors: Athanassiou Christos[2], Rumbos Christos[1] and Rigopoulou Marianna[1],

[1]Laboratory of Entomology and Agricultural Zoology, Department of Agriculture, Crop Production and Rural Environment, University of Thessaly, Magnesia, Greece, [2]University of Thessaly, Greece

Abstract: Although still in the early stages, the insect protein sector is expected to rapidly grow within the next few years. The number of companies doing business on insects as a nutrient source is increasing globally, whereas insect meal production is expected to further rise in the coming years. As with all agricultural commodities, insect meals may be vulnerable to infestations by stored-product insects during storage. However, information on the susceptibility of insect meals to infestations by storage insects is rather limited. To fill this gap, in the present study we investigated the susceptibility of substrates based on insect meals made of the yellow mealworm, Tenebrio molitor (Coleoptera: Tenebrionidae) or the lesser mealworm Alphitobius diaperinus (Coleoptera: Tenebrionidae) larvae to major stored-product insects. Both T. molitor and A. diaperinus are promising insect species for industrial utilization and commercial large-scale production. Indicatively, both species are allowed to be used for the production of insect meals as aquafeed ingredient in Europe. In laboratory bioassays, we studied the population growth of major storage insects, such as the confused flour beetle, Tribolium confusum (Coleoptera: Tenebrionidae) and the khapra beetle, Trogoderma granarium (Coleoptera: Dermestidae) on insect meals made of T. molitor or A. diaperinus larvae, as well as on substrates based on these insect meals with different percentages of wheat bran (0, 25, 50, 75, 90, 95 and 100%). Based on our results, T. molitor can infest 100% T. molitor and A. diaperinus meal and develop significant populations on these substrates. The same counts for T. confusum on 100% T. molitor meal. However, the growth and development of both species on 100% insect meal was slower in comparison to the respective growth on substrates with wheat bran. In contrast, other insect species, such as A. diaperinus and T. granarium did not manage to infest 100% T. molitor meal, whereas both species exhibited poor growth on substrates with high percentage of insect meal. To conclude, the results of our study show the susceptibility of T. molitor and A. diaperinus meals to infestations by major stored-product insects.

This work was supported by a postdoctoral scholarship program (Acronym: FISHECT, Project number: 5394.02.13) implemented by University of Thessaly and funded by Stavros Niarchos Foundation.

Digitizing phosphine to manage stored product insect resistance to phosphine: the paradox of the “sweet spot”

Authors: Athanassiou Christos[4], Mpaliota Georgia[3], Bochtis Dionysis[2], Lampiri Evaggelia[3], Sakka Maria[3], Gourgouta Marina[3] and Sotiroudas Vasilis[1], [1]Centaur Analytics INC, United States, [2]Center for Research and Technology Hellas, Institute of Bio-Economy and Agri-Technology, Greece, [3]University of Thessaly, Department of Agriculture, Crop Production and Rural Environment, Greece, [4]University of Thessaly, Greece

Abstract: We used sensing devices to monitor spatio-temporal distribution of phosphine gas in various types of commercial facilities and commodities. Overall, more than 100 “real-world” fumigations were monitored, in facilities ranging from ships to flourmills and containers and commodities ranging from grains and flour to dried fruit and tobacco. Based on our results, distribution in large warehouses is not usually adequate for a satisfactory level of insect control and any application may not have even distribution of phosphine, which will lead to insect survival and resistance development. One of the critical factors is that some biotic and abiotic conditions may have different weight per fumigation, i.e. often temperature may have less important role in phosphine concentration and distribution of phosphine than humidity or the commodity that is to be fumigated. As a result, concentrations are either over- or underestimated, with the concomitant implications in the expected insect control. Nevertheless, longer exposure intervals, can greatly contribute to the increased mortality of the exposed insects, regardless of their resistance status. Longer exposures and, as an extent, better fumigations, can also be used to mitigate resistance of stored product insects to phosphine. In this context, best management practices in fumigation can totally control insects that are resistant to phosphine, in non-properly performed applications. In contrast with other types of insecticides, where concentration may be more important, duration of exposure to phosphine is much more critical than the concentration, and as such, longer exposures are needed, even if concentrations are not high, to control insect strains that are resistant to this gas. However, exposures at elevated concentrations are very likely to reveal the “sweet spot”, which is the increased survival with the increase of the concentration. This is particularly important as, in contrast with what was believed, resistance to phosphine can be built at high concentrations, just like the same phenomenon occurs in the low concentrations.

Population growth performance of South American tomato moth, Tuta absoluta (Meyrick) under different temperatures and CO2 concentrations

Authors: Atlihan Remzi[3], Chakravarthy Akshay[2], Nitin K.S.[1], Naik Onkara[2] and Sridhar Vaddi[2], [1]Division of Entomology and Nematology, ICAR- Indian Institute of Horticultural Research, Hesaraghatta, Bengaluru, Jain University, India, [2]Division of Entomology and Nematology, ICAR- Indian Institute of Horticultural Research, Hesaraghatta, Bengaluru, India, [3]Van Yuzuncu Yil University Agriculture Faculty Department of Plant Protection, Turkey

Abstract: Understanding the effects of temperatures and increased carbon dioxide levels to the survival, development and fecundity of insects is important for pest management in future. In this context, the population growth performance of the South American Tomato moth, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) was evaluated at four constant temperatures (26, 28, 30 and 32°C), and in ambient and elevated CO2 concentrations (aCO2; 380 and eCO2; 550 ppm) in BOD incubation chambers providing at 75 ± 5% RH and a photoperiod of 14:10 (L: D) h. The life history raw data of the pest were analyzed based on the age-stage, two-sex life table theory which takes into account the stage differentiation, real survival, and the male population. The projected population growth potential of the pest increased as temperature increased; the highest population growth was obtained at 32°C. The population growth rates at aCO2 conditions were higher than those obtained at eCO2 conditions at all temperatures tested. The variability in population growth increased with increasing temperatures, and in general, CO2 conditions did not affect variability that is characteristic of population growth.

Role of warm blood in the reproductive output of blood feeding arthropods

Authors: Attardo Geoffrey[2], Benoit Joshua[1], Oyen Kennan[3] and Aksoy Serap[4], [1]Department of Biological Sciences, University of Cincinnati, Cincinnati, OH, United States, [2]Department of Entomology, University of California, Davis, United States, [3]University of Cincinnati, United States, [4]Yale School of Public Health, United States

Abstract: Blood feeding arthropods experience a substantial thermal shock with each meal, which can be a 10-15?C increase within seconds depending on ambient and host temperatures. To prevent this thermal stress, a variety of mechanism exist, which includes evaporative cooling, counter-current heat exchange, and expression of heat shock proteins to prevent/repair damage. Previous studies have shown this heat response can be damaging, but the potential benefits of a warm bloodmeal remain unclear. Here, we used tsetse flies and soft ticks to evaluate if warm blood is critical for maximizing progeny output. We noted a delay in the production of eggs or larvae when vectors consumed a cool blood meal compared to those offered a warm bloodmeal. To determine the role of the warm bloodmeal, we measured transcript levels of a milk gland protein in tsetse flies following a cool, warm, or hot bloodmeal, which showed the highest expression when tsetse flies consumed warm blood. There were no differences in the size of larvae or number of eggs produced by tsetse flies or soft ticks, respectively, which suggests that bloodmeal temperature alters the timing of egg production but not overall fecundity. These studies suggest that warm bloodmeals reduce the time of each reproductive cycle and play a minor, yet critical, role in maximizing the reproductive output of blood feeding arthropods.

Tracing the post-mating molecular interactions between male and female in the viviparous Glossina morsitans

Authors: Attardo Geoffrey[1], Carraretto Davide[2], Malacrida Anna R.[3], Rossi Irene[2], M.M. Abdalla Adly[4], Scolari Francesca[2], M. Gomulski Ludvik[2] and Aksoy Serap[5], [1]Department of Entomology, University of California, Davis, United States, [2]Dept. of Biology and Biotechnology, University of Pavia, Italy, [3]University of Pavia, Italy, [4]Joint FAO/IAEA Division of Nuclear Applications in Food and AgricultureInsect Pest Control Section, Austria, [5]Yale School of Public Health, United States

Abstract: The identification of molecular pathways shaping short- and long-term mating-induced changes in Glossina morsitans females may reveal specific effector genes that contribute to the regulation of key reproductive processes such as ovulation and egg development in the uterus of this viviparous species.

Transcriptome analyses of the post-mating response in the reproductive tissues of Glossina females revealed dramatic changes in gene transcription. Different waves of transcriptional changes for different gene functions are specifically activated across a post mating interval of 72 hours. Ovaries, oviducts, spermathecae and uterus differentially contribute to the activation of these transcriptional waves. At 2-4 hours post mating, the upregulated genes code for functions primarily associated with biochemical binding, cell receptor/transport and cell signaling activities. The genes upregulated 72 hours post mating code for proteins primarily associated with structural and remodeling activities such as chitin binding, cuticular proteins, cell matrix components and protease activities. The association of these activities at these timepoints suggest that the 2-4 hours post-mating period is associated with reception and uptake of components of the male seminal secretions while the 72 hours post mating period is associated with developmental changes and remodeling of reproductive tract-associated tissues.

These data reveal interspecific differences with Drosophila and provide knowledge on the components of post-mating molecular targets of manipulation for the control of reproduction of this vector of trypanosomiasis in Africa.

Understanding the Post Mating Response in Tsetse – Characterization of Mating Associated Structural and Biochemical Changes in the Female Reproductive Tract

Authors: Attardo Geoffrey[1], Malacrida Anna R.[4], Rossi Irene[2], Scolari Francesca[2], Arguellez Jocelyn[3] and Aksoy Serap[5], [1]Department of Entomology, University of California, Davis, United States, [2]Dept. of Biology and Biotechnology, University of Pavia, Italy, [3]University of California, Davis, United States, [4]University of Pavia, Italy, [5]Yale School of Public Health, United States

Abstract: The post-mating response (PMR) in tsetse flies causes female flies to become refractory to mating, stimulates ovulation and results in increased host seeking behavior and blood meal size. The PMR phenomena is exploited via the Sterile Insect Technique strategy to reduce female fertility in wild populations. However, the biology underlying this response remains unknown in tsetse. Female flies were mated and subjected to microCT and metabolomic analyses to characterize the structural and biochemical changes occuring after mating. Three-dimensional structural analysis of mated female reproductive tracts reveal that the male spermatophore is shaped such that it protects the sperm, directs them into the spermathecal ducts and creates a physical barrier preventing sperm from other matings reaching the spermatheca. Metabolomic analysis of female reproductive tracts before and after mating reveal significant changes in the biochemical constitution of this tissue after mating. At 2-4 hours post mating significant changes in lipid concentrations are observed. These include the enrichment of phosphatidyl choline and ethanolamine moieties, ceramides and cholesterol esters. These observations suggest that these compounds are being transferred from the male into the female as components of the spermatophore. These compounds may function to maintain the structural integrity of the spermatophore as well as functioning as signaling molecules or acting as nuptial gifts from the male to enhance female fertility.

Current knowledge of diving beetles (Dytiscidae) of Thailand

Authors: Atthakor Wisrutta, Srinakharinwirot University, Thailand

Abstract: Straddling two major biogeographical subregions, the Indochinese Region in the north and the Sundaic Region in the south, Thailand enjoys a high level of biodiversity, which supports an interesting mix of flora and fauna representative of both regions. This pattern is also visible in the distribution of diving beetles.

To date, 128 species of diving beetles belonging to 23 genera and 7 subfamilies are known from Thailand. Although this can be considered a moderate number, most of the records were reported over twenty years ago. Current research in water beetle taxonomy is limited, and new records are quite rare. Furthermore, a comprehensive catalogue has not yet been compiled. Here, I present some of the known species, together with photos and distribution maps. Comments are made on species that I expect to be present in Thailand, given the distribution in neighbouring countries, but have not yet been reported. The state of water beetle research in Thailand is also remarked upon, including challenges and potential solutions.

Developing a long-term insect biodiversity monitoring program for a South African semi-arid savanna ecosystem

Authors: Au Michelle[2], Spencer Craig[1] and Wright Mark[2], [1]Transfrontier Africa Balule Nature Reserve, South Africa, [2]University of Hawaii at Manoa Honolulu, Hawaii, United States

Abstract: There is increasing global concern that insect diversity and abundance is under severe duress from impacts such as habitat destruction, pollutants, and global warming. Most long-term studies of insect diversity and abundance have been conducted in European countries and North America, with very few in place in Africa. African ecosystems contain large conservation areas that are subject to many of the same impacts that have been identified to reduce insect biodiversity. These areas may serve as significant reservoirs of insect biodiversity and may ensure that ecological services in adjacent agricultural areas are conserved. Conservation management actions (e.g. controlled fires, artificial waterholes, installation of infrastructure), in protected areas have the potential to impact insect communities as well. Here we describe the initiation of a project intended to provide long-term data on insect biodiversity in Balule Nature Reserve, a component of the Great Kruger Park in South Africa. The area is dominated by semi-arid savanna that comprise a number of distinct plant communities, but with limited topographical variation. We are developing baseline data for long-term monitoring efforts intended to track changes in biodiversity over time which, relates to changes in vegetation quality, conservation management, and climate change. Substantial biomass and diversity of insects is supported by seasonal grass growth, and largely determines patterns of Lepidoptera collected to date. Some trees species (e.g. shepherd's tree, Boscia albitrunca) harbor a large diversity of species of Hemiptera, Coleoptera and Lepidoptera, providing a perennial resource for insects with some turnover in species composition seasonally. Further sampling will include vegetation zones at varying distances from external impacts, such as areas transformed to agricultural production lands. In addition to providing long-term biodiversity data, this project is expected to provide options for monitoring ecosystem condition more accurately than relying on large herbivores.

Genome evolution in termites

Authors: Audisio Tracy[2], Bourguignon Thomas[1], [1]Okinawa Institute of Science & Technology Graduate University, Japan, [2]Okinawa Institute of Science and Technology, Japan

Abstract: Structural changes to genomes can alter phenotypes and result in major ecological and evolutionary shifts. Termites provide an excellent model to study the evolutionary implications of genome structural variants, since different lineages are known to have divergent chromosome numbers and genome sizes. Despite these differences, the extent of variation and association with different feeding ecologies, developmental pathways, and social structures remain unknown. In this project, a hybrid sequencing and multiplatform assembly approach was used to integrate long-read, short-read, and long-range data to generate 50 de novo genome assemblies that span the breadth of termite diversity. Structural variants were characterized across termite genomes and differences were assessed using a comparative phylogenetic framework to provide insight into how variants evolve, how they are maintained, and how they shape termite phenotypes.

Are the damage of an invasive seed insect directly dependent of the spatial structure and genetics of the host trees in an infested seed orchard?

Authors: Auger-Rozenberg Marie-Anne[3], Papaix Julien[2], Roques Alain[4] and Gross Louis[1], [1]French National Institute for Agricultural Research, France, [2]INRAE, BioSP, Avignon, France, [3]INRAE, URZF, Orleans, France, [4]INRAE, Zoologie Forestière Orléans, France

Abstract: The increase of the forest seed trade with globalization is a source of introduction of exotic species of specialized seed insects. These insects generate significant economic losses in seed orchards producing seeds with added genetic value. The seed chalcid Megastigmus spermotrophus, introduced in Europe from North America at the end of the 19th century, is strictly associated with Douglas fir, its host tree, and is a good model for studying the relationship between insect attack and genetic composition of seed orchards, especially since Douglas-Fir is one of the first reforestation species currently used in Europe.

The French seed orchard of Lavercantière in the southeast of the Massif Central consists of nearly 800 plants belonging to more than 100 genetically different clones, with a random geographical distribution of the plants. The majority of the trees in this orchard, established 35 years ago, regularly grow with years of high production that alternate with years of low or no production. The cones being harvested in summer while the insect is still in the larval stage in the seed, all the insects of the orchard are in theory eliminated, and the infestation of the orchard the following year proceeds from the arrival of insects coming from the surrounding areas. Therefore, each annual infestation can be considered a replicate. The annual number of infested seeds, one larva being present per infested seed, has been estimated since the creation of the orchard on a limited number of randomly selected plants, one per line on the 70 planted lines. Moreover, in 2018, 2020 and 2021 (years of heavy cone crop) and 2019 (a year of light cone crop), all trees in the orchard were sampled with a minimum of 10 cones per tree. The number of infested, healthy and aborted seeds per cone and per tree was estimated using X-rays. The geographic coordinates and clonal identity of each plant is known, and its annual cone production has been measured.

In this study, spatial statistics allowed to study if the seed infestation per tree is linked to its clonal/ genetic identity. We tested whether the insects are distributed among the plants according to this identity, or if they are simply distributed according to the volume of cones carried by each tree regardless of the clone.

This study is expected to identify a possible clonal susceptibility to chalcid attack, and conversely to select the clones that could serve as natural traps for these insects, which is important to take into account in the establishment of new plantations in the context of climate change.

Bio-economic modelling for optimizing surveillance effort for invasive forest pests in Switzerland

Authors: Augustinus Benno[1], Queloz Valentin[1], Epanchin-Niell Rebecca[2], Lischke Heike[1] and Brockerhoff Eckehard[1], [1]Swiss Federal Institute for Forest, Snow and Landscape Research WSL, [2]University of Maryland, United States

Abstract: Switzerland has joined an EU-wide effort for early detection of several priority and other quarantine forest pests (Agrilus anxius, Agrilus planipennis, Anoplophora chinensis, Anoplophora glabripennis, Bursaphelenchus xylophilus, Dendrolimus sibiricus, Fusarium circinatum and Phytophthora ramorum). To conduct these surveys as effectively and cost-efficiently as possible, we are considering relevant international trade flows, population density, climatic suitability, host availability, costs of trapping/monitoring and eradication of detected populations for Switzerland. We adapted the bio-economic surveillance model CESAT to evaluate where in Switzerland the probability is highest that the target organisms are introduced and establish. The model is also used to estimate a cost-efficient sampling effort to optimise the surveillance effort across Switzerland while ensuring engagement with all regional forest health agencies. In this presentation, we show challenges and opportunities in handling the relevant data, and discuss which data are necessary to further improve modelling the arrival and establishment of surveyed quarantine organisms. Our results demonstrate that a data-based approach can shift geographical focus of sampling, help define regions of interest, and establish a cost-efficient survey network. Furthermore, we show how model outcomes can be used in practice, and what the stumbling stones for implementations are.

Epiblema sp. in Israel no suitable biocontrol agent of Parthenium hysterophorus

Authors: Augustinus Benno Andreas[5], Rubin Baruch[2], Müller-Schärer Heinz[3], M. Gilligan Todd[4], Schaffner Urs[1] and Yair Yifat[2], [1]CABI, Switzerland, [2]Hebrew University of Jerusalem, Israel, [3]University of Fribourg, Switzerland, [4]USDA APHIS, United States, [5]WSL, Switzerland

Abstract: The North-American Ambrosia confertiflora and Parthenium hysterophorus are noxious and allergenic invasive weeds in Israel. In 2008, a North-American-stem galling moth was found in Israel on A. confertiflora. It was first identified as Epiblema strenuana, which is used as a biocontrol agent of P. hysterophorus in Australia, but was rejected for introduction in South Africa after host range testing, because it feeds also on Guizotia abyssinica, an oil crop in Eastern Africa.

We assessed the risk of non-host target feeding of Epiblema in Israel, as well its potential benefits as a biocontrol agent of A. confertiflora and P. hysterophorus. For this, we performed no-choice host range tests, and field samplings to assess its present distribution. We found that the moth had recently extended its geographic range in central Israel to the West Bank up to the Jordan River. The moth did not attack P. hysterophorus and G. abyssinica, but attacked Ambrosia tenuifolia and Ambrosia artemisiifolia. Subsequent analyses showed that the moths introduced to Israel are not E. strenuana, but rather E. minutana. This taxon was treated as a synonym of E. strenuana in the past but should be elevated to species status based on molecular and morphological data.

Associational protection: protecting trees against emerald ash borer using systemic insecticide treatments

Authors: Aukema Brian[2], Mwangola Dorah[2], Ambourn Angie[1], Burington Jennifer[1] and Abrahamson Mark[1], [1]Minnesota Department of Agriculture, United States, [2]University of Minnesota, United States

Abstract: Emerald ash borer, Agrilus planipennis, is an invasive wood boring insect, introduced to North America in the 1990s that attacks ash trees, Fraxinus species. A major control strategy in urban environments is the use of systemic insecticide treatments. In our study, we are investigating whether treating a subset of trees in a susceptible ash population could confer benefits to untreated trees i.e. associational protection. This treatment regime could lower insecticide use and costs of treating trees. We present results of a three-year study comprising 1200 trees in cities across Minnesota, USA, where we explore how gradients of injections may create associational protection for individual high-value trees as well as effects on non-target species.

Intracontinental and intercontinental exchange of semiochemicals allows for their use as allochthonous kairomones

Authors: Aukema Brian[4], Müller Michael[2], Barnes Brittany[3], J. K. Gandhi Kamal[3] and Chase Kevin[1], [1]Bartlett Tree Research Laboratories, United States, [2]Chairholder, Chair of Forest Protection, Technische Universität Dresden, Germany, [3]The University of Georgia, United States, [4]University of Minnesota, United States

Abstract: The principle of allochthonous kairomones in bark beetle management is originally described and based on exchanging kairomones between coniferous and broadleaf forests in Europe with the aim of attracting bark beetle antagonists without attracting bark beetles. In our study, we applied this principle in a wider context not only by an exchange between different local habitats but also by an exchange on a larger geographical scale. Dendroctonus frontalis is a bark beetle native to the southeastern United States. Frontalin is a pheromone component of D. frontalis. We installed frontalin and some European bark beetle lures in southern (Georgia) where D. frontalis is native and northern (Minnesota) pine forests where D. frontalis does not occur. Our results suggest among others things that frontalin worked as an allochthonous kairomone in Minnesota by attracting Thanasimus dubius, an important predator, without attracting bark beetles.

Screening of a potential predatory mite for control of tomato russet mite, Aculops lycopersici

Authors: Aussems Evelien[1], Bosmans Lien, Van Heghe Benedikte, Vervaet Lore, Van Leeuwen Thomas, De Clercq Patrick and De Vis Raf, [1]Belgium

Abstract: The tomato russet mite (TRM), Aculops lycopersici, is an important pest species in greenhouse grown tomato crops around the world. At this moment controlling of A. lycopersici relies solely on the use of sulphur and synthetic chemical acaricides. To establish a durable IPM (Integrated Pest Management) strategy for the tomato russet mite, there is a need for an efficient biological control agent. In our laboratory experiments, the predatory mite Pronematus ubiquitus showed promising results for the biological control of TRM. Small scale greenhouse experiments demonstrated that the mite can successfully colonize a tomato crop. The potential of the iolinid mite P. ubiquitus to colonize a tomato crop and suppress A. lycopersici was also tested in a high-tech tomato greenhouse in Belgium. Here, an experiment was set up to compare a tomato cultivation cycle with and without P. ubiquitus. The results showed a clear benefit of the presence of the mite. When P. ubiquitus was present, almost no damage was seen on the tomato plants. Without the beneficial the plants turned brown, started wilting and fruits became corky. Supplementation with cattail pollen caused the P. ubiquitus population to grow faster, but also slightly reduced its efficacy as a biological control agent

Origins of parasitoid diversity: integration of sensory physiology, chemical ecology, and phylogenetics to understand diversification in Platygastroidea

Authors: Austin Andy[1], Johnson Norman[4], Chen Huayan[3] and Dowton Mark[2], [1]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, Australia, [2]Centre for Medical and Molecular Bioscience School of Biological Sciences University of Wollongong, Australia, [3]Sun Yat-Sen Univeristy, China, [4]The Ohio State University, United States

Abstract: Parasitoid wasps are an extraordinarily diverse group of insects, yet the proximate drivers of species richness are poorly known. Chemosensory speciation offers a framework for understanding the proximate mechanisms of diversification and why some groups appear to be prone to rapid speciation. The repertoire of chemoreceptors in a model species, Trissolcus basalis (Wollaston) (Hymenoptera: Scelionidae) is described including olfactory binding proteins, chemosensory proteins, olfactory receptors, gustatory receptors, and ionotropic receptors. The expression patterns of these proteins are described on the basis of transcriptomes and qPCR assays, and differences in expression profiles between the antennae and the rest of the body and between sexes is described. The evolution of these protein families is then traced on a newly developed phylogeny for the group based on whole-genome sequencing.

Unravelling the diversity of Australia's megadiverse hymenopteran fauna: current status, directions and new technologies

Authors: Austin Andy[1] and Fagan-Jeffries Erinn[1], [1]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, Australia

Abstract: The isolation of the Australian continent, its Gondwanan origins, and unique fauna and flora have contributed to a hymenopteran fauna that is both hugely diverse and fundamentally different in many ways to that of the Northern Hemisphere. Although there has been substantial effort directed to documenting Australian Hymenoptera over the last 70 years, morphological-based taxonomic treatments are waning, in large part, due to a reduced systematics workforce and funding base. Current data on the proportional species diversity of families/superfamilies reveal the major differences between Australia and other regions, and serve to highlight its unique and archaic elements. Approximately 80% of the hymenopteran fauna is undescribed, with the parasitic superfamilies being the least known. Clearly the major challenge for the next 2-3 decades will be how to make significant headway in developing a robust understanding of the continent's hymenopteran diversity. Here we provide an overview of the Australian fauna, highlighting its uniqueness, and discuss the potential of new technologies for documenting diversity relevant to conservation, biological control and evolutionary studies.

Whole-genome sequencing, aTRAM, and the classification of Platygastroidea (Hymenoptera: Proctotrupomorpha)

Authors: Austin Andy[1], Johnson Norman[4], Chen Huayan[3] and Dowton Mark[2], [1]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, Australia, [2]Centre for Medical and Molecular Bioscience School of Biological Sciences University of Wollongong, Australia, [3]Sun Yat-Sen Univeristy, China, [4]The Ohio State University, United States

Abstract: The field of phylogenetics is experiencing a Renaissance. Traditional Sanger sequencing strategies have been all but abandoned for phylogenetic reconstruction methods that utilize hundreds to thousands of genetic markers mined from next-generation sequencing data. The methods used most widely in hymenopteran systematics are genome reduction approaches that target genomic regions typically associated with protein-coding genes. While useful for phylogenetics, these techniques (i.e., UCE, AHE, RNA-seq) generate data that have limited application for addressing additional questions related to organismal biology. Enter aTRAM (automated Target Restricted Assembly Method), a genome reduction approach to phylogenetics that leverages whole-genome sequencing (WGS) reads to assemble large phylogenomic datasets. Here, we document the utility of WGS and aTRAM by constructing nuclear and mitochondrial phylogenies for the parasitic wasp superfamily Platygastroidea. The application of this sequence data to test hypotheses related to host shifting and diversification within Platygastroidea will be discussed and the implications of this phylogenetic reconstruction method will be highlighted.

Delivery of Lethal dsRNAs in Insect Diets by Branched Amphiphilic Peptide Nano-Capsules

Authors: Avila Flores Adriana, Auburn University, United States

Abstract: Development of new and specific insect pest management methods is critical for overcoming pesticide resistance and off-target killings. Gene silencing by feeding dsRNA to insects has promise as one of these methods. We recently described a new class of nanomaterials made of Branched Amphiphilic Peptide Capsules (BAPCs) [1]. In this study, BAPCs were employed to facilitated uptake of dsRNA by insects through feeding. The insect diets included dsRNA with and without complexation with BAPCs. The selected insect species come from two different Orders and with different feeding mechanisms: Tribolium castaneum and Acyrthosiphon pisum. The gene transcripts tested (BiP and Armet) are part of the unfolded protein response (UPR) and suppressing their translation resulted in lethality. For Acyrthosiphon pisum, ingestion of BiP-dsRNA associated with BAPCs led to the premature death of the aphids (t1/2 = 4 - 5 days) compared to ingestion of the same amounts of free BiP-dsRNA (t1/2 = 11-12 days). Tribolium castaneum was effectively killed using a combination of BiP-dsRNA and Armet-dsRNA complexed with BAPCs; most dying as larvae or during eclosion (?75%). Feeding dsRNA alone resulted in fewer deaths (?30%). The results show that complexation of dsRNA with BAPCs enhanced the oral delivery of dsRNA over just dsRNA.

A world first: What pre-emptive biocontrol might mean for BMSB?

Authors: Avila Gonzalo[2], Hoelmer Kim A.[3], MacDonald Frances[1], Charles John[1], Hunt Sophie[1] and Davis Vicky[1], [1]The New Zealand Institute for Plant & Food Research Limited, Mt Albert Research Centre, Auckland; Better Border Biosecurity, [2]The New Zealand Institute for Plant & Food Research, New Zealand, [3]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States

Abstract: The brown marmorated stink bug (BMSB), Halyomorpha halys, is an invasive temperate/subtropical pest of many horticultural crops, and is considered to be one of the world's worst insect biosecurity threats. BMSB is regarded as a major economic and environmental threat to New Zealand, and although it is not yet known to be present in New Zealand, it has been repeatedly intercepted at the border and there remains a high risk of entry and establishment. In preparation for its possible arrival, a pro-active (or pre-emptive) classical biocontrol programme using the egg parasitoid Trissolcus japonicus has been initiated. The potential host range of the parasitoid in New Zealand was investigated by importing parasitised BMSB eggs into quarantine from Newark, DE, USA. Emerging female T. japonicus were mated and exposed to eggs of seven species and one sub-species of Pentatomidae in no-choice laboratory experiments. Results showed that egg of the predatory pentatomids C. nasalis nasalis, C. nasalis hudsoni and O. schellenbergii, and the phytophagous M. humeralis, D. caenosus, G. amyoti, and C. simplex were all confirmed as physiological hosts for T. japonicus, although not all were equally susceptible to parasitism. Eggs of the cosmopolitan pentatomid plant pest N. viridula were not attacked. In addition to laboratory host specificity testing, climatic modelling work was also conducted to estimate the potential global distribution of T. japonicus with particular reference to New Zealand. The north of New Zealand appears moderately to highly suitable for T. japonicus, while southern regions are mostly marginal. The risk posed by T. japonicus to non-target species in New Zealand is predicted to vary between different non-targets. The likely ecological consequences of releasing T. japonicus into New Zealand are discussed, as is the subsequent decision of New Zealand's Environmental Protection Authority to approve the conditional release of T. japonicus should a BMSB incursion occurs in New Zealand.

Introducing CoRoSect, an European project for technological and sustainable insect farming

Authors: Avosani Sabina[2], Vitale Maria Luisa[2], Mockel Rico[3], Lamaj Flutura[2], Papadimitriou Alex[1] and Verrastro Vincenzo[2], [1]CERTH, [2]CIHEAM-BARI, [3]Maastricht University

Abstract: Insect farming is a promising resource supporting food security, the big challenge of our century. Besides representing excellent food sources for farming animals, edible insects were recently approved as novel food for human in the EU. Even so, many rearing processes need to be improved and innovated, to scale the production, decrease production costs and labor, and mitigate the environmental impacts. Sustainable rearing substrates, standardized farming protocols, robotization and automatization are pivotal factors around which the project CoRoSect turns, and for this reason received funding from the EU's Horizon 2020 research and innovation programme under grant agreement No. 101016953.

Here, we introduce the audience of the ICE22 to CoRoSect, whose scopes include the (i) characterization of the biological, technical, and economic requirements of insect rearing, (ii) development of standardized diets based on side-streams, (iii) creation of a novel integrated cognitive robotic ecosystems. CoRoSect is expected to foster safe and technological rearing farms where humans and robot collaborate in the framework of environmentally friendly food chains. The first pilot insect farms involved in the project are placed in different European countries and are rearing three of the leading edible species. While presenting the state of the art and the current results and perspectives, we expect to encourage a fruitful discussion in the context of the symposium.

How is Aleppo pine responding to infestation by the giant pine scale Marchalina hellenica (Hemiptera, Margarodidae): Gas exchange and water status

Authors: Avtzis Dimitrios[2], Andreadi Anneliza[5], Lyrou Fani[1], Spyroglou Gavriil[3], Radoglou Kalliopi[1] and Fotelli Mariangela[4], [1]Department of Forestry and Management of the Environment and Natural Resources School of Agricultural and Forestry Sciences Democritus University of Thrace Ores, [2]Forest Research Institute - Hellenic Agricultural Organization Demeter, Greece, [3]Forest Research Institute Hellenic Agricultural Organization - Demeter Vassilika - Thessaloniki, Greece, [4]Forest Research Institute Hellenic Agricultural Organization - Demeter Vassilika, Greece, [5]Forest Research Institute Hellenic Agricultural Organization Demeter, Greece

Abstract: Aleppo pine (Pinus halepensis Mill.) is a forest species widespread in most countries of the Mediterranean. In Greece and Turkey, it is often infested by Marchalina hellenica (Gennadius) (Hemiptera: Margarodidae), an endemic honeydew-producing scale insect, that has recently invaded Croatia and Australia. To date, there is no information available about the impact of infestation on the physiology of Aleppo pine. In the present study, we assessed the seasonal variation of gas exchange (maximum photosynthesis – Amax, stomatal conductance – gs) and water status (water use efficiency – WUEi, relative water content - RWC) in healthy and infested P. halepensis stands during one year. These findings were then juxtaposed to the infestation level of each individual tree. The impact of infestation was most pronounced from April to June, when the abundance of M.hellenica nymphs increased. Then Amax and gs of infested trees declined significantly and were strongly correlated with M. hellenica nymphs' abundance. At the same time, WUEi of infested trees was increased, thus leading to a favorable RWC regardless of the infestation. In addition, both Amax and gs recovered when the abundance of M.hellenica nymphs declined (in July) and exhibited then the highest seasonal values, despite the drought conditions of mid-summer. These results indicate that although the gas exchange of Aleppo pine is impaired under moderate infestation, still this pine species has developed mechanisms to compensate and maintain a favorable carbon and water balance. Further analysis is focused on detecting which metabolites are involved in these Aleppo pine's responses to infestation.

Taxonomic and functional diversity patterns of butterflies in Olympus and Rhodopes mountains (Greece)

Authors: Avtzis Dimitrios[2], Vlachaki Despoina[3], Kaltsas Dimitrios[3], Raptis Dimitrios[1], Dede Konstantinia[3] and Franses Rolanda[3], [1]Department of Forestry and Natural Environment Management, Laboratory of Forest Management and Economics, Technical University of Kavala, Drama, Greece, [2]Forest Research Institute - Hellenic Agricultural Organization Demeter, Greece, [3]HOMEOTECH Environmental Management Company, Thessaloniki, Greece

Abstract: We explored the different aspects of diversity of butterfly communities along altitudinal gradients within the NATURA 2000 sites of Olympus and Rhodopes mountains in Greece during 2014-2015 in a total of 24 sampling sites on each mountain using the line transect technique.

Species richness and abundance declined monotonically with elevation on the much higher and steeper Olympus that also has a smaller area size, whereas there was no significant pattern on Rhodopes where average richness and abundance were highest at the extended mid-elevations with flatter landscape. Richness and diversity patterns along the altitudinal gradient were caused by the topographical peculiarities of the landscape on each mountain and specifically by the specificity of some xeromontane red-listed species to high elevations, and the preference of common butterfly species for low or intermediate altitudes.

Additive partitioning and null model analyses suggest an ecological redundancy on both mountains, as the environment is filtering species in terms of their environmental requirements (Grinnellian niche) rather than their functional position (Eltonian niche) per se. The turnover component was the primary cause of the major diversity components. Trait convergence through environmental filtering led to the dominance of generalist species which were taxonomically and functionally close.

The application of complementary networks on the two altitudinal gradients supported the importance of the conservation targeting of butterfly SPEC's (Species of European conservation Concern) which are good indicators for the maintenance of the whole butterfly fauna, especially at high elevations, where red-listed butterflies are more frequent and potentially threatened by climate change.

Resolving the identity and occurrence of Thaumetopoea pityocampa in Greece

Authors: Avtzis Dimitrios[3], Eleftheriadou Nikoleta[3], Kavallieratos Nickolas[4], Athanassiou Christos[6], Papachristos Dimitrios[5], Mihaelakis Antonios[5], Schebeck Martin[2] and Stauffer Christian[1], [1]Department of Forest and Soil Sciences, University of Natural Resources and Life, [2]Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences Vienna, BOKU, Austria, [3]Forest Research Institute - Hellenic Agricultural Organization Demeter, Greece, [4]Laboratory of Agricultural Zoology and Entomology, Department of Crop Science, [5]Scientific Directorate of Entomology and Agricultural Zoology, Benaki Phytopatho, [6]University of Thessaly

Abstract: The Pine Processionary Moth, Thaumetopoea pityocampa (Lepidoptera, Notodontidae) is one of the most abundant and widely distributed forest insects of Greece. This species occurrs both in continental parts and on islands, whereas the sister species T. wilkinsoni is limited to south Aegean islands (Crete, Rhodes). Recently, individuals assigned to the East-North African (ENA) mtDNA lineage were found in the broad region of Attika (south eastern part of Greece). Repeated sampling of Greek populations revealed that the ENA lineage was gradually expanding northwards from the Attika region, occupying areas that were formerly inhabited by T. pityocampa. To get a better understanding of the mechanism underlying the expansion of the ENA lineage, populations were screened for various heritable bacterial endosymbionts that are known to manipulate the reproduction of insects and might facilitate the spread of infected hosts, including Wolbachia, Cardinium, Rickettsia and Spiroplasma. However, none of these endosymbionts was detected. Therefore, the expansion of the ENA lineage is most likely not driven by bacterial endosymbionts. Finally, the nitrogen content of larvae belonging to T. pityocampa and ENA lineage has been previously assessed, but nonetheless, did not exhibit any statistically significant differences between them.

Entomological assessment of the risk of outbreak of Aedes-borne diseases during the Covid 19 restriction period in Cape Coast, Ghana

Authors: Ayettey Joana[1], Kudom Andreas A.[1] and Mensah Benjamin A.[1], [1]University Of Cape Coast, Ghana

Abstract: The study assessed the risk of transmission of Aedes-borne arboviruses in the Duakor community in Cape Coast during the Covid-19 restriction period in 2020, using entomological indices. A household container survey was conducted in 100 randomly selected houses. All water-holding-receptacles were examined for the presence of mosquito juveniles. House index, Container index, and Breteau index were calculated from the household data. Ecological succession and prey-predator activities of household-container breeding mosquitoes were also investigated. Only the Container index marginally exceeded the WHO threshold. The risk of a potential outbreak of Aedes-borne diseases in the Covid 19 restriction period was much lower than in 2018 when a similar assessment was done. Community clean-up exercises during the period of Covid 19 restriction may have improved the sanitation condition in the community. This, in turn, may have led to the reduction of discarded items infested by mosquitoes, which was the main cause of high larval indices in the previous study. Notwithstanding, majority (86%) of the mosquitoes were collected from water storage containers. The results from this study show the need for education on good water storage practices as part of the various health promotion activities in this pandemic period.

Population dynamics and species interactions of mosquitoes in a rapidly changing Arctic

Authors: Ayres Matthew P.[1], Culler Lauren[2], [1]Department of Biological Sciences Dartmouth College Hanover, United States, [2]Environmental Studies Program, Dartmouth College Institute of Arctic Studies, Dartmouth College, United States

Abstract: Tundra arthropods are sensitive to temperature change and serve as useful indicators of rapid environmental change in Arctic ecosystems. For example, we have used natural history observations, experimental approaches, and population models to show how warming Arctic temperatures drive changes in the timing and intensity of Arctic mosquito (Aedes nigripes, Diptera: Culicidae) emergence. As mosquitoes emerge and enter the terrestrial system, they become prey for arthropod predators such as wolf spiders (Araneae: Lycosidae) and parasites of vertebrates such as caribou. Here we present results from two studies that aim to quantify impacts to these species interactions. First, we used pitfall traps to compare the densities, sizes, and fecundity of wolf spiders collected near versus far from the margins of mosquito ponds. We found approximately equal densities and sizes of wolf spiders across the landscape. However, female spiders collected near ponds, where we regularly observed spiders consuming newly emerged mosquitoes, had larger egg sacs with more 20% more eggs, indicating that emerging mosquitoes may have a role in shaping wolf spider fitness. Second, we used four years of observational data on emergence timing to build a degree day model. When we applied the model to 70 years of historical weather data, we found that mosquito emergence has advanced by about 8 days during this time period. The phenology of vertebrate hosts, however, has not changed. The degree of temporal overlap between mosquitoes and their hosts may have important consequences for the population dynamics of both parasite and host. For example, the presence of higher densities of caribou was correlated with a 150% increase in the proportion of mosquitoes that successfully got a blood meal. The ecological roles of mosquitoes and other biting insects in the Arctic are far from fully described but our results suggest that changes to biting insect populations will have consequences for the broader tundra ecosystem, mediated through terrestrial-aquatic species interactions.

Why is the southern pine beetle not so southern anymore?

Authors: Ayres Matthew P.[2], Aoki Carissa[1], Lombardo Jeffrey[4], Cancelliere Jessica[3] and Clark Kenneth[5], [1]Bates College, United States, [2]Department of Biological Sciences Dartmouth College Hanover, United States, [3]New York State Department of Environmental Conservation, United States, [4]St. Mary's College of Maryland, United States, [5]USDA-FS Silas Little Experimental Forest, United States

Abstract: Dendroctonus frontalis Zimmermann is among the most aggressive tree-killing insects in the world. D. frontalis is indigenous to southern North America, where it has historically been the dominant source of disturbance in extensive tracts of southern pine forests. Over the last two decades, D. frontalis has extended its distribution northward, first in the New Jersey Pinelands, then on Long Island, and now in New England at multiple points north, east, and west of Long Island. At the same time, D. frontalis has become effectively extinct in East Texas and Louisiana, which was epicenter for D. fontalis outbreaks up until only 20 years ago. Our research has addressed the following questions. Why the northward expansion of D frontalis? Has the northward expansion been facilitated by D. frontalis reaching ecosystems that were ecologically and evolutionarily naïve to this southern pest? Is the explanation for the disappearance of southerly D. frontalis symmetrical to that for the expansion of northern populations (as predicted by the Climatic Envelope concept)?

Predicting the impact of non-native forest insects prior to arrival or establishment

Authors: Ayres Matthew P.[3], Thomas Kathryn[8], Hoover Angela[8], Mech Angela[9], Schulz Ashley[2], Allen Craig[7], Uden Dan[10], Herms Daniel[5], Gurevitch Jessica[4], J. K. Gandhi Kamal[6], Raffa Kenneth[12], Havill Nathan[13], Tobin Patrick[11] and Marsico Travis[1], [1]Arkansas State University, Jonesboro, Arkansas, United States, [2]Colorado Sate University, Fort Collins, Colorado, United States, [3]Department of Biological Sciences Dartmouth College Hanover, United States, [4]Stony Brook University, New York, United States, [5]The Davey Tree Expert Company, Kent, Ohio, United States, [6]The University of Georgia, Athens, Georgia, United States, [7]U.S. Geological Survey, Nebraska Cooperative Fish and Wildlife Unit, Lincoln, Nebraska, United States, [8]U.S. Geological Survey, Southwest Biological Science Center, Tucson, Arizona, United States, [9]University of Maine, , United States, [10]University of Nebraska, Lincoln, United States, [11]University of Washington, Seattle, United States, [12]University of Wisconsin, Madison, United States, [13]USDA Forest Service, Northern Research Station, United States

Abstract: A small proportion of non-native insects cause widespread ecological and/or economic damage on a global scale, but the ability to predict their level of damage prior to arrival has eluded scientists for decades. Advancements in the study of invasion biology and fields such as computational phylogenetics provide tools that could help to quantify the drivers that influence the eventual impact of a non-native insect. Understanding these drivers can inform management decisions including risk assessments for insects not yet established but have a high likelihood of introduction given global trade pathways. Using available data pertaining to currently established non-native insects in North American forest systems, we evaluated factors that could explain why some invading insects cause high impacts while others are benign. These drivers included 1) insect traits, 2) host tree traits, especially those related to host defenses, 3) divergence time between the insect's native and novel (North American) host trees, and 4) the relationship of the invader to insects coevolved with the novel host. We quantified the relative combined contributions of these drivers to the magnitude of impact and developed composite predictor models that can be used to predict the risk of non-native insects to cause tree mortality should they successfully become established in North America. The results from our work, both the predictive models and the compiled databases, can be significant tools for regulatory and pest management efforts in North America, and represents a successful protocol that can be extended globally.

IPM package for pearl millet in the Sahel

Authors: Ba Malick, ICRISAT, Niger

Abstract: For more than 20 years, the head miner Heliocheilus albipunctella (de Joannis) (Lepidoptera: Noctuidae), has regularly devastated crops of pearl millet, a major subsistence food crop in the Sahelian region of West Africa. Currently, the development of biological control has been given priority and augmentative releases of the endogenous larval parasitoid Habrobracon hebetor Say can lead to up 80% of MHM larval mortality. Recent trials have confirmed that the release of H. hebetor can be practically applied at the village level. Commercialization of the technique has been proposed and may prove to be a profitable business for local entrepreneurs. In addition to the larval parasitoid, the egg parasitoid Trichogrammatoidea armigera Nagaraja (Hymenoptera: Trichogrammatidae) inflicts up 60% egg mortality. Host plant resistance has been found in genotypes Gamoji, LCIC9702, Souna 3, and PE08043. Effort are being taken to combine resistance genotypes with augmentative releases of egg and larval parasitoids for an integrated management of the MHM.

Phylogenomic reconstruction, evolution and biogeography of Atta leaf-cutting ants (Hymenoptera: Formicidae)

Authors: Bacci Mauricio[4], Anahí Barrera Corina[3], Sosa-Calvo Jeffrey[2], Schultz Ted[2] and Rabeling Christian[1], [1]Arizona State University, [2]National Museum of Natural History-Smithsonian Institution, [3]Sao Paulo State University, Rio Claro, SP, Brazil, [4]Sao Paulo State University, Rio Claro, SP, Brazil

Abstract: Atta is an ecologically dominant leaf-cutting ant genus, the major herbivore of the Neotropics, and an agricultural pest of great importance. We reconstructed the most comprehensive phylogenetic estimate to date of Atta by employing 2340 ultraconserved elements loci from 224 Atta specimens, which include 14 out of the 15 identifiable species from across their geographic distributions, and 49 outgroup specimens. Our results support the monophyly of Atta and of the four clades that coincide with the previously recognized subgenera. The Archeatta clade contains three species occurring in North and Central America and the Caribbean and is the sister group of the remainder of all other Atta species. The Atta s.s. clade is composed of two species occupying North, Central, and South America. The Epiatta clade contains seven entirely South American species and the two species of the Neoatta clade occur in Central and South America. The crown-group origin of Atta was around 8.5 Ma and the extant Atta species evolved in the early Pleistocene, 1.8–0.3 Ma. The range of the most recent common ancestor of Atta consisted of the combined North/Central America and NW South America bioregions and that one daughter lineage subsequently dispersed into South America.

Population and Biodiversity Trends of Ground Beetles and Butterflies in Europe - A Review of Drivers and Pressures

Authors: Baden Christian[2], Bergtold Matthias[1], Schade Michael[5], Marx Michael[3], Toschki Andreas[4], Oellers Johanna[4] and Rumohr Quintana[4], [1]BASF, [2]Bayer AG, Germany, [3]Bayer, Germany, [4]GAIAC, [5]Syngenta

Abstract: Declines of insect biodiversity and abundances have frequently been reported. Although a broad variety of potential causative factors of these declines have been proposed, the drivers of the phenomenon are not yet fully understood. One possible way of elucidating them is the systematic analysis of published historic population data. We conducted an evaluation of scientific literature reporting data on Carabidae and Lepidoptera population and biodiversity trends in Europe. From the relevant publications identified, we extracted reported trends and classified the environmental stressors discussed along with the respective trends according to the DPSIR model (drivers, pressures, state, impact, and responses). We analyzed the level of scientific verification behind the discussed stressors. The analysis of extracted trends shows that declines are more frequent than increasing trends. For both trends, our analysis confirms that changes in populations are primarily anthropogenically driven. The reported drivers are diverse, for instance agricultural intensification, climate change, conservation activities, and urbanization. Most of the reported stressors were acting on habitat level, rather than directly affecting the organisms. The scientific verification level of the indicated drivers is different between trend types. The results of our analysis contribute to a better understanding of insect decline as a complex phenomenon.

Electronic monitoring of the potato psyllid feeding behavior on susceptible and resistant tomato lines

Authors: Badillo-Vargas Ismael E.[1], Koch Kyle G.[3] and Bernal Jimenez Estephanie K.[2], [1]South Texas College - Biology Department, [2]Texas A&M AgriLife Research, [3]University of Nebraska - Lincoln

Abstract: The potato psyllid, Bactericera cockerelli, is a significant pest of vegetables throughout Central and North America, New Zealand, and Australia. This psyllid is the vector of “Candidatus Liberibacter solanacearum” (Lso), which is the causative agent of diseases in several solanaceous crops. Currently, five Lso haplotypes have been identified, two of which (LsoA and LsoB) are exclusively transmitted by potato psyllids in their shared geographic range within the Americas. Plant resistance as a component of a management strategy for this pathosystem presents an attractive option. Resistance factors which reduce the time psyllids spend in phloem phases, especially salivation, could play an important role in reducing pathogen transmission. Previously, several recombinant inbreed lines (RILs) were reported to carry potato psyllid resistance from a wild tomato relative, Solanum habrochaites, in the S. lycopersicum (cv. Moneymaker) background. In this study, we used the electrical penetration graph technique to elucidate the feeding behavior of potato psyllids on five tomato RILs and each parental line to better understand the underlying resistance factors. In general, potato psyllids took longer to reach the sieve elements on S. habrochaites. Furthermore, potato psyllids were unable to sustain ingestion on S. habrochaites and one RIL relative to psyllids on Moneymaker.

A new record of the genus Euderus Haliday (Hymenoptera: Chalcidoidea: Eulophidae) from Korea

Authors: Bae Jongmin[2], Youn Young Nam[1] and Jung Sunghoon[1], [1]Department of Applied Biology, Chungnam National University, [2]Department of Smart Agriculture Systems, Chungnam National University

Abstract: The genus Euderus Haliday is a cosmopolitan genus with 80 described species. Until the present, only one species of the genus has been reported from Korea. In this presentation, we report a new record of the genus Euderus from Korea, with its figures.

Winterblues: Colour Preference of overwintering flies

Authors: Baele Amber, Ghent University, Belgium

Abstract: Water towers are a popular overwintering place for several fly species (Musca autumnalis, Pollenia spp. and Thaumatomyia notata) in Europe.

During late summer, early autumn massive swarms of flies enter buildings to seek shelter against upcoming winter conditions in crevices of their refugia. In inhabited buildings, the aggregation of flies can be a big nuisance just by their numerous presence. In industry, utility buildings and more specific water towers, their presence can pose a threat to public health as flies are known vectors of pathogens. Unraveling the preferences of these hibernating flies can thus be useful in the control of the pests in places where they can cause damage.

It is striking that the same water towers get infested year after year, while others never get visited. Colour preference could be an influencing factor to determine if a place is worth visiting or not. To test this hypothesis, tarpaulins with different colours were erected on top of a tower in the four wind directions. The flies preferred to land on the sides away from prevailing wind and preferentially on the colour blue. Yellow, a colour typically used as an attractant on insect traps, was under no circumstances an attractive colour.

Rearing insects - lessons to be learned from the housefly (Musca domestica)

Authors: Bahrndorff Simon, Aalborg University, Denmark

Abstract: Insects for food and feed is an environmentally friendly and sustainable production form. Mass rearing of insects holds many advantages over traditional domestic animals in terms the requirement for energy, space, and the efficiency accumulating biomass from a given resource. However, a number of challenges related to the genetic makeup of insects should be addressed in order to optimize the production. Using next generations sequencing technologies we investigate the genetic variation and associated microbiome within and between populations of houseflies sampled across Denmark. There was evidence for sub-structuring of Danish housefly populations and with genetic structure that differed across season and sex. Large individual variations were observed in the community structure of the microbiome and it was found to be dependent on location, sex, and collection time. Furthermore, the relative prevalence of putative pathogens was highly dependent on location and collection time. These results may have implications for large scale production of insects.

A comparative RNAseq study between phases of two pest locusts

Authors: Bakkali Mohammed[1], Bakkali Noureddine[1], Saadi Somia[1] and Obispo Valencia Alejandro[1], [1]Universidad de Granada, Spain

Abstract: Recurrent locust population outbreaks harm agriculture, livestock, ecosystems, economies and, ultimately, humans in large parts of the world. At outbreaks, locusts shift from the normal, harmless, solitarious phase to the devastating, gregarious phase in response to extraordinary increase in their population size. Locusts of the two phases differ in almost every aspect of their biology; including the level of activity, tendency to aggregate, tendency to migrate (swarming), color, morphology, physiology, development… The shift from one phase to the other is due to changes in gene expression, not to mutation, as the same individual can shift from one phase to the other. Furthermore, this striking case of phenotypic plasticity (called polyphenism) is tightly linked to perception of life conditions and to behaviour. Its most obvious association is hence expected to be with changes of the nervous system.

Identifying genes that are associated with, if not responsible for, the development and/or maintenance of the gregarious state of the locusts should provide invaluable material and information for the efforts on the fight against these pest insects.

In this study we compare the levels of gene expression between the nervous systems of solitarious and gregarious Schistocerca gregaria (desert locust) and Locusta migratoria (migratory locust).

We identify genes whose change in the levels of expression between phases is consistent between these two main pest locusts and we discuss the results at the light of the current knowledge on the phenomenon in order to highlight their potential interest.

Shotgun metagenomics as a training tool in molecular biomonitoring

Authors: Balint Miklos[1], Schneider Clément[2], Feldmeyer Barbara[3] and Prost Stefan[2], [1]LOEWE Centre for Translational Biodiversity Genomics (LOEWE-TBG) Senckenberg Biodiversity and Climate Research Centre (SBiK-F), Germany, [2]LOEWE Centre for Translational Biodiversity Genomics (LOEWE-TBG), Germany, [3]Senckenberg Biodiversity and Climate Research Centre (SBiK-F), Germany

Abstract: Genomic tools are increasingly relevant for the monitoring of ecological communities. It is essential that new generations of biodiversity experts are both fluent in their use, and aware of new developments and perspectives. With this in mind we developed a field course in monitoring of insects with shotgun metagenomics. Shotgun metagenomics promises to solve problems with the quantification of biomass through DNA-sequences in metabarcoding, and might become an alternative approach in the nearer future. The field course took place at a field station in a remote area of Romania, where MSc students designed a study to compare insect biodiversity on traditionally managed (grazed or mown) grassland plots. They also contrasted a morphospecies approach and shotgun metagenomics to record differences among communities. All steps of the shotgun metagenomics study were performed at the station, from sampling through DNA extraction, library preparation and DNA sequencing to bioinformatics, data analysis and interpretation. Both morphospecies identification and metagenomics recorded that grazed meadows have considerably lower insect richness than mown meadows, and differences in community composition were not statistically, partially confirming expectations about the effects of grazing-related fertilization. In our experience the metagenomics field course format provides a rather simple and straightforward opportunity to expose future experts to the strengths and challenges of emerging molecular approaches in biomonitoring.

Two high-quality de novo genomes of the gall inducing Diplolepis rosae and D. eglanteriae (Hymenoptera: Cynipidae)

Authors: Balint Miklos[4], László Zoltán[2], Schardt Leonie[5], Veres Robert[1], Dénes-Avar Lehel[2], Szabó Emerencia[3], Mátis Attila[2], [1]Babeş-Bolyai University, Romania, [2]Hungarian Department of Biology and Ecology, Babeş-Bolyai University, [3]Hungarian Department of Biology and Ecology, Babeş-Bolyai University, Romania, [4]Loewe Centre for Translational Biodiversity Genomics, Frankfurt am Main, [5]Senckenberg Biodiversity and Climate Research Centre (SBiK-F), Frankfurt am Main

Abstract: Gall wasps (Hymenoptera: Cynipidae) which specialize on wild roses (Rosa sp.) are relatively species-poor and ecologically well-studied. Gall formation can damage economically important host plants and provides habitat for numerous parasitoids, but the mechanisms of gall formation are poorly understood. For example, it is unclear whether gall formation is induced by substances produced by the wasps themselves, or by their microbiome. Biodiversity genomics is increasingly used to answer similar questions and to identify genes behind natural substances, both in prokaryotes and eukaryotes. Today we can use long-read DNA sequencing to generate high-quality (complete and contiguous) genomes for many non-genetic model species. Here we present two de novo genomes of the gall inducer Cynipidae Diplolepis rosae and D. eglanteriae. We extracted RNA and high molecular weight DNA from single individuals. We prepared ultra-low input PacBio libraries for HiFi long-read sequencing with a protocol that requires only 5 ng DNA input, followed by whole genome amplification. We also prepared Omni-C libraries for scaffolding, and RNA-Seq libraries for genome annotation, and sequenced these on Illumina. The assembled, scaffolded and annotated genomes promise insights into the genomic mechanisms of plant gall induction and provide valuable opportunities to identify potentially involved genes.

Identification of the novel antimicrobial peptides from a rice planthopper, Nilaparvata lugens

Authors: Bao Yanyuan[2], Peng Luyao[2], Song Qisheng[1], Zhou Xiang[2] and Wang Zhechao[2], [1]University of Missouri, [2]Zhejiang University, China

Abstract: In this study, two novel antibacterial peptide genes, termed lugensin A and B were identified and characterized from a rice sap-sucking hemipteran insect pest, the brown planthopper, Nilaparvata lugens. Lugensin gene expression was significantly induced by Gram-negative and Gram-positive bacterial stains under the regulation of a signal receptor, the long peptidoglycan recognition protein (PGRP-LC) in the IMD pathway. Knockdown of PGRP-LC by RNAi eliminated bacterium induced Lugensin gene expression. Lugensins had the apparent antibacterial activities against Escherichia coli K12, Bacillus subtilis and the rice bacterial brown stripe pathogen Acidovorax avenae subsp. avenae (Aaa) strain RS-1. Lugensins inhibited bacterial proliferation by disrupting the integrity of the bacterial membranes. Scanning electron microscopy revealed abnormal membrane morphology of the recombinant Lugensin-treated bacteria. Lugensins induced complete cell disruption of E. coli K12 and B. subtilis strains while formed the holes on the cell surface of Aaa RS-1 strain. Immunofluorescence showed that Lugensins localized in the cell membrane of E. coli K12 while accumulated in the cytosol of B. subtilis. Differently, Lugensins remained in both the cell membrane and the cytosol of Aaa RS-1 strain, suggesting different action modes of Lugensins to different microbes. This is the first report of the novel antibacterial peptides found in the rice sap-sucking hemipteran insect species.

First report of tussock moths (Bracharoa mixta (Lepidoptera: Erebidae)), scarring avocado fruit in KwaZulu-Natal, South Africa

Authors: Bara Gracian Takudzwa[2] and Laing Mark[1], [1]University of KwaZulu-Natal School of Agricultural, Earth and Environmental Sciences Scottsville, Pietermaritzburg, South Africa, [2]University of KwaZulu-Natal School of Agricultural, Earth and Environmental Sciences Scottsville, Pietermaritzburg, South Africa

Abstract: Avocado (Persea americana) is an important export crop for South Africa contributing ZAR 1.75 billion in export revenue to the gross domestic product. As an export-oriented industry, increasing the exportable percentage of avocado fruit is a major concern. A tussock moth, Bracharoa mixta (Snellen) is reported for the first time on avocado trees, scarring fruit and defoliating leaves. Feeding damage by the larva results in corky tissue development, making the fruit unsuitable for export. The study aimed to determine the identity of the larvae (morphologically and DNA barcoding) and ascertain levels of damage. Sequencing of the barcoding region of cytochrome oxidase subunit I (COI) gene was done. In-field fruit damage assessment of infested trees showed an 11 % scarring damage level resulting in 3.67 % downgrading of fruit. This represents a potential revenue loss of up to ZAR 1,352.90 per tonne (2.26 % revenue loss). The defoliating caterpillars also caused an 18.22 % reduction in leaf area. This study documents the potential of B. mixta to cause economic loss and sporadic, isolated outbreaks.

Acoustic mimicry in myrmecophilous butterflies

Authors: Barbero Francesca, Dept Life Sciences and Systems Biology - Turin University, Italy

Abstract: The ability to communicate efficiently and coordinate the actions of up to a million specialised nestmates has enabled ants to be among the most successful animals globally, frequently dominating several terrestrial ecosystems. Their means of communication include the multifarious use of chemical signals, posturing, and tactile interactions, and the comparatively poorly studied channel of vibro-acoustical signals. Ant defences are largely based on possessing impressive weaponry, including poisons, acids and biting, and their ability to deploy them, thanks to communication, in coordinated attacks that marshal overwhelming numbers of workers.

Nevertheless, several species of invertebrates have evolved adaptations to establish associations with ants, living undisturbed in the surroundings or even within their colonies.

Myrmecophilous interactions are well known to occur in Lycaenids, a family of Lepidoptera which accounts for 30% of butterfly species. Most Lycaenids establish associations with ants that can be facultative or obligate and range from mutualism to parasitism, with loose interactions in which larvae are only occasionally visited by several species of ants, to complex obligate associations in which larvae need to be constantly tended by ants.

Myrmecophilous butterflies show morphological, behavioural, chemical or acoustical strategies for cohabiting with ants including armour, stealth and, in the case of most mutualists, the secretion of attractive food rewards. However, the most intriguing adaptations involve the subversion of the ants' honest acoustical signalling, enabling butterfly social parasites of the genus Maculinea to achieve a high social status in the host colony hierarchy. Immature Maculinea instars mimic the stridulations emitted by host queen ants to enhance their retrieval, survival and full integration into the host society. Recent data suggest that, among lycaenid butterfly larvae, convergence has generated similar sophisticated calls that are more closely associated with the strength and specificity of a species' relationship with ants than its phylogeny.

I will present examples of acoustic mimicry, and I will discuss the function of vibro-acoustic signalling in symbioses involving butterflies and ants. The study of acoustic communication in myrmecophilous systems could bring about significant insights for understanding complex mechanisms underlying the origin, evolution, and stabilisation of many multitrophic relationships.

Hell ants

Authors: Barden Phillip, Department of Biological Sciences, New Jersey Institute of Technology, Newark, NJ, Division of Invertebrate Zoology, American Museum of Natural History, United States

Abstract: Among the oldest fossil ants known, haidomyrmecine "hell ants" are highly specialized predators. Comprising nine genera, these enigmatic ants are preserved in Cretaceous amber from Canada, France, and Myanmar, and exhibit an array of cranial features not found in any modern lineages. Hell ants are characterized by dramatic scythe-like mouthparts that are dorso-ventrally expanded into a diverse array of mandibles that are specialized for prey capture. Remarkably, these unique mandibles appear to be accompanied by a novel mode of articulation; hell ant mandibles are suspected to open vertically, in an axial plane parallel to that of all living ants. This unique feature in turn has led to the development of striking "horns" which work in conjunction with the mandibles to pin, restrain, or impale prey. Here, I will survey the diversity of this unique lineage, interpret preserved instances of prey capture, and discuss hell ants in the broader context of extinct adaptive radiations.

Biological Control Genetic Resources and Access and Benefit-Sharing

Authors: Barratt Barbara I. P.[1], Mason Peter[2], [1]AgResearch, New Zealand, [2]Agriculture and Agri-Food Canada, Canada

Abstract: The third objective of the Convention on Biological Diversity, the fair and equitable sharing of benefits arising out of the utilization of genetic resources was formally implemented when The Nagoya Protocol came into effect in 2014. However, participating countries were not provided with guidance for developing legislation on access and benefit-sharing, thus interpretation on what is equitable sharing and what are benefits is likely to be wide-ranging. The implications for biological control in the future include how biological control agents will be utilized and exchanged, how biological control will benefit the global community, and how response times for implementing biological control may be affected. The free use and exchange of biological control genetic resources has provided benefits to the global community, including to both providers and recipients of biological control agents. Consideration of this principal should be a key element of Access and Benefit-Sharing measures.

Spiny snout mite 25 years on: how relevant is the Tasmanian experience of clover flea biocontrol to New Zealand?

Authors: Barratt Barbara[2], Gerard Philippa[1], Wilson Derrick[1], [1]AgResearch Ltd, New Zealand, [2]AgResearch Ltd, Nicaragua

Abstract: A French ecotype of the Bdellid mite, Neomolgus capillatus (Kramer) (spiny snout mite) was introduced into Tasmania, Australia, in 1985 to control clover flea (L.), a serious Collembolan pest of clover in dairy pastures. Its main limitation to effectiveness was its very slow dispersal which was addressed through an extensive redistribution programme over 800 sites. The success of the spiny snout mite as a biocontrol agent in Tasmania has initiated investigations into the feasibility of introducing it into New Zealand where clover flea remains a problem in localised areas in the North Island and may intensify with expansion of irrigation and climate change. While both Australia and New Zealand have markedly tightened regulations around the introduction of new species, we postulate that past and future research in Tasmania could provide adequate risk assessment data to enable the mite to be introduced from there to New Zealand. Tasmanian and New Zealand pasture and natural ecosystems in the target regions are compared and results from a survey on presence of the mite in non-target habitats are presented. Knowledge gaps are identified where additional research should be focused to meet New Zealand regulatory system standards .

Species distribution modeling to evaluate the impact of climate change on the distribution of Nysius simulans (Stål) (Hemiptera: Lygaeidae) in soybean crops in South America

Authors: Barreto Carlos[2] and S. de Paula Alexandre[1], [1]Federal University of Ouro Preto, Brazil, [2]The University of Western Ontario, Canada

Abstract: Nysius simulans (Stål) is an economically important plant pest for soybean in South America, and a suctorial, fluid feeding herbivore that can transmit toxins and spread pathogens via saliva. Currently, the distribution of N. simulans on soybean is predominantly found in Argentina, but changes in the distribution from natural dispersal and range shifts due to climate change may affect a large soybean cultivation in south of Brazil. We compared the potential distribution of N. simulans under current and future projected climatic conditions in order to identify future areas of natural occurrence with ecological niche models produced using Maxent. Current records of N. simulans show that while the species is present in Argentina, Brazil, Paraguay, Peru and Uruguay, and our models suggest that many new suitable areas will be available for N. simulans under climate change including north, central and southern Argentina, and southern Chile. Our results also predict potential future range shifts and distributions into Bolivia, but not Peru nor Brazil. In our model, seasonal trends in temperature was shown to have the greatest contribution to the potential distribution, whereas isothermality (i.e. temperature variability) was negatively correlated to potential future distribution ranges. We conclude that current populations of N. simulans may be expanding its distribution range by diffusion (i.e., range expansion over generations at the margins of populations), and regions with potential future N. simulans distribution should be closely monitored.

Insects, robots and zombies

Authors: Barron Andrew, Macquarie University, Australia

Abstract: Insects are small but they are not simple animals. They are capable of impressive cognitive feats and have complex lifestyles and life histories. The accessibility and small size of their nervous system and brain means that we have made great progress in understanding the mechanisms of insect behaviour. The mechanisms of even complex insect behaviour are often deceptively simple. Here we discuss the consequences of a mechanistic understanding of insect behaviour for our appreciation of animal consciousness. If mechanisms of insect behaviour can be described in mechanistic and deterministic terms does this make an insect a robot or a ‘zombie’ with, as Chalmers has put it, “no inner life at all”?

Plant Derived Insecticidal Proteins for Protection of Crop Plants

Authors: Barry Jennifer, Corteva Agriscience, United States

Abstract: Current commercialized insect traits in corn, soy, and cotton are based on genes discovered by mining the soil bacterium, Bacillus thuringiensis, for proteins with insecticidal activity. These traits have been an important tool utilized by farmers to maximize productivity. However, the development of resistance to these traits has generated urgency to discover new proteins with novel Sites of Action (SoA) that can complement or replace existing products. We have identified many plants that naturally produce insecticidal proteins and have mined these plants as a source of novel actives for Corteva's insect trait development pipeline. Transgenic soybean (Glycine max L. Merill) and corn (Zea mays L.) plants expressing plant derived insecticidal proteins show protection from feeding damage by insect pests. This talk will focus on novel plant derived proteins that demonstrate promise for developing new transgenic crops for pest control.

Meeting the Challenge of Training a Next Generation of Public Health Entomologists

Authors: Bartholomay Lyric, University of Wisconsin-Madison, United States

Abstract: Given the state and rate of global change and ready movement of vectors and pathogens, the need for preparing a next generation of highly trained public health professionals is particularly pressing. The outbreak of Zika in the United States revealed a profound shortfall of public health entomologists at the ready to tackle emerging vector-borne diseases, and precipitated the establishment of 5 regional Centers of Excellence supported by the Centers for Disease Control and Prevention. Each Center developed regionally responsive training approaches and delivery modalities, to include competitive grants programs, professional development workshops, a Masters Degree Program, internships and fellowships, in-person and online training offerings. After 5 years, the Centers of Excellence trained more that 600 undergraduate, graduate and professional students, and reached more than 8,000 local vector control professionals. At the same time, a major initiative from the American Mosquito Control Association was initiated to Train the Trainers to improve vector control practices across the country. Vector control, public health and academic institutions are witnessing the benefit of this new generation of trainees who are well-versed in vector biology and vector control.

Bark beetle outbreaks and meta-population dynamics of woodpeckers in Switzerland.

Authors: Basile Marco, Swiss Federal Research Institute WSL

Abstract: Resource pulses can affect animal populations in various ways. One such pulse is the increased availability of spruce bark beetle (Ips typographus), the most common forest pest in Central and Northern Europe, following disturbances such as storms and dry summers, and the subsequent increase of other wood-boring insects. Woodpeckers are considered important predators of bark beetle, but their relationship has not been studied thoroughly. Therefore, we investigated the bark beetle-woodpeckers system using a multi-decade long dataset to understand whether increases in population size of woodpeckers can be related to bark beetle outbreaks, and whether the relationship is density-dependent. We also investigated the role of standing deadwood and salvage logging as moderators of woodpecker responses to bark beetle outbreaks. We infer on the importance of deadwood for woodpecker per se, and as a pulsing resource linked to bark beetle outbreaks. We expect that bark beetle outbreaks have positive direct effects on the abundance of woodpecker species over short time periods. Our model can be used to estimate the role of bark beetle outbreaks in influencing bird population trends and whether birds contribute to stabilizing or even controlling bark beetle infestations over time.

Latitudinal patterns in herbivory and plant defense depend on leaf age and spatial scale

Authors: Baskett Carina, Institute of Science and Technology Austria, Austria

Abstract: The biotic interactions hypothesis posits that biotic interactions are more important drivers of adaptation closer to the equator, evidenced by "stronger" contemporary interactions (e.g. greater interaction rates) and/or patterns of trait evolution consistent with a history of stronger interactions. Support for the hypothesis is mixed, but few studies span tropical and temperate regions while experimentally controlling for evolutionary history. Here, we integrate field observations and common garden experiments to quantify the relative importance of herbivory in a pair of tropical-temperate congeneric perennial herbs. Phytolacca rivinoides and P. americana are pioneer species native to the Neotropics and the eastern USA, respectively. We compared plant-herbivore interactions between three tropical populations of P. rivinoides from Costa Rica and three temperate populations of P. americana from its northern range edge in Michigan and Ohio. For some metrics of interaction importance, we also included three subtropical populations of P. americana from its southern range edge in Florida. This approach confounds species and region but allows us, uniquely, to measure complementary proxies of interaction importance across a tropical-temperate range in one system. To test the prediction that lower-latitude plants experience more herbivore pressure, we quantified herbivory rates, herbivore abundance, and leaf palatability. We found evidence supporting the biotic interactions hypothesis for most comparisons between P. rivinoides and north-temperate P. americana (herbivory, herbivore abundance, and young-leaf palatability). Results for subtropical P. americana populations, however, were typically not intermediate between P. rivinoides and north-temperate P. americana, as would be predicted by a linear latitudinal gradient in interaction importance. Subtropical young-leaf palatability was intermediate, but subtropical mature leaves were the least palatable. These nonlinear patterns of interaction importance suggest future work to relate interaction importance to climatic or biotic thresholds. In sum, we found that the biotic interactions hypothesis was more consistently supported at the larger spatial scale of our study.

Investigating resistance mechanisms and fitness costs related to avermectin resistance in the diamondback moth, Plutella xylostella L. (Lep: Plutellidae)

Authors: Bass Chris[5], Oplopoiou Maria[4], Zimmer Christoph[3], M. Leroux Alicia[2], Elias Jan[2], Guest Marcus[3], Kanitz Ricardo[1] and Slater Russell[1], [1]Syngenta Crop Protection AG, Werk Rosental Schwarzwaldallee, Basel, Switzerland [2]Syngenta Crop Protection, Stein, Switzerland, [3]Syngenta, United Kingdom, [4]University of Exeter, College of Life and Environmental Sciences, UK Syngenta Crop Protection, Switzerland, [5]University of Exeter, United Kingdom

Abstract: Plutella xylostella (Lepidoptera: Plutellidae) is an oligophagous species and an abundant pest in cruciferous crops which causes a severe threat to crop production worldwide. P. xylostella is a high-risk pest concerning resistance development, having developed resistance against > 90 active ingredients, including avermectins. Emamectin-benzoate is a potent lepidoptericide, belonging to the group of avermectin. It is synthesized from the macrocyclic lactone abamectin which is derived from fermentation of the soil actinomycete Streptomyces avermitilis. Reduced field performance of emamectin-benzoate in P. xylostella has been reported in isolate localities in Japan.
This project aims to elucidate the resistance mechanisms provoking this phenomenon and to investigate any plausibly relevant fitness costs. Two field-collected resistant strains were established in the laboratory and are artificially selected with emamectin-benzoate every two generations. Dose-response leaf dip bioassays are followed every other generation to detect any susceptibility shift.

Avermectins act as allosteric modulators to the glutamate-gated chloride channels (GluCls) and target-site mutations have been described in the literature pertaining abamectin resistance in the two spotted spider mite, Tetranychus urticae, and in P. xylostella. Our results showed that those mutations are not present in our resistant strains. Ongoing analysis includes sequencing the full length of GluCl gene to screen it for novel mutations. The results may explain the observed resistance and potentially provide us with paramount information on avermectins binding site. Isolation of the resistant trait in a susceptible background achieved by back-crossings will determine the mode of inheritance and aid genetic trait mapping.

A computer model will be adopted and different scenarios i.e. different starting allele frequencies and treatment regimens (dose, application frequency, mode of action, mixtures and rotational applications) will be tested in silico. The modelling approach will allow simultaneous testing of numerous scenarios and will help to make informed decisions on which scenarios have the potential to better manage resistance. Knowledge about the mechanism, the mode of inheritance, the persistence of resistance under different treatment scenarios and the potential impact of resistance on fitness is critical for the design of a sustainable integrated pest management (IPM) program.

Revisiting an old resistance story in the genomic era, unravelling the genomic mechanisms of esterase mediated resistance in Myzus persicae.

Authors: Bass Chris[3], Troczka Bartlomiej[1], Hunt Benjamin[1], Saurabh-Singh Kumar[3] and Field Linda[2], [1]College of Life and Environmental Sciences, Biosciences, University of Exeter, Penryn Campus, Penryn, Cornwall, United Kingdom, [2]Department of Biointeractions and Crop Protection, Rothamsted Research, Harpenden, United Kingdom, [3]University of Exeter, United Kingdom

Abstract: Nearly 30 years ago it was shown that resistance to organophosphates in Myzus persicae is mediated by increased activity of two closely related carboxyesterase genes called E4 and FE4 both being able to hydrolyse and sequester insecticidal esters. Subsequent molecular characterization at the time pin-pointed the mechanism of resistance to increase in gene copy number and changes in methylation for either E4 or FE4. However, the specific mechanism(s) by which these genes were amplified was never elucidated.
With the arrival and subsequent improvement of third generation sequencing technologies it is now possible to understand the molecular mechanisms underpinning this adaptation at much greater resolution. We have analysed sequence data from a selection of susceptible and esterase resistant M. persicae clones with various amount of amplified enzymes and are using this to understand molecular evolution at the esterase gene locus.

The genomics of adaptation to natural and synthetic xenobiotics in the aphid Myzus persicae

Authors: Bass Chris, University of Exeter, United Kingdom

Abstract: The process by which genetic novelty is created and drives the evolution of key innovations required for ecological adaptation is still relatively poorly understood. In this talk I will outline recent work investigating the mutational events driving host-range expansion and xenobiotic resistance in the peach potato aphid, Myzus persicae, the most economically important aphid pest worldwide. M. persicae is globally distributed and highly polyphagous with a host range of over 400 species including many important crop plants. Relatively recently this species host-shifted to tobacco, and we have previously demonstrated that the constitutive overexpression of a cytochrome P450, CYP6CY3, allows tobacco-adapted races of M. persicae to efficiently detoxify nicotine and has preadapted them to resist neonicotinoid insecticides. Our recent work has employed a suite of genomic, transcriptomic and post-genomic functional approaches to demonstrate the role of chromosomal rearrangements and transposable elements in creating the genetic novelty required for M. persicae to resist xenobiotics and exploit a new ecological niche.

Advancing our understanding of spatial distributions of an endangered wasp at different spatial scales

Authors: Batsleer Femke[1], Maes Dirk[2] and Bonte Dries[1], [1]Ghent University, Belgium, [2]Research Institute for Nature and Forest, Belgium

Abstract: The spatial distribution of insects is typically anticipated to be driven by environmental heterogeneity. Internal mechanisms related to social attraction and competition are from a theoretical perspective as important and may lead to stable self-organisation. Such insights are elementary to predicting changes in future distributions, but as these processes act in concert, they are extremely hard to disentangle. Understanding these mechanisms is important to make well-informed conservation decisions.

We quantified spatial pattern formation of nest aggregates of the dune inhabiting digger wasp Bembix rostrata within a local, population scale and the distribution of these aggregates at a larger landscape scale. The processes leading to the local spatial distribution were investigated by the development of a microhabitat model from remote sensing drone data and a pattern-oriented Individual Based Model (IBM). Bottom-up factors and social attraction were found to be the most important drivers to explain this local spatial pattern. At the landscape scale, we used a small scale Species Distribution Model (SDM) using remote sensing aerial and LIDAR data and data on grazing management. These analyses demonstrated the importance of landscape-structure as bottom-up driver and nature management as top-down driver of the species' distribution at the landscape scale.

We critically discuss the importance of incorporating remote sensing and pattern oriented modelling for not only the detection of spatial distribution patterns but also to understand the putative mechanisms underlying these patterns. Both important for the conservation of this dune inhabiting digger wasp.

Bark and ambrosia beetles associated with imported non-coniferous wood

Authors: Battisti Andrea[1], Jactel Herve[4], Grégoire Jean-Claude[6], Hulcr Jiri[5], Orlinski Andrei[2], Benko-Beloglavec Anita[8], Hrasovec Boris[7], Inward Daegan[3], Grousset Fabienne[2] and Petter Françoise[2], [1]DAFNAE, University of Padua, Italy, [2]EPPO, France, [3]Forest Research, United Kingdom, [4]INRA, France, [5]School of Forest, Fisheries, and Geomatics Sciences, University of Florida, United States, [6]Spatial Epidemiology lab Universite libre de Bruxelles, Belgium, [7]Šumarski Fakultet, Hungary, [8]Varstvo Gozdov Slovenije, Slovenia

Abstract: Many bark and ambrosia beetle species (Coleoptera: Scolytinae and Platypodinae) are known to have spread worldwide in relation to international trade. Concerns were expressed within the European and Mediterranean Plant Protection Organization (EPPO) about recent introductions of non-indigenous species of those groups. Regulation for non-coniferous wood trade into many EPPO member countries is currently not considered sufficient to cover such risks. In 2018, an EPPO Study on the risk of bark and ambrosia beetles associated with imported non-coniferous wood was carried out. The main characteristics of bark and ambrosia beetles that contribute to the pest risk were analysed. Biological and other factors were identified and illustrated with examples from 26 representative beetle species or groups of species. The outcomes of the study as well as the measures proposed will be presented.

Following the leader: processionary behaviour of urticating caterpillars from opposite hemispheres

Authors: Battisti Andrea[1], Zalucki Myron[4], Uemura Mizuki[2] and Perkins Lynda[3], [1]DAFNAE, University of Padua, Italy, [2]Department of Agronomy, Food, Natural Resources, Animals and Environment (DAFNAE), University of Padova, Agripolis campus, Italy, [3]School of Biological Sciences, The University of Queensland, Brisbane, Australia, [4]The University of Queensland, Australia

Abstract: Investigating movement behaviour of organisms has economic, societal, and conservation benefits. Larval movement of insects for example, plays many significant ecological roles, and with the expansion of the human population, encounters and conflicts with insects have increased. Urticating caterpillars are a health concern to people and animals, especially when they disperse in a gregarious and synchronised manner in areas frequented by humans. Ochrogaster lunifer and Thaumetopoea pityocampa from the southern and northern hemispheres respectively, are two geographically-isolated species with similar gregarious urticating caterpillars that can outbreak causing defoliation and medical issues. Each year from March to May, O. lunifer and T. pityocampa caterpillars leave their nesting sites and form head-to-tail processions on the ground in search of pupation sites. This pre-pupation procession behaviour and its associated risk of human contact with caterpillars was studied and compared in Australia (O. lunifer) and Italy (T. pityocampa). The duration, distance, orientation and response to light of the pre-pupation processions were studied in both species to determine general patterns. In the morning, O. lunifer and T. pityocampa processions travelled on average 40 and 16 metres per day from the nest in 153 and 223 min respectively, in search for potential pupation sites. Ochrogaster lunifer pre-pupation processions travelled generally to the north or south when leaving the nest, as was their final orientation to the bivouac/pupation site. Whereas T. pityocampa processions had no preference in orientation. Ochrogaster lunifer and T. pityocampa pre-pupation processions travelled towards the darker and the lighter areas of the environment, respectively. We hypothesize that these caterpillars use polarised light to navigate through the environment; laboratory and field experiments are currently ongoing. Some 27% of O. lunifer and 44% of T. pityocampa processions had contact with humans driving, cycling or walking. Understanding the movement behaviour of O. lunifer and T. pityocampa pre-pupation processions around populated areas is crucial for predicting exposure risk and application of management strategies.

Processionary caterpillars down-under: biology, ecology and associated risks.

Authors: Battisti Andrea[1], Zalucki Myron[4], Uemura Mizuki[2], Farrell Julianne[3] and Perkins Lynda[3], [1]DAFNAE, University of Padua, Italy, [2]Department of Agronomy, Food, Natural Resources, Animals and Environment (DAFNAE), University of Padova, Agripolis campus, Italy, [3]School of Biological Sciences, The University of Queensland, Brisbane, Australia, [4]The University of Queensland, Australia

Abstract: Processionary caterpillars, Ochrogaster lunifer Herrich-Schäffer (Lepidoptera: Notodontidae); also known as bag-shelter moths, bunny tail moths or itchy grubs; are a relatively common, univoltine, endemic Australian species found feeding on the foliage of a wide range of host trees and shrubs including Eucalyptus, Corymbia and Acacia.
In outbreak years severe defoliation can result from feeding. Egg masses are laid in spring and development takes place through summer and autumn. The gregarious larvae are social throughout the immature stage moving daily from a silken nest or bag-shelter to feed. The final instars disperse in processions to locate pre-pupation sites in the soil. Various nesting forms have been described and recent genetic and cuticular hydrocarbon evidence suggests a species complex. The processionary caterpillars are separated into at least three distinct forms by development periods, minor colour differences in the larvae and moths, and their nest-building habits, namely the construction of silken nests in the canopies, on the trunks, or at the base of their host trees. Like their counterparts in the northern hemisphere, caterpillars from the third instar on carry large numbers of urticating javelin-shaped and barbed true setae (modified hairs) in mirror fields which are shed into the nest with the exuviae at each moult and passively while moving. When the late-instar caterpillars leave the nest in autumn to diapause and pupate through winter and early spring in nearby soil, the nests begin to disintegrate. Nest contents, including millions of setae, exuviae and frass drop and are spread around the local environment by wind. Contact with setae causes various allergenic reactions in mammals and ingestion by pregnant mares can cause the foal to be aborted, a condition known as Equine Amnionitis & Foetal Loss. The likely risks of exposure to setae are described as well as the potential global regions at risk of establishment should the species be introduced.

Study of some aspects of ecology of cedar processionary moth, Thaumetopoea bonjeani powell (lepidoptera, notodontidae) and its egg parasitoids in Algeria

Authors: Battisti Andrea[2], Rahim Noureddine[3], Chakali Gahdab[1], [1]Agronomic National High School, Algeria, [2]DAFNAE, University of Padua, Italy, [3]National High School of Biotechnology, Algeria

Abstract: Background: In this study, the diversity, abundance and impact of entomophagous associated with cedar processionary moth Thaumetopoea bonjeani which is one of the most serious pests of Cedrus atlantica in north-western Africa (Algeria and Morocco) were investigated.
Materials/Methods: The study was carried out in a C. atlantica forest in the Djurdjura Park (North Algeria), in 2014 and 2015. The occurrence of the egg parasitoids was studied during spring by weekly quantitative observations of the egg masses. 223 egg batches were collected and processed. The identity of the egg predators was assessed through observations made during daytime on a total of eight ?eld visits in August and September.
Results and discussion: The average number of eggs per egg batch increased from 143 in 2014 to 171 in 2015, while the egg mortality decreased from 47.4% and 23.9%, respectively, possibly because of a dilution effect. The most important factors of egg mortality were parasitoids and predators, with hymenopteran egg parasitoids killing from 12.1% to 34.9%, and predators from 5.2% to 7.4% of the eggs. The pattern of egg parasitism was driven largely by Ooencyrtus pityocampae, accounting for about 94% of the total parasitoids, followed by Baryscapus servadeii and Trichogramma embryophagum. An hyperparasitoid Chartocerus sp. was collected for the ?rst time from eggs of Thaumetopoea species. Field observations allowed the identi?cation of three bush crickets (Tettigonia viridissima (Linnaeus), Ephippiger ephippiger (Fiebig), and Uromenus brevicollis (Chopard)) as likely predators of eggs.
The number of eggs with dead larvae was signi?cantly higher in the 2014. The proportion of eggs with dead larvae averaged 3.9% in the 2014 and 2.3% in the 2015 cohort, with no signi?cant differences among years (one-way ANOVA, F = 98.23, p = .513). Less than 2% of the eggs were infertile showing dried-up yolk, and a very small but distinct percentage of the eggs was totally empty (below 1%).
Conclusion: During the embryonic stage, the action of parasitoids and predator is significant, given the high mortality of the host during this stage. The examined parasitoids represent, together with other beneficial insects, an important component of mortality to Cedar processionary moth. Closer studies on the sequence of pupal parasitoid emergence could provide guidance on the use of these natural enemies in the Mediterranean forest areas for summer processionary moths pest control.

The eggs of T. bonjeani in Algeria appear to be more affected by mortality than those of other species included in the same clade of the summer processionary moths associated with conifers. The egg parasitoids are the main factors in egg mortality and they are the same species affecting the more common pine processionary moth in the whole Mediterranean Basin.

Vector-Borne Disease Prevention and Control Activities at the U.S. Centers for Disease Control and Prevention

Authors: Beard Charles (Ben), Division of Vector-Borne Diseases, U.S. Centers for Disease Control and Prevention, United States

Abstract: Vector-borne diseases are an important cause of morbidity and mortality each year in the United States. Tick-borne disease cases are increasing annually, and mosquito-borne arbovirus outbreaks are occurring in an intermittent but increasing frequency. Currently, no vaccines are available for any of the vector-borne diseases that are endemic in the continental United States, and effective vector control faces many challenges. The U.S Centers for Disease Control and Prevention maintains a comprehensive program that includes conducting reference diagnostics and national disease surveillance, responding to disease outbreaks, providing prevention education and recommendations, and conducting applied research to better understand and prevent vector-borne diseases.

Snapshot of microgastrine parasitoid wasp (Hymenoptera: Braconidae) diversity in the Kaisaniemi Botanic Garden of Helsinki, Finland

Authors: Beaudin Melanie[2], Paukkunen Juho[3], Fernandez-Triana Jose[1], [1]Canadian National Collection of Insects, Ottawa, Canada, [2]Carleton University, Ottawa. Canadian National Collection of Insects, Ottawa, Canada, [3]Finnish Museum of Natural History, Finland

Abstract: The Kaisaniemi Botanic Garden (KBG) is located in the heart of the city of Helsinki, Finland (60.17° N, 24.94° E). It comprises an area of approximately 40,000m2 (four hectares) with a collection of over 1,300 living plant species. Its insect diversity has been scarcely studied. Microgastrine parasitoid wasps are a cosmopolitan subfamily, with almost 3,000 described species worldwide and 162 species recorded in Finland (Fernandez et al., 2020). A Malaise trap was run in the KBG from early May to mid-September 2018, comprising 19 collecting events during the season. A total of 1,445 specimens of Microgastrinae were collected. The female specimens were studied further and were found to represent 44 species within 12 genera. We identified a new species to science of Microgaster, as well as six new species records for the fauna of Finland. The most commonly collected species were Cotesia vestalis (Haliday, 1834) and Microplitis spectabilis (Haliday, 1834). Cotesia vestalis is a parasitoid of the major cruciferous pest, Plutella xylostella (diamondback moth). The most species-rich genera were Cotesia and Microplitis, with seven and eight species, respectively. A total of 17 species (39%) were represented by only one or two specimens, suggesting the actual diversity of the area to be much higher. Considering that the botanical garden is in the heart of a heavily developed urban landscape, and that the sampling only spanned one collecting season, the diversity in the area is remarkable, representing 27% of the known species and 71% of the known genus diversity in Finland.

CRISPR/Cas9 at the service of the molecular neurobiology of moth olfaction

Authors: Becher Paul[6], Jacquin-Joly Emmanuelle[3], Montagné Nicolas[2], Koutroumpa Fotini[2], De Cian Anne[8], Maria Annick[5], Monsempès Christelle[2], Concordet Jean-Paul[7], Bastin-Heline Lucie[5], François Marie-Christine[1], Revadi Santosh[4] and Chertemps Thomas[5], [1]iEES-Paris Institute, Paris, France, [2]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [3]INRA, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [4]SLU, Alnarp, Sweden, [5]Sorbonne University, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [6]Swedish University of Agricultural Sciences, Sweden, [7]TACGENE, MNHN Paris, France

Abstract: Entomology is facing the new era of high-throughput sequencing, with cumulative transcriptomics and genomics data available on a diversity of model and non-model insect species. Challenges are now to develop functional tools, especially in non-model species, to translate genome research into insect physiology.

We report here the development of the Clustered regularly interspaced palindromic repeats (CRISPR)-Cas9 technology in a moth, the crop pest Spodoptera littoralis (Lepidoptera; Noctuidae), and its use as a reverse genetic tools to decipher the molecular bases of the moth chemical ecology. We present several examples of knocked-out odorant receptor (OR) genes and the effects on the insect physiology and behavior. Among these examples, we showed that the knock-out of the Orco gene induced large anosmia. The knock-out of a single pheromone receptor impaired sex pheromone detection and disrupted mating. In Lepidoptera, loss of-function studies using RNAi are generally difficult to achieve and heritable transgenesis has been developed on a very limited number of species. Thus CRISPR, because of its simplicity, opens unprecedented routes in the understanding of Lepidoptera olfaction and, more generally, in non-model insect functional genomics.

DROMYTAL: Drosophila suzukii management through yeast-based trapping lures

Authors: Becher Paul[7], Rehermann-delRio Guillermo[1], DUMENIL CLAIRE[4], Simone Cossu Carlo[2], Eisenstecken Daniela[5], Bianchi Flavia[6], Castellan Irene[3], Robatscher Peter[5], Favaro Riccardo[3], Angeli Sergio[3], Schmidt Silvia[2] and Spitaler Urban[2], [1]Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Sweden, [2]Entomology Group, Institute for Plant Health, Laimburg Research Centre, Italy, [3]Faculty of Science and Technology, Free University of Bozen-Bolzano, Italy, [4]Faculty of Science and Technology, Free University of Bozen-Bolzano, Italy, [5]Laboratory for Flavours and Metabolites, Institute for Agricultural Chemistry and Food Quality, Laimburg Research Centre, Italy, [6]Laboratory for Flavours and Metabolites, Institute for Agricultural Chemistry and Food Quality, Laimburg Research Centre, Italy, [7]Swedish University of Agricultural Sciences, Sweden

Abstract: Drosophila suzukii Matsumura (Diptera: Drosophilidae) originates from South-East Asia and was first detected in Europe in 2008 as a pest insect of soft- and thin-skinned fruit crops. D. suzukii is responsible for major commercial losses in small stone fruit, berry fruit farms and viticulture in Italy and in many other countries. Female flies lay eggs in ripening fruits through a punctured hole in the skin. Larvae feed on the flesh and the punctured skin is prone to infestations by microorganisms and other insects, leaving fruits unmarketable. Integrated pest management methods are currently developed to limit the use of insecticides. One possibility to maintain a low population of D. suzukii in the field is the manipulation of insect behavior with semiochemicals. Notably, several yeast species localized on grape fruits have been associated with feeding and egg laying in D. suzukii. The interaction between yeasts and D. suzukii can be exploited in pest control strategies to protect commercial crop systems.

The present project aims to create an attract-and-kill tool with a yeast lure which can selectively attract adults D. suzukii onto insecticide-based substrates. The final goal of this system is to reduce D. suzukii infestation and reduce the use of insecticides on commercial crops. For these reasons we developed a multidisciplinary approach consisting in: 1. The selection of the most attractive yeast strains among eight yeast strains that can be used as an attractive feeding source for D. suzukii; 2. The identification of attractive yeast volatiles for D. suzukii; 3. The identification of phagostimulants from yeasts to create a feeding substrate; 4. The characterization of D. suzukii behavior towards yeasts, plants and insecticides; 5. Semi-field and field experimentation in vineyards of susceptible cultivars (e.g. Schiava) to test the efficacy and persistence of the novel attract and kill system.

Among the eight yeast strains tested, Hanseniaspora uvarum showed to be the most attractive one. Volatile compounds were collected from yeast headspace with closed loop stripping analysis (CLSA), solid-phase microextraction (SPME) and direct headspace, and then characterized by gas chromatography - mass spectrometry (GC-MS). Bioactive compounds were characterized using gas chromatography electroantennography detection (GC-EAD) on adult flies. The detection of these chemicals was characterized with EAG dose-responses on adult flies. Metabolites were analyzed using ion chromatography with pulsed amperometric detection (IC-HPAE-PAD) and a conductivity detector and liquid chromatography-electrospray ionization-triple quadrupole mass spectrometry (UHPLC-QqQ). For testing the attractiveness and adulticide efficacy of our yeast-based trapping lure laboratory and semi-field trials were performed with and without insecticides.

The project DROMYTAL is funded by “European Regional Development Fund (ERDF) 2014-2020“.

Host preference and interspecific interactions between Drosophila suzukii and Drosophila melanogaster

Authors: Becher Paul[3], Rehermann-delRio Guillermo[2] and A. Kwadha Charles[1], [1]Chemical Ecology - Horticulture, Dep. of Plant Protection Biology, Swedish University of Agricultural Sciences, Alnarp, Sweden, [2]Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Sweden, [3]Swedish University of Agricultural Sciences, Sweden

Abstract: Many Drosophila species develop on overripe fruit substrate and associated microorganisms. Interestingly, the agricultural pest, Drosophila suzukii, is capable of attacking fresh soft-skinned fruit causing economic losses to the fruit industry. From early ripening, fruit gets pierced and damaged through egg-laying and larval feeding inside the pulp. Moreover, wounding facilitates secondary microbial infections and furthermore makes ripening fruit accessible for D. melanogaster infestation. Interested in the ecological interactions between D. suzukii and D. melanogaster, we first examined the olfactory preference of D. suzukii and D. melanogaster for different developmental stages of raspberry fruits. We demonstrate that in competitive choice-assays between unripe, ripe and overripe fruit, the olfactory preference of D. suzukii females is dependent on mating state. Furthermore, fruit preference differed between females of D. suzukii and D. melanogaster. Secondly, we studied how heterospecific interactions influence the flies’ oviposition behaviour. Overall, our results suggest that the specific preference for fruit in D. suzukii and D. melanogaster is not only dependent on the fruit’s developmental stage but also the flies’ mating state as well as interspecific cues. Insight into the behavioural responses to host odours and fly signals facilitates understanding of the ecological and evolutionary relations between D. melanogaster and D. suzukii.

Influence of elevated CO2 content in ambient air on emitted leaf volatiles of Vitis vinifera and Pyrus communis.

Authors: Becker Christine[1], Gross Jürgen[2], Reineke Annette[1], Gallinger Jannicke[2] and Rid Margit[3], [1]Dept. of Crop Protection, Hochschule Geisenheim University, Geisenheim, Germany, [2]Julius Kühn-Institut, Federal Research Centre for Cultivated Plants, Institute for Plant Protection in Fruit Crops and Viticulture, Germany, [3]Julius Kühn-Institut, Institute for Plant Protection in Fruit Crops and Viticulture, WG Applied Chemical Ecology, Dossenheim, Germany

Abstract: Climate change can threaten our food production. Because of changing temperatures and concentrations of greenhouse gases, well-established pest insect control techniques may have to be adapted to the changing requirements to stay effective. Especially temperature, elevated carbon dioxide (CO2) and ozone concentrations will have significant impacts on the environment and therefore certainly on control strategies based on chemical ecology of insects. Here we test the hypothesis that allelochemically mediated communication is influenced by the determinants of climate change. The main question posed in this study is: Does the volatilomes of grapevine (Vitis vinifera) and of pear (Pyrus communis) got altered by climate change determinants. We present the results of a two-year survey on the effects of elevated CO2 from a field study carried out in a German vineyard equipped with a FACE (free air carbon dioxide enrichment) ring system, which enables to measure the effects of elevated (500 ppm) to ambient (400 ppm) directly.

Plant nutrient supply alters the magnitude of indirect interactions between insect herbivores: From foliar chemistry to community dynamics

Authors: Becker Christine[2], Lavoir Anne-Violette[4], Le Bot Jacques[3], Desneux Nicolas[3], Han Peng[1] and Larbat Romain[3], [1]Chinese Academy of Sciences, China, [2]Dept. of Crop Protection, Hochschule Geisenheim University, Geisenheim, Germany, [3]INRAE, France, [4]University Cote d'Azur, France

Abstract: Density- and trait-mediated indirect interactions (DMIIs and TMIIs, respectively) are important drivers of community dynamics. However, it remains unclear how plant nutrient supply affects the magnitude of such interactions. A series of experiments were performed by setting up a four-species "diamond" food web, comprising a plant species (tomato), two insect herbivore species (a leaf miner and an aphid), and a shared natural enemy (a predatory bug). We found strong indirect effects of the leaf miner on the aphid. Leaf miner eggs negatively affected aphid populations due to increased predator abundance (DMIIs), while the presence of leaf miner larvae delayed aphid development and increased its risky defence behaviour (TMIIs). The latter scenario could be further explained by enhanced foliar chemical defence and decreased nutritional quality.

Will climate change affect biological control of the European grape berry moth (Eupoecilia ambiguella)? Lessons learned from a VineyardFACE facility.

Authors: Becker Christine[1], Reineke Annette[1] and Capponi Lisa[1], [1]Dept. of Crop Protection, Hochschule Geisenheim University, Geisenheim, Germany

Abstract: The increasing atmospheric carbon dioxide (CO2) concentration is expected to influence trophic interactions between plants and associated insects. While the direct effect on insects may be negligible, the indirect effect, mediated by altered host plant quality, can change the herbivore's performance and, hence, can result in bottom-up effects on natural enemies. Since CO2 assimilation via photosynthesis is a fundamental process of plant metabolism, increased availability thereof can have a major impact on plant quality, both in terms of nutritional quality and level of chemical defense. Such tritophic interactions between crop plants, herbivores, and natural enemies are pivotal components of many biological control strategies.

European grape berry moth (GBM; Eupoecilia ambiguella, Tortricidae) is an important insect pest on grapevine in Europe. In the vineyard, E. ambiguella eggs are subject to parasitism by the egg-parasitoid Trichogramma cacoecia. Larval food quality can influence numerous life history traits of tortricid moths, for instance the number and size of eggs laid by adults. Larger eggs often contain more nutrients than smaller ones which makes egg size an important factor for parasitoid fitness, possibly affecting their parasitism preference and/or performance.

We used grapes cultivated in the Geisenheim VineyardFACE (Free-Air Carbon dioxide Enrichment; Vitis vinifera cv. 'Riesling') to test whether elevated CO2 indirectly affects GBM life history traits. In laboratory experiments, we reared GBM on artificial diet enriched with grapes cultivated under ambient (aCO2: 400 ppm) or elevated CO2 (eCO2: 480 ppm). On diet containing eCO2-grapes, larval survival was lower and more females hatched successfully compared to aCO2-grape diet. The eggs females laid, however, were smaller when larvae fed on eCO2- compared to aCO2-grape diet. While increased larval mortality might lead to reduced pest pressure in the future, decreased egg size might result in reduced parasitism. The respective parasitism and emergence rate as well as tibia length of T. cacoecia are being investigated and will be presented at the congress.

While elevated CO2 concentration is only one facet of climate change, our results demonstrate that its indirect effect on insects can be complex and might differ between trophic levels. In order to anticipate future success of biological pest control, comprehensive studies are crucial.

Are we able to stop the invasion of Aedes albopictus in Germany?

Authors: Becker Norbert, 1) Institute of Dipterology (IfD), Speyer, Germany; 2) University of Heidelberg, Germany

Abstract: In Germany the Asian tiger mosquito Aedes albopictus was first recorded in 2007 north of Basel at highway 5 coming from Italy via Switzerland. Since that this species expanded tremendously and is found almost at each resting/service station along the highway. The main tool for introduction to Germany are vehicals e.g. returning tourists or trucks coming from the heavily infested mediterranian area. Whereas, up to 2017 in 5 communities established populations were recorded, in 2019 16 communities were infested by Aedes albopictus. Our ultimate goal is the immediate assessment of the Ae. albopictus populations, to assess the size of the infested area and abundance of tiger mosquitoes, and if necessary set up a control programme with the city authorities in close cooperation with the health departments. The public awareness (passive monitoring) is a very powerful tool to record tiger mosquitoes area-wide. Inhabitants send us suspected specimen or pictures of invasive mosquitoes. Control operations are immediately implemented if a established population is indentified. The control strategy comprises 4 colums: 1) Community participation stimulated by thorough information of the public by flyers, press releases or exhibitions in the communities which are affected. 2) and 3) the main asset to strongly reduce or even eliminate the population are „door-to-door“ inspections in a three week interval going along with the applications of Bti (Vectobac WDG) at high dosages to achieve long-term effects for at least two months in mass breeding sites as rainwater containers or small water collections. Despite all efforts in some locations we achieved only a reduction of the Aedes albopictus population for about 95% due to cryptic breeding sites or non accessability of the promises. Therefore, we implement as 4. column the SIT (Sterile Insect Technique) in close cooperation with the Centro Agricolura Ambiente (CAA) in Crevalcore (Italy). Our genotype is massed reared, sexed by sieving at CAA and finally the males are sterilized by Gamma-radiation (35 Gray). About 1500 males/ha were released at a weekly basis in the infected areas from May till October. Employing ovitraps the sterility and occurrence of Tiger mosquitoes were determined. As a result in some areas the Aedes albopictus populations were wiped out. Nonetheless, it seems that Aedes albopictus is established in South-West Germany and needs a long-tern control activity and engagements of the communities. The establishment of the Asian Tiger mosquito is favorited by climate extremes the last years such as very hot sommers which increase the likelihood of transmission of arbovirus.

Mating system, control of breeding resources, and body size predict acoustic signalling in bark and ambrosia beetles

Authors: Bedoya Carol[4], Brockerhoff Eckehard[2], Kirkendall Lawrence[3], Hofstetter Richard[1] and Nelson Ximena[4], [1]Northern Arizona University, United States, [2]Swiss Federal Research Institute WSL, Switzerland, [3]University of Bergen, Norway, [4]University of Canterbury, New Zealand

Abstract: Playing a significant role in sexual behaviours, such as premating recognition, courtship, and copulation, acoustic communication in beetles is diverse and often sexually dimorphic. However, the factors that determine the presence of acoustic signalling in a given species remain unclear. We examined acoustic communication in bark and ambrosia beetles, a speciose group with diverse forms of reproduction and mating systems taking place within plant tissue. For the first time, we show that, for any given species, mating system, sex that defends breeding resources, and size predict both the presence of acoustic communication and the sex that signals.

Attack of the clones

Authors: Beekman Mariska, Wageningen University & Research, Netherlands

Abstract: The green peach aphid (Myzus persicae) (Hemiptera: Aphididae), is the most economically important aphid pest worldwide. This species is highly polyphagous and is well known for its ability to become resistant against many different groups of insecticides. We aimed to gain insight into the genetic structure of M. persicae populations in both conventional (insecticides are used in addition to biological control) and organic (no insecticides are used, and only biological control is used) Dutch sweet pepper greenhouses. We sampled aphids over four consecutive years (2019-2022) and determined aphid multilocus genotypes with the use of microsatellite analysis. Our results indicate that M. persicae populations in sweet pepper greenhouses are strongly affected by pest control strategy, as well as by the usage of specific pesticides. These strong differences in population genetic structure of M. persicae between organic and conventional greenhouses mean that biocontrol agents have to deal with different types of aphid populations in greenhouses using these two types of aphid control (organic versus conventional). Furthermore, our results seem to indicate that M. persicae continues to develop resistance against the currently used insecticides, and emphasize the need for successful biocontrol practices to keep on controlling these insect pests in agricultural systems.

Aphids out of control? The role of symbiont-driven resistance to parasitoids in greenhouse biocontrol success

Authors: Beekman Mariska[2], Donner Helena[3], Pannebakker Bart[4], Verhulst Eveline[2], Zwaan Bas[3], Dicke Marcel[1], [1]Laboratory of Entomology, Wageningen University, Wageningen, The Netherlands, Netherlands, [2]Wageningen University & Research, Netherlands, [3]Wageningen University, Netherlands

Abstract: Parasitoid wasps are widely deployed in greenhouses to biologically control aphid pests. From time to time, however, the success of parasitoids aphid pests control is unsatisfactory. In 2003, it was first published that specific bacterial endosymbionts can protect their hosts against parasitoid wasps, potentially explaining the occasional failure of parasitoids to suppress greenhouse aphid populations. Nowadays we know of multiple endosymbionts of which specific strains can protect aphids against their hymenopteran enemies. Previous studies have shown that these endosymbionts are prevalent in natural aphid populations but the occurrence and effects of these protective endosymbionts in greenhouse aphids remain unstudied. This is striking since control of greenhouse aphids relies heavily on the use of parasitoid wasps, both in organic and conventional greenhouses. Protective endosymbionts are expected to greatly affect aphid-parasitoid community dynamics in greenhouses. Because of this reason, greenhouses harboring endosymbiont-infected aphids might need alternative control strategies to optimize the control of their aphids.

In our study, we investigate the occurrence and prevalence of aphids and their endosymbionts in greenhouses and field populations in the Netherlands. Our aim is to understand which aphid-symbiont combinations are present, and how they affect parasitism rates.

La Cage aux Feuilles: Physical Exclusion of Brown Marmorated Stink Bug in Tree Fruits

Authors: Beers Elizabeth[1] and Marshall Adrian[2], [1]Department of Entomology, Washington State University, United States, [2]Washington State University, United States

Abstract: Brown marmorated stink bug is a recent invader of the tree fruit growing regions of the western US. In an effort to avoid the disruption of IPM programs that has occurred in other invaded regions, we explored a non-pesticidal method of control: physical exclusion. Using native stink bugs as a proxy, we found that damage inside a multiple-tree cage was lower than in the sprayed or unsprayed check. Additional benefits of the cage included reduced levels of sunburn and damage from a key pest, codling moth. However, there were consistently higher levels of woolly apple aphid inside the cages, associated with greatly reduced abundance of lacewings and syrphids, known aphid predators. Single wall barriers were also tested as a less expensive alternative to orchard cages. We determined that the majority (94%) of stink bugs migrated into the orchard from native shrub-steppe vegetation between 0.4 and 3.2 meters. Replicated single-wall barriers 4 m in height were constructed on orchard borders where the native vegetation was known to harbor stink bugs. The barriers included 15 cm flaps to trap stink bugs migrating upwards on the net. These were compared with flaps fitted with insecticide-infused netting, which killed more stink bugs than the net-only flaps, but also more non-target organisms.

Cacopsylla pyricola uses substrate-borne vibrations to communicate with and attract mates (Hemiptera: Psyllidae)

Authors: Beers Elizabeth[1], Jocson Dowen[3], Crowder David[3], Horton David[2], [1]Department of Entomology, Washington State University, United States, [3]Washington State University, United States, [2]United States Department of Agriculture, United States

Abstract: There are a number of species within the family Psyllidae that are economic pests in fruit crops. One of the most prevalent is the pear pyslla, Cacopsylla pyricola (Förster) (Hemiptera: Psyllidae). This psylla can transmit disease, inject phytotoxin, and cause fruit russetting on pear trees. In depth understanding of their mating behavior, specifically their communication system can provide a more targeted integrated pest management strategy. Here, we report one of the first evidence of substrate-borne vibrations in C. pyricola as a way to communicate with, attract, and locate mates. We also characterized and identified signal traits of male courtship songs that can be influenced by environmental stimuli such as temperature, substrate and pheromone presence, which could provide potential mating disruption mechanisms.

From pest to delicacy: entomophagy as boon for managing scarab beetle in Majuli river island of Assam, India

Authors: Begum Ashma[2], Bhattacharyya Badal[1], Bidyarani Devi Elangbam[1] and Bhagawati Sudhansu[1], [1]All India Network Project on Soil Arthropod Pests, Department of Entomology, Assam Agricultural University, Jorhat, India, [2]Assistant Food Analyst, State Public Health Laboratory, Assam, India

Abstract: Bioecology of the white grub beetle, Lepidiota mansueta was studied in Majuli river island and Department of Entomology, Assam Agricultural University during 2005-2010. This species had appeared as a severe key pest of many field crops in Majuli, the largest mid-river deltaic island of the world. The most severely affected crops were potato, sugarcane, colocasia and green gram and the extent of damage varied from 42-48, 15-20, 35-40 and 30-35 per cent, respectively. L. mansueta is a unique biennial species, which is the first of its kind from North East India. It has the unique distinction as the first Indian phytophagous white grub species with nonfeeding adults. The species spent its entire life cycle under the ground except for a very short period (2-3 weeks) during which adults come out of the ground for mating and oviposition. Light trap was found highly effective to catch the beetles during their premating flight (6.15-7.15 pm) and thereafter scouting to pick up the mated pairs found abundantly on sheltering plants was also feasible. To combat the beetle menace, a massive mass campaigning was conducted in the island embracing social engineering approaches exploring light traps and scouting by deploying 400 farmers at 40 beetle endemic villages during 2010-2019 leading to massive collection and killing of approximately 11.33 lakhs beetles.

Efforts were made to analyze the nutritional profiling of the beetles for their further exploration as human food/animal feed. The proximate analysis of the beetles revealed a higher amount of crude protein content (76.42%) along with other proximate parameters like crude fat (4.10%), crude fibre (5.16%), total mineral (2.98%), carbohydrate (9.18%) and moisture (2.16%). The energy content was 379.29 kcal/100g of sample. Elemental analysis revealed the presence of 7 minerals viz., Na (27.76), K (14.20), Ca (33.33), Fe (1.64), Cu (6.52), Zn (15.55) and Mn (1.30) mg/100 g of sample. As antioxidant properties, the phenol and flavonoid content was found to be 4.00 mg catechol equivalent/g and 1.59 mg quercetin equivalent/g, respectively. The DPPH was registered 22.60 per cent whereas tannin (3.24 mg/g) as antinutritional compound was recorded at acceptable level. Fatty acid profiling showed maximum amount of saturated fatty acid (2.24%) followed by mono unsaturated fatty acid (0.57%) and polyunsaturated fatty acid (0.49%). Altogether 10 fatty acid were estimated, of which palmitic acid content was recorded in maximum amount (0.28%). Amino acid profiling registered 17 amino acids, of which 8 were found essential. Considering the immense nutritional value of the beetles, two dishes viz., beetle fry and roasted beetles were developed and popularized through community feast. This mass campaigning programme had tremendous impact in terms of protecting the crops, disseminating ecofriendly technologies, enhancing crop productivity as well as improving both livelihood and nutritional security.

Improving an attract and kill strategy targeting wireworms: influence of biotic and abiotic parameters

Authors: Beitzen-Heineke Elisa[2], Przyklenk Michael[1], Vidal Stefan[3], Laurenz Sebastian[3] and Patel Anant[4], [1]Biocare GmbH Biological Plant Protection, Dassel-Markoldendorf, Germany, [2]BIOCARE GmbH, Germany, [3]Georg-August-Universität Göttingen, Department of Crop Sciences, Agricultural Enettingen, Germany, [4]WG Fermentation and Formulation of Biologicals and Chemicals; Faculty of Engineeing and Mathematics Bielefeld University of Applied Sciences, Germany

Abstract: Wireworms, the polyphagous soil-dwelling larvae of click beetles (Coleoptera: Elateridae), are major insect pests of worldwide relevance causing tremendous yield losses in several crop production systems, like potatoes. In the projects ATTRACT and ATTRACAP, we developed novel mechanically stable beads containing CO2 emitting baker's yeast as an attract component, an isolate of M. brunneum as a kill component and a substrate as a nutrient source and drying aid. Commercialized as ATTRACAP®, the beads are produced by bioencapsulation of both the micoorganisms and the substrate in alginate and dried with a fluidized-bed drying process. The attract and kill formulation allows an application dose of 30 kg/ha with an active substance of 1,2 x 1010 conidia/ha, thus making the product cost-effective and eco-friendly. New insights into which external factors influence the efficacy of ATTRACAP® and how new adapted formulations and application technologies are able to level out these variations will be presented.

To conclude, this novel CO2-releasing bead system is not only suitable for cost-effective delivery of low doses of fungal biological control agents to the soil against wireworms, but it can also be transferred to other soil dwelling pest species.

A long non-coding RNA modulates tiger mosquito reproductive ability and points to species-specific insecticide applications

Authors: Belavilas-Trovas Alexandros[1], Gregoriou Maria-Eleni[1], Soukia Olga[1], Tastsoglou Spyros[2], Giakountis Antonis[1], Mathiopoulos Kostas[1], [1]Dept of Biochemistry & Biotechnology, University of Thessaly, Greece, [2]Dept of Computer Science and Biomedical Informatics, University of Thessaly, Greece

Abstract: Long non-coding RNA (lncRNA) research has emerged as an independent scientific field in recent years. Despite their association with critical cellular and metabolic processes in plenty of organisms, lncRNAs are still a largely unexplored area in mosquito research. We propose that they could serve as exceptional tools for pest management due to their unique advantages, such as low inter-species sequence conservation and high tissue specificity. In the present study, we investigated the role of ovary-specific lncRNAs in the reproductive ability of the Asian tiger mosquito, Aedes albopictus. Through the analysis of transcriptomic data, we identified several lncRNAs that were differentially expressed upon blood feeding. Then, we applied an RNAi pipeline and observed that silencing of a lncRNA (Norma3) resulted in significant impact on its fecundity and fertility. Specifically, compared to anti-GFP control, anti-Norma3 group laid 57% eggs, while out of the laid eggs 47% hatched. Moreover, we scrutinized the expression profile of deficient ovaries and detected a significant expression drop in a cluster of mucins, indicating a potential mechanism of in cis regulation between them. Our work demonstrates the first, to our knowledge, experimental proof-of-evidence connecting lncRNAs with mosquito reproduction and opens a novel path for pest management.

Screening of biocontrol agents in Russia: long-run experience and new approaches

Authors: Beliakova Natalia, All-Russian Institute of Plant Protection, Russia

Abstract: The current approach to the screening of natural enemies is mostly just a long process of “trial and error”, which is based on comparative analysis of species in relation to some traits (so-called criteria of natural enemy efficacy). However, the same traits may have different effects depending on their combination and under different conditions.

We need an approach that could bring all the information about the species together, process it mathematically, and summarize it all in one final indicator. The methodological basis for that would be the system of life strategies invented by Grime (1973), which includes three primary strategies: violents, patients, and ruderals. In their pure form, those primary life strategies are connected by trade-off relations, i.e. mutually exclusive of each other. However, different strategies may appear in the same species depending on the Spatio-temporal changes in the environment, primarily limiting factors, the fluctuation of which put at risk the species survival. We determine the position of the species in the three-dimensional space of life strategies, taking into account indicators reflecting its resistance to stress and competitive crowding out, as well as the ability to quickly realize the reproductive potential in the presence of a competitor-free food resource. We are not limiting ourselves to analyzing the life history strategies of only predators and parasitoids, but also conducting a similar analysis of their victims and host plants. It let us expand our understanding of the co-evolutionary relationships of organisms at three trophic levels in the triotroph system (plant-phytophagous-entomophagous).

The key problem of natural enemy screening is that quick adaptation to new conditions could make species effective biocontrol agents and harmful invaders as well. Despite all the external differences, biocontrol and invasion have much in common.

Thanks to the data accumulated over the last 150 years of biocontrol development, we have a unique opportunity to “have a sneaky peek at the correct answer”. The life-history strategies of successfully used and relatively safe natural enemies might be compared with those species that are not considered promising for biocontrol. An analysis of the distribution of “successful” and “unsuccessful” natural enemies within the Grime’s triangle opens up new possibilities for selecting species within certain systematic groups. This analysis helps to identify the combination of signs and environmental factors (including anthropogenic ones) that have turned some species into our indispensable helpers in pest control, while others - into dangerous invaders.

Factors driving the within-plant patterns of resource exploitation in a herbivore

Authors: Bellec Laura, University of Rennes1, France

Abstract: In herbivores, although specific within-plant patterns of resource exploitation at the intra-individual scale have been reported, such patterns remain scarcely described and their determinants poorly understood. Here, we describe and try to decipher the determinants of the foraging pattern of the pollen beetle (Brassicogethes aeneus), a pollinivorous insect that is a pest of oilseed rape (Brassica napus). This insect feeds from flowers for almost all of its life cycle, except for a couple of weeks preceding blossoming. During this period, only flower buds are available and the insect destroys them to feed from the pollen they contain, causing serious yield losses. We found that during this critical period, pollen beetles exhibit a stereotypic intra-inflorescence feeding pattern that depends on flower bud maturity. To explain this pattern, we first deciphered the selective pressures driving pollen beetles’ feeding behavior. Since flowers are the natural food source of this insect, we used the preference for flowers over flower buds to achieve that goal. Our results reveal that pollen beetles’ feeding behavior seems to be driven by a process of maximization of total macronutrient intake. We next found that the intra-inflorescence feeding pattern of pollen beetles could be well explained through this lens.

Could E93 play the adult specifier role in the embryo?

Authors: Belles Xavier[1], Ylla Guillem[3], Daimon Takaaki[5], Fernandez-Nicolas Ana[2], Machaj Gabriela[4], Ventos-Alfonso Alba[2], Pagone Viviana[2], Minemura Toshinori[5], Ohde Takahiro[5], [1]Institute of Evolutionary Biology (CSIC-UPF), Spain, [2]Institute of Evolutionary Biology, CSIC-Universitat Pompeu Fabra, [3]Jagiellonian University, NIP: PL675-000-22-36, Poland, [4]Laboratory of Bioinformatics and Genome Biology, Jagiellonian University, [5]Laboratory of Insect Physiology, Kyoto University

Abstract: E93, the factor that triggers metamorphosis in insects, has an expression peak in the preadult stage of hemimetabolans and holometabolans. We observed another E93 expression peak in early embryo of the hemimetabolan Blattella germanica, whereas E93 expression is low in the embryo of the holometabolan Drosophila melanogaster. Depletion of E93 transcripts in B. germanica embryos interrupted the development. RNA-Seq analysis of these embryos revealed a number of up- and down-regulated genes compared with controls. Downregulated genes were enriched for functions involved in development. We wondered whether low and high embryonic levels could be a general trend in hemimetabolans and holometabolans, respectively. Thus, we queried publicly available RNA-seq datasets from embryos and preadult stages of insects to estimate the expression of E93. The results showed that hemimetabolan embryos tend to express E93 at high levels, comparable to those of the last nymphal instar. In contrast, E93 in holometabolan embryos tends to be very low compared to pupal expression levels. We conjecture that E93 expression in the hemimetabolan embryo could drive the development of the adult-like morphology shown by the nymphs. Also, that the reduction of embryonic expression of E93 could have been instrumental for the emergence of the larva and holometaboly.

Paleopterans join the MEKRE93 club

Authors: Belles Xavier[3], Kamsoi Orathai[2], Ventos-Alfonso Alba[2], Casares Fernando[1] and Almudi Isabel[1], [1]Centro Andaluz de Biología del Desarrollo (CSIC-UPO-JA), [2]Institute of Evolutionary Biology (CSIC-UPF), [3]Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: larva (divergent from the adult), pupa and adult. Hormonal control of metamorphosis is based on ecdysone, which triggers molts, including metamorphic ones, and juvenile hormone, which represses metamorphosis. At the molecular level, metamorphosis is regulated by the MEKRE93 pathway, by which the juvenile hormone, through its Met receptor, induces the expression of the transcription factor Kr-h1, which represses the expression of the E93 factor, which is the trigger of metamorphosis. The MEKRE93 pathway is conserved in Polyneoptera and Paraneoptera (hemimetabolans) and in Endopterygota (holometabolans), although in the latter it is more complex, as it incorporates the transcription factor Br-C, which determines the pupal stage. We have found that metamorphosis in Cloeon dipterum (Ephemeroptera) is also regulated through the MEKRE93 pathway, similarly to Polyneoptera. More recently, Okude, Futahashi and collaborators have shown that Ischnura senegalensis (Odonata) also regulates metamorphosis by the MEKRE93, although with some specific variations. Thus, we can conclude that this pathway regulates metamorphosis in all insects, which suggests that its origin coincides with the emergence of wings and metamorphosis, about 410 million years ago.

African parasitoid mass rearing for Coffee Berry Borer Area-Wide control in Colombia

Authors: Benavides Pablo[2], Escobar Luis [1], Gil Zulma[1], Follett Peter[4], Diaz-Soltero Hilda[4], Navarro-Escalante Lucio[3], Giraldo-Jaramillo Marisol[3], [1]Cenicafé, [2]FNC-CENICAFE, Colombia, [3]Research Scientist Department of Entomology Colombia National Coffee Research Center - CENICAFE, Colombia, [4]USDA

Abstract: The coffee berry borer, Hypothenemus hampei (Coleoptera: Curculionidae: Scolytinae), native to Africa, is the most serious insect pest of coffee globally. H. hampei has invaded many new coffee production areas without its natural enemies. Two African parasitoids, Prorops nasuta (Hymenoptera: Bethylidae) and Phymastichus coffea (Hymenoptera: Eulophidae), were mass reared for field release against H. hampei in Manizales, Colombia. On a 70-hectare coffee farm, releases of more than 2 million wasps of each species resulted in parasitism rates of up to 12% for P. nasuta and 45% for P. coffea. Parasitoid releases lead to in a 28% reduction in H. hampei populations in replicated dispersion patches (old coffee) and a 68% reduction in colonization patches (new coffee) within this farm. Results support the technical and economic feasibility of area-wide parasitoid releases in Colombian coffee for H. hampei population suppression.

Disentangling the genetic and morphometric history of the migrant butterfly Vannesa carye (Lepidoptera: Nymphalidae), An altitudinal starting point at northern Chile.

Authors: Benitez Hugo[4], Escobar Scott[5], Villalobos-Leiva Amado[3], Cruz Franco[6], Mendez Marco[2] and Ordenes Rodrigo[1], [1]Departamento de Biología, Universidad de Tarapacá, Arica, Chile, [2]Departamento de Ciencias Ecológicas Facultad de Ciencias, Universidad de Chile, Chile, [3]Departamento de Zoología, Universidad de Concepción., Chile, [4]Universidad Católica del Maule, Maule, Chile, [5]Universidad de Concepcion, [6]Universidad Santo Tomas, Chile

Abstract: The cosmopolitan butterfly genus Vanessa (Lepidoptera: Nymphalidae) is well known as a migratory genus that comprises approximately 20 species, which are present on all continents except Antarctica. In South America, the species Vanessa carye occurs from Venezuela to the Chilean Patagonia and it is suspected to be a long-distance migrant. In Chile, V. carye has been reported performing active flying at extreme high levels of altitude, in areas such as the Chilean Andean Altiplano at 5200 mt altitude (Casiri Lake and Sora Pata Lake), as well as at the sea level in the Arica & Parinacota Region. Nevertheless, in insects, and particularly for Chilean butterflies, there is an absence of studies focusing on migratory patterns, let alone studies analyzing the mechanism that these species might be using as part of their life histories to survive the extreme environmental conditions of the Andes in northern of Chile.
The following research will give a good starting point to collect information on the wing morphometrics and genetic characteristics of V. carye's. All of these information will contribute to elucidate some fundamental questions regarding V. carye's migratory patterns and adaptation to the high altitudes of the Chilean Andes. Therefore, it of vital importance understand that landscape and environments where an organism lives can strongly affect dispersal and gene flow and it is essential to clarify the biotic and/or abiotic factors influencing the differentiation of the V. carye´s populations. This can help in the understanding of the underlying mechanisms that explain the observed genetic and morphological diversity of this species.

Molecular mechanisms supporting survival of ticks (Ixodidae) following environmental, physiological, and chemical stress

Authors: Benoit Joshua[1], Rosendale Andrew[2] and Oyen Kennan[3], [1]Department of Biological Sciences, University of Cincinnati, United States, [2]Department of Biology, Mount St. Joseph University, Cincinnati, United States, [3]University of Cincinnati, United States

Abstract: Ticks are obligate blood feeders but spend the majority of their lives off host where they must contend with a multitude of stresses that can influence distribution and population dynamics. Ticks must tolerate extended periods of thermal stress, desiccation, lack of food, and acaricide exposure; however, little is known about the mechanisms underlying survival of ticks under these stresses. To uncover specific aspects associated with stress survival in ticks, we examined the transcriptomic responses of several hard ticks (Ixodidae) in relation to thermal stress, dehydration, starvation, and chemical exposure. RNA sequencing was used to analyze transcriptional changes following stress exposure and revealed 500 to ~3,000 differentially expressed genes with the enrichment of stress-response, proteolysis, and detoxification pathways as well as shifts in expression of metabolic-related genes. Up- and down-regulated pathways were compared among treatments and species to identify common stress response genes. Follow up analyses found the accumulation of several metabolites, including amino acids, suggesting that these molecules may protect against each stress. Finally, analysis of tick energetics demonstrated that lipid and protein resources are critical for energy during extended starvation and sufficient stores of these reserves are critical to stress tolerance. Overall, our results identified specific molecules and pathways that contribute to tick stress tolerance and lay the groundwork for further studies on biotic and abiotic stress for these important disease vectors.

Dehydration of mosquitoes alters blood feeding dynamics

Authors: Benoit Joshua[1], Holmes Chris[2], [1]Department of Biological Sciences, University of Cincinnati, United States, [2]University of Cincinnati, United States

Abstract: The goal of this study was to assess the effects of dehydration on the retention of a bloodmeal and the resulting effects on survival, nutritional reserves, reproduction, and overall hydration status in mosquitoes. This study focused on Culex pipiens (Culicinae), the northern house mosquito and a vector of Sindbis and West Nile viruses, and Aedes aegypti (Culicinae), the yellow fever mosquito and a vector of Zika. In this study we exposed C. pipiens and Ae. aegypti to different relative humidities, recovery conditions, and blood feeding opportunities to compare changes in hydration status and nutritional reserves derived and retained from a bloodmeal. Results indicate that dehydrated mosquitoes increase fluid acquisition, improve retention, and decrease excretion of a post-dehydration bloodmeal. These findings ultimately suggest the involvement of compensatory and/or regulatory hydration mechanisms associated with blood feeding by dehydrated mosquitoes. Although the effects of dehydration on survival appear to be curtailed by blood feeding, increased survival appears to come at the cost of reduced reproductive output. Due to obvious implications in vectorial capacity, we expect our studies to provide insight into the mechanisms that underlie bloodmeal utilization and conservation in dehydrated mosquitoes and how that may impact arbovirus transmission dynamics. Ultimately, these results become increasingly important as drought intensifies with climate change and may be utilized to improve the efficacy of control efforts.

Effects of seed beetles and their parasitoids on plant performance and defence across generations

Authors: Benrey Betty[1] and Cuny Maximilien[2], [1]University of Neuchatel, Switzerland, [2]University of Wageningen

Abstract: For seeds of wild lima bean plants, seed damage by seed beetles is not always lethal. We investigated the wider consequences of seed herbivory on seedling performance and on plant quality and whether parasitoids that kill seed-feeding larvae can mitigate such effects. We found that pre-dispersal seed damage by seed-feeding beetle larvae strongly affects plant performance, from germination and early plant development to chemical defence and resistance to a generalist lepidopteran herbivore. Some of these effects were dramatically attenuated by parasitism, resulting in a net increase in the number of viable seeds. However, despite their strong beneficial effects on germination and plant growth, parasitoids did not affect the infested plants' reduced ability to invest in defence chemistry. Our findings show an important role of seed feeders in the long-lasting consequences of indirect plant-mediated interactions in a community-wide ecological context and the important mitigating effects of parasitoids in terms of plant fitness.

Detection of forest insects by insect borne volatiles using IMS

Authors: Bentele Maja[3], Rachow Christiane[2] and Müller Michael[1], [1]Chairholder, Chair of Forest Protection, Technische Universität Dresden, Germany, [2]Georg-August-Universität Göttingen, [3]Research Associate, Chair of Forest Protection, Technische Universität Dresden, Germany

Abstract: Forest insects use pheromones for inter- and intraspecific communication. These pheromones can be used to detect those insects in an early stage of infestation. Ion mobility spectrometry was used to detect specific volatiles emitted by the European spruce bark beetle (Ips typographus (L.)) during early artificial infestation in the laboratory. After only a few days of infestation, detection was possible. Detection of nun moth (Lymantria monacha (L.)) egg masses, oak processionary moth (Thaumetopoea processionea (L.)) egg masses, spruce wood engraver (Pityogenes chalcographus (L.)) adults/infestation and bore dust of European spruce bark beetle (Ips typographus (L.)) was successful. Further research is planned to transfer the laboratory achievements into practice.

The making of an olfactory specialist

Authors: Benton Richard, University of Lausanne, Center for Integrative Genomics, Switzerland

Abstract: The evolution of animal behaviour is poorly understood. Despite numerous correlations of behavioural and nervous system divergence, demonstration of the genetic and cellular basis of interspecific behavioural differences remains rare. We have developed a novel neurogenetic model, Drosophila sechellia, a close cousin of D. melanogaster that displays profound behavioural changes linked to its extreme specialisation on noni fruit. Using calcium imaging, we identify D. sechellia olfactory pathways detecting host fruit volatiles. Mutational analysis indicates roles for different olfactory receptors in long- and short-range attraction to noni. Cross-species allele transfer demonstrates that tuning of one of these receptors is important for species-specific host-seeking. We identify the molecular determinants of this functional change and characterise their evolutionary origin and behavioural significance. Through circuit visualisation, we find that these noni-sensing pathways are also distinguished by increases in olfactory sensory neuron (OSN) population size in D. sechellia; partner projection neurons (PNs) do not change in number, but some display novel wiring properties in this species. Comparative neurophysiology of odour-evoked responses of PNs in D. sechellia and D. melanogaster reveals that increased sensory pooling results in reduced post-synaptic depression at OSN:PN synapses. This phenomenon enables more persistent transmission of repeated or prolonged olfactory signals in D. sechellia, synergising with the increases in sensory sensitivity conferred by receptor tuning changes. Together, this work reveals the accumulation of molecular, physiological and anatomical traits linked to behavioural divergence, and defines a powerful model for investigating behavioural evolution and neuroecology.

Defense characteristics among Pinus and vulnerability to mountain pine beetle

Authors: Bentz Barbara[1], Soderberg David[2], Runyon Justin[1] and Hood Sharon[1], [1]USDA Forest Service Rocky Mountain Research Station, United States, [2]Utah State University Rocky Mountain Research Station, United States

Abstract: Long-term contact and evolutionary history between specific plant and herbivorous insect species are expected to increase plant allocation to secondary metabolic defenses. In turn, insect species can evolve counter-adaptations to avoid, tolerate, and even benefit from plant defense allocations. For example, the mountain pine beetle (Dendroctonus ponderosae, Coleoptera: Curculionidae, Scolytinae), one of the most impactful native forest insects in North America, has evolved to use host tree terpene defense compounds as pheromone precursors that facilitate mass attacks. This evolutionary arms-race between insect herbivore and host tree has undoubtedly been on-going at least since community reorganization and diversification of both trees and insects during the Quaternary. Mountain pine beetle is polyphagous on multiple Pinus species, which have evolved differing defense strategies including long-term (constitutive) and short-term (induced) responses. Plant defense is costly, however, and trees with high investment in constitutive defenses are expected to invest less in induced defenses, and vice versa. Moreover, slow growing trees and trees in resource-poor environments are hypothesized to invest a greater proportion of carbon into secondary constitutive defense metabolites than into growth. How these differing Pinus defense strategies influence vulnerability to mountain pine beetle remains unclear. We measured defense traits of several high-elevation Pinus within the range of mountain pine beetle in the western United States. Included in our study are the three species in the ancient Balfouriana group, including the notoriously slow growing and long-lived Great Basin bristlecone pine (P. longaeva). In a lab study, Great Basin bristlecone pine phloem was shown to be toxic to developing mountain pine beetle brood, and in the field Great Basin bristlecone pine had high levels of constitutive defenses and was apparently less preferred by mountain pine beetle relative to co-occurring Pinus species. Comparisons of defense strategies among and within Pinus species will be presented and discussed as they relate to vulnerability to mountain pine beetle.

Distinct genes are responsible for myrosinase activity in larvae and adults of the horseradish flea beetle, Phyllotreta armoraciae

Authors: Beran Franziska[1], Körnig Johannes[2], Ortizo Kris, [1]Max Planck Institute for Chemial Ecology, Germany, [2]Research Group “Sequestration and Detoxification in Insects” Max-Planck-Institute for Chemical Ecology, Jena, Germany

Abstract: The horseradish flea beetle, Phyllotreta armoraciae, possesses an activated chemical defense that consists of sequestered glucosinolates and endogenous myrosinase enzymes capable of converting these glucosinolates to toxic isothiocyanates. Here, we identified three genes that encode enzymes with myrosinase activity in P. armoraciae. These myrosinase genes differ regarding their expression in larvae and adults: PaMyr1 is expressed in adults, while PaMyr2 is expressed in larvae. Compared to PaMyr1 and PaMyr2, expression of PaMyr3 was very low in all life stages. Using RNA interference, we confirmed that PaMyr1 and PaMyr2 are responsible for myrosinase activity in adults and larvae, respectively, whereas the function of PaMyr3 is currently unknown. Predation experiments with Harmonia axyridis showed that PaMyr2 expression correlates with larval survival, confirming that the glucosinolate-myrosinase system protects P. armoraciae larvae against generalist predators. Silencing PaMyr2 expression additionally resulted in higher levels of sequestered glucosinolates, and decreased the proportion of hydrolysis products of ingested glucosinolates detected in the body, suggesting that endogeneous myrosinase activity also mediates the turnover of sequestered glucosinolates in larvae. In summary, we show that different genes are responsible for myrosinase activity in P. armoraciae larvae and adults, suggesting that myrosinases have different ecological functions in these life stages.

Evolution of traits associated with the utilization of brassicaceous host plants in the genus Psylliodes

Authors: Beran Franziska[1], Krempl Corinna[1], Ren Lin-Ling[1], Gikonyo Matilda[1], Ahn Seung-Joon[2] and Yang Zhi-Ling[1], [1]Max Planck Institute for Chemial Ecology, Germany, [2]Mississippi State University

Abstract: The flea beetle genus Psylliodes (Chrysomelidae, Galerucinae, Alticini) comprises more than 200 species that are associated with host plants belonging to at least 24 different plant families. About 50 Psylliodes species, including the cabbage stem flea beetle, Psylliodes chrysocephala, are specialized on Brassicaceae. We investigated how Psylliodes flea beetles have adapted to the characteristic chemical defense in Brassicaceae, the glucosinolate-myrosinase system. Glucosinolates and the enzyme myrosinase are stored separately in intact plant tissue, but get into contact upon tissue damage, leading to glucosinolate hydrolysis. The resulting unstable aglucone can give rise to different toxic products of which isothiocyanates are the most reactive ones. Studies on glucosinolate metabolism in P. chrysocephala revealed that the beetles convert a fraction of ingested glucosinolates to desulfo-glucosinolates, a detoxification mechanism that prevents the hydrolysis of glucosinolates by the myrosinase. We identified a family of glucosinolate sulfatases in P. chrysocephala and could show that these evolved by duplications of a conserved arylsulfatase gene. Glucosinolate sulfatases were also identified in other Psylliodes species that feed on Brassicaceae, but appear to be absent in Psylliodes species associated with other plant families. Phylogenetic studies suggested that arylsulfatase genes diversified and evolved a novel function within the genus Psylliodes following specialization on Brassicaceae. Although desulfation reduces glucosinolate breakdown in P. chrysocephala, it does not fully prevent isothiocyanate formation. To reduce the toxicity of isothiocyanates, P. chrysocephala partially detoxify them by conjugation to glutathione. We compared glutathione-S-transferase (GST) activity towards isothiocyanates in crude protein extracts of different Psylliodes species and observed a higher capacity to detoxify isothiocyanates in species that use glucosinolate-containing plants as hosts than in non-glucosinolate feeding species. The P. chrysocephala genome encodes about 27 GSTs and members of two subfamilies were active towards isothiocyanates upon heterologous expression. To understand how isothiocyanate-specific GST activity evolved, we functionally characterized the orthologous enzymes from the Solanaceae-feeding potato flea beetle, Psylliodes affinis, and from the polyphagous hop flea beetle, Psylliodes attenuata. Interestingly, these recombinant enzymes also used isothiocyanates as substrates, but differed in specific activity and substrate spectra from their P. chrysocephala counterparts. Based on the phylogenetic relationship of these Psylliodes species, our results suggest that the ability to detoxify isothiocyanates by conjugation to glutathione was already present before specialization of Psylliodes beetles on Brassicaceae. This pre-existing trait might have facilitated the adaptation of Psylliodes species to glucosinolate-containing plants.

Specialization of Psylliodes flea beetles on Brassicaceae is associated with the evolution of glucosinolate sulfatase activity

Authors: Beran Franziska[1], Gikonyo Matilda[1], Letsch Harald[4], Ahn Seung-Joon[2] and Biondi Maurizio[3], [1]Max Planck Institute for Chemial Ecology, Germany, [2]Mississippi State University, [3]University of L'Aquila, [4]University of Vienna

Abstract: The leaf beetle genus Psylliodes comprises about 200 species that feed on plants in at least 24 different families. About 50 species are specialized on brassicaceous plants, which defend themselves against herbivores with glucosinolates that are hydrolyzed upon tissue damage to release toxic breakdown products. We previously demonstrated that Psylliodes chrysocephala detoxifies glucosinolate by converting them into desulfo-glucosinolates, and identified a family of glucosinolate sulfatases (GSS) that originates from duplications of the conserved arylsulfatase gene Sulf4. In this study, we inferred the evolutionary history of specialization on Brassicaceae and the origin of GSS in the genus Psylliodes. A reconstruction of the phylogenetic relationships and ancestral host use of 60 Psylliodes species associated with different plant families indicated that specialization on Brassicaceae has evolved at least twice independently from polyphagous ancestors, which in one case was followed by a species radiation. In this phylogenetic framework, we examined the diversification and function of Sulf4-like genes using comparative transcriptomic and biochemical analyses. Our results suggest that a Sulf4 gene duplication associated with the evolution of GSS activity preceded the radiation of Psylliodes species on Brassicaceae, while subsequent lineage-specific duplications of GSS may have facilitated the adaptation to plants with different glucosinolate profiles.

Redistribution of adventive Trissolcus japonicus (Hymenoptera: Scelionidae) in Virginia, USA

Authors: Bergh Chris[3], Elliott Alyssa[2], Edwards Ashley[2], Talamas Elijah[1], Reed Kathleen[2], Kate Lawrence[2] and Quinn Nicole[3], [1]Florida Department of Agriculture and Consumer Service, United States, [2]Virginia Cooperative Extension, United States, [3]Virginia Tech, ASAREC Winchester, VA, United States

Abstract: Brown marmorated stink bug (BMSB), Halyomorpha halys (Hemiptera: Pentatomidae), has been established in Virginia, USA since the late 2000's and has caused significant ongoing agricultural and nuisance issues there and elsewhere in the Mid-Atlantic region since 2010. In 2014, an adventive population of its highly effective Asian egg parasitoid, Trissolcus japonicus (Hymenoptera: Scelionidae), was discovered in Maryland, USA. In 2015, it was detected in Frederick County, Virginia, where it has established well, although surveillance elsewhere in Virginia resulted in very few or no T. japonicus detections. With approval from the Virginia Department of Agriculture and Consumer Services, efforts to promote and accelerate the establishment of adventive T. japonicus more widely the state were initiated in 2018. At ten woodland sites from northern to southwestern Virginia, all near commercial tree fruit orchards, pre-release surveillance for T. japonicus used yellow sticky traps deployed in the mid-canopy of BMSB host trees. Sampling in early June, 2018 resulted in the detection of one specimen at the site closest to Frederick County. This was followed by two sequential releases of BMSB egg masses parasitized by T. japonicus at all sites in mid-June and late July, then post-release sampling of T. japonicus and BMSB in August, 2018. Trissolcus japonicus was not detected at any site in August, but relatively large captures of BMSB adults, and most importantly of nymphs in pheromone traps at many sites indicated that BMSB eggs had been present during the second and likely during the first T. japonicus release, potentially boding well for parasitoid establishment. In 2019, sampling in June yielded 2 to 6 T. japonicus at 3 of the 10 sites and August samples resulted in detections of 1 to 6 specimens at 3 sites, including two where it had been detected in June. Native parasitoids known to attack BMSB eggs also were captured in the yellow sticky traps. Detection of T. japonicus at 4 of the 10 release sites in 2019 is encouraging. Continued sampling and potentially additional T. japonicus releases in 2020 and beyond are hoped to yield detections at additional sites and increasing detection frequency at the positive sites from 2019.

Macronutrient balance and the longevity/fecundity trade-off in ants

Authors: Bernadou Abel[3], Dussutour Audrey[2], Heinze Jürgen[1] and Vidal Mathilde[3], [1]Department of Zoology University of Regensburg, Germany, [2]Research Centre on Animal Cognition, Toulouse University, CNRS, France, [3]Zoology / Evolutionary Biology, University of Regensburg, Germany

Abstract: In social insects, queens ensure the reproduction while workers take over all non-reproductive tasks. Several studies have highlighted the effects of environmental factors and in particular nutrition on the development of individual traits and caste determination. However, it remains unclear how food affects fecundity, longevity and task allocation in social insect colonies. Clonal ants, such as Platythyrea punctata, are a suitable model to study direct effects of nutrition while avoiding any other confounding factors. Despite their clonality, colonies have a well-ordered reproductive division of labor based on rank orders established through fighting. Each colony contains only one, rarely several, reproductive workers, while the majority of individuals has inactive ovaries. In this study, we investigated how different diets influenced life history traits in P. punctata workers and in particular fecundity and longevity. Contrary to solitary insects, we found that ants confined to a high-protein diet lived longer but also laid more eggs than ants raised on a low-protein diet. When we induced a nutritional bias between same-aged workers, ants fed with a high-protein diet became dominant and had better developed ovaries than workers on a low-protein diet. This study shows the importance of nutrition in task allocation and highlights the mechanisms that might lead to the evolution of life history traits in social insects.

Underground cooperation helps to increase rice yield after root herbivore injury

Authors: Bernaola Lina[2] and Stout Michael[1], [1]Louisiana State University, United States, [2]Texas A&M University, United States

Abstract: Associations with arbuscular mycorrhizal fungi (AMF) have been shown to both increase or decrease resistance to herbivory in different crop systems, but the impact of AMF on plant tolerance to root herbivory remains unknown. We investigated whether AMF inoculation of rice can stimulate rice yields and/or tolerance to rice water weevil (RWW, Lissorhoptrus oryzophilus) injury. We hypothesized that rice growth and yields would be greater and yield losses from RWWs would be smaller in the presence of AMF. We used a 2x2 factorial design, using two levels of insecticide (presence or absence of NipsIt INSIDE, a neonicotinoid seed treatment) and two levels of AMF (presence or absence of an AMF seed treatment) with 10 replications each in four field experiments over three years. Our results showed that AMF treatments slightly increased population densities of RWW relative to control plants, while insecticidal seed treatments significantly reduced weevil densities. AMF inoculation increased rice biomass before and after flooding, and a clear but not always significant increase in yield was observed. Plants treated with AMF showed higher yields compared to the untreated plants; however, treatment with AMF did not reduce percent yield losses after root injury. Analyses of nutrient contents in roots and shoots revealed inconsistent effects of AMF inoculation. In conclusion, this study shows for the first time the potential for AMF seed treatments to increase rice tolerance to root herbivory, by influencing plant biomass and yields. Rice inoculated with either AMF or NipsIt+AMF may provide an effective method for weevil control and for increasing rice yields.

Attract and Kill Technology using HOOK-RPW to Control Red Palm Weevil Rhynchophorus ferrugineus (Olivier)

Authors: Bernardi Carmem[4], El-Shafie H.A.F.[2], R. Faleiro J.[3], Saroli Jesse[5] and Silva Rodrigo[1], [1]Bedoukian Research, United States, [2]Date Palm Research Centre of Excellence, King Faisal University, Kingdom of Saudi Arabia, Saudi Arabia, [3]Independent Red Palm Weevil Consultant, India, [4]ISCA Inc., Riverside, CA, United States, [5]ISCA Technologies, Inc., Riverside, CA, United States

Abstract: The Red Palm Weevil (RPW), Rhynchophorus ferrugineus (Olivier) is a key pest of palms worldwide that has significantly expanded its geographical range since the mid-1980s. RPW is currently being managed in area-wide Integrated Pest Management (IPM) programs that mainly rely on the use of Food Baited Pheromone (ferrugineol) Traps and insecticide applications that are inadequate to eradicate adult weevils.

Since 2011, Attract and Kill (A&K) technology using Hook-RPW TM has been extensively validated in multilocational field trials in the Kingdom of Saudi Arabia in RPW infested date palm Phoenix dactylifera L., plantations. In all the test sites, Hook-RPW TM effectively killed adult weevils for as long as five months after application as evidenced by dead weevils in the containers with A&K dollops and suppressed RPW population densities to extremely low levels as indicated by the monitoring captures in the traditional FBPTs in treated plots as compared to the control plots where weevil captures were significantly higher. Hook-RPW TM has been successfully used to eradicate RPW in Mauritania and more recently registered for use against RPW in Jordan. Eradicating the adult floating RPW population using Hook-RPW TM in the field not only breaks the life cycle of RPW, but also significantly limits the dependence of prophylactic insecticide spray applications.

This presentation gives an overview on strengthening the existing RPW-IPM strategy through Attract and Kill technology using Hook-RPW TM.

Insecticide-Treated Clothing

Authors: Bernier Ulrich[2], Johnson Amy[1] and Perry Melynda[1], [1]Natick Soldier Research, Development, and Engineering Center, United States, [2]USDA-ARS Center for Medical, Agricultural, and Veterinary Entomology, United States

Abstract: Historically, the greatest cause of casualties in military operations has come from disease rather than from combat. Since 1951, the US military combat uniforms have had chemicals added to them to protect personnel from bites of arthropods. In 1991, the pyrethroid permethrin became the standard treatment of US military combat uniforms. In 2007 the U.S. Marine Corps transitioned from treatment with permethrin in the field to factory treatment of their 50/50 nylon/cotton Marine Corps Combat Utility Uniforms (MCCUUs). The US Army transitioned to factory treatment of uniforms in 2009. Over the past few years, an increasing proportion of combat uniforms are constructed from fabric comprised of nylon, rayon and fire resistant materials such as para-aramid or meta-aramid. These uniforms cannot be treated with in the field and must therefore be treated at the factory level. In 2015, the evaluation of etofenprox-treated clothing was completed and the data were submitted to US EPA for registration. Etofenprox has an improved toxicological profile compared to permethrin and due to this, it can be impregnated into clothing at a higher concentration. The treated uniforms were highly protective out to 75 wash cycles. This chemical is being evaluated for use in additional fabrics.

Invasiveness increases commercial success in the global pet trade

Authors: Bertelsmeier Cleo[2], Gippet Jérôme[1], [1]Department of Ecology and Evolution University of Lausanne, Switzerland, France, [2]University of Lausanne, Switzerland

Abstract: Wildlife trade is a rapidly expanding multibillion-dollar global business. Each year, millions of individuals from thousands of species are traded legally and illegally as ornamentals and pets. This movement of species worldwide acts as a major introduction pathway for plants and animals that escape or are released into the wild. Some of these traded species are invasive alien species (IAS), impacting native biodiversity, agriculture and public health. It is of great concern that IAS are overrepresented among traded species, relative to native species. This may occur because trade has introduced species in the past, creating opportunities for them to become invasive. Alternatively, IAS could have a greater commercial success than native species. But so far, the causal link between invasiveness and commercial success remains unknown. To test if invasiveness increases commercial success, we used an emergent, but substantial, pet trade that cannot be responsible for invasions yet : the trade in ants as exotic pets. We found 520 ant species that are sold as pets worldwide. Invasive alien species were 6.6 times more likely to be traded than native species and were sold by almost twice as many sellers as native species. Greater commercial success was linked to three ecological characteristics that were also associated with greater invasiveness: larger range size, greater habitat generalism and smaller body size. By selecting species with ecological traits characteristic of IAS, the pet trade will likely contribute to the accelerating global spread of current invaders. It may also generate opportunities for future invaders, which have not yet been transported outside of their native range.

Intra- and interspecific variation in functional traits along elevational gradients in Swiss ants

Authors: Bertelsmeier Cleo[1], Szewczyk Tim[1], [1]University of Lausanne, Switzerland

Abstract: The variation of traits within populations is central to species coexistence, biogeographical patterns, and responses to anthropogenic change. Incorporating individual-level variability has advanced our understanding of community assembly, structure, and dynamics. A trait-based approach may yield more fruitful insights into the shifts in community structure expected with a changing climate. However, intraspecific variation has often been neglected in ecological studies of broad geographic extents; basic patterns for most taxa – particularly insects – remain unknown. As eusocial organisms, ants present an additional level of biological complexity that alters predictions stemming from physiology-based and community-based theory. Here, we detail the changes in functional traits within ant communities across elevations in western Switzerland, and investigate the environmental factors driving the variation in traits. Specifically, we ask whether trait mean and variance vary predictably across elevations at the colony, species, and community scale, and if so, which climatic and vegetation variables are most strongly related. We sampled the soil for ant colonies at 1,147 plots at 44 sites between 365–2,225m during a single summer, collecting 10 workers from each detected colony, and pair this sampling with a broad citizen science effort. We focus our study on traits previously shown to be influential to the fitness and feeding ecology of ants, namely body size, relative leg length, and color. We find considerable variability in trait values within and among colonies of the same species, and elevational trends within the trait-space at the species and community level. For the majority of all taxa, including ants, across the majority of the globe the geographic patterns of traits have not yet been identified, whether at the species or community level. This study aims to help clarify biogeographic patterns in species traits and the underlying processes responsible to improve our understanding of ecological patterns, and our ability to detect and predict impacts of anthropogenic changes in species distributions.

A novel instructor signal in insect sex determination

Authors: Beukeboom Leo W[2], Verhulst Eveline[4], Zou Yuan[1], Geuverink Elzemiek[1] and van de Zande Louis[1], Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [2]University of Groningen, Netherlands, [3]Wageningen University & Research, Netherlands

Abstract: Insect sex determination depends on a primary instruction during early zygotic development. This primary instruction induces (female instruction) or represses (male instruction) the production of a functional transformer (TRA) protein. Hymenopteran insects have haplodiploid sex determination; males develop from unfertilized eggs and are haploid, whereas females develop from fertilized eggs and are diploid. The allelic state of the complementary sex determiner (csd) gene in the honeybee is the only identified instructive sex determination signal thus far in hymenopterans. To identify the instructor signal of the parasitoid wasp Nasonia vitripennis, that has no csd, we compared transcriptomes of early male and female embryos. We identified a novel gene, named womanizer (wom), that is only expressed in early diploid embryos and only from the paternal, not the maternal allele. Wom is required for female development, as its knockdown led to male development of diploid embryos. Wom knockdown also significantly decreased tra transcripts, indicating that its mode of action is activation of zygotic tra expression. Wom has arisen by exon-shuffling and has homology with p53 genes and a Nasonia-specific gene (LOC100678853). It encodes a P53-like protein that may act as a transcription factor in Nasonia sex determination. This study is another demonstration of the diverse recruitment of primary instructions in insect sex determination.

Genomic localization and characterization of male determining loci in the housefly (Musca domestica)

Authors: Beukeboom Leo W[5], Bopp Daniel[4], LI Xuan[2], Geuverink Elzemiek[2], Marec František[3], Wimmer Ernst[1] and van de Zande Louis[2], [1]Department of Developmental Biology, Johann-Friedrich-Blumenbach Institute of Zoology and Anthropology, Göttingen Center of Molecular Biosciences, University of Göttingen, Germany, [2]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [3]Institute of Entomology, Biology Centre CAS, České Budějovice, Czech Republic, [4]Institute of Molecular Life Sciences University of Zürich, Switzerland, [5]University of Groningen, Netherlands

Abstract: In insects, sex determination is regulated by hierarchical gene-cascades that are conserved at the bottom but variable at the top. In the housefly, a male-determining (M) locus directs male development by disrupting transformer feminizing function. M loci are located on the Y–chromosome in some populations, where males are XY and females XX, but can also be present on any of the five autosomes or on the X chromosome. M loci consist of repetitive sequences that undergo extensive duplication and translocation in the genome.

M loci on Y and autosomes II-IV contain at least one functional copy of the gene Musca domestica male determiner (Mdmd), a paralog of the spliceosome factor CWC22. An unknown gene that is not Mdmd acts as a male determiner on autosome I. To better understand the genomic complexity and dynamics of M loci, we determined the chromosomal location of different M by cytogenetic mapping and re-sequenced and assembled the male housefly genome, with M locus on autosome III. The MIII locus is over 500Kb in size and contains many copies of both complete and fragmented Mdmd sequences. Transcriptomic analysis revealed that multiple copies of Mdmd are transcribed. We discuss how our findings contribute to understanding the evolution of insect sex determination and sex chromosomes.

Host-range evolution in parasitoid wasps: potential of native parasitoid, Leptopilina heterotoma, to adapt to Drosophila suzukii

Authors: Beukeboom Leo W[2], Kruitwagen Astrid[1] and Wertheim Bregje[2], [1]Groningen Institute for Evolutionary Life Sciences (GELIFES), University of Groningen, Netherlands, [2]University of Groningen, Netherlands

Abstract: Host-range evolution by native species in response to biological invasions augments their ability to reduce the impact of the invader and their value for biological control. We assessed the adaptation potential of the larval parasitoid, Leptopilina heterotoma, to the invasive pest Drosophila suzukii. For this native species to evolve, heritable variation is required in traits involved in the different steps of the parasitization process: (1) host selection, (2) host attack, (3) host killing and (4) offspring development (reproduction). Although this relatively virulent parasitoid has been found to attack the novel host, offspring generally fails to develop due to high resistance of D. suzukii. We did find, however, variation in the preceding steps of the parasitization process. We investigated seven European populations and found significant variation to induce host mortality. We then tested whether we could improve killing performance by crossing these populations to produce a genetically variable source population, followed by seven generations of artificial selection on ability to kill D. suzukii. Moreover, we determined how selection on killing performance influences evolution of the preceding step of parasitization, attack rate, and the sequential last step, reproduction success, as correlated responses would promote host range evolution. Our study reveals that native parasitoids can be exploited as biological control agent of D. suzukii as they significantly reduce fly survival. Moreover, selected wasps showed an increase in their ability to reduce fly survival compared to unselected wasps, indicating that killing performance can evolve. Evolution of this performance trait was also correlated with an increased attack rate and wasps with high killing performance had a higher reproductive success. These results thus demonstrate the adaptation potential of L. heterotoma to the invasive fruit fly pest. Moreover, it demonstrates that different steps of parasitization need to be considered in the evolution of host-range and that evolutionary principles can be applied to optimize performance of native species for biological control.

Microorganisms induce asexual reproduction of haplodiploid wasps by manipulating splicing and transcription of maternally provided sex determination genes

Authors: Beukeboom Leo W[2], Ye Fuyu[1], Geuverink Elzemiek[1], Chen Fangying[1], van de Zande Louis[1] and van Leussen Marloes[1], [1]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [2]University of Groningen, Netherlands

Abstract: Sex determination in insects involves a cascade of genes leading to differential sex-specific splicing of doublesex that controls downstream sexual differentiation. The doublesex splicing regulator transformer (TRA) is present in most insect orders. Only female-specific tra mRNA (traF) yields a functional TRA protein. In haplodiploid Hymenoptera, haploid males develop from unfertilized eggs that contain insufficient traF and diploid females from fertilized eggs. Apparently, diploidy after fertilization ensures sufficient traF for female development. Nevertheless, two parasitoid species, Asobara japonica and Leptopilina clavipes, can reproduce asexually when females are infected with endosymbiotic Wolbachia bacteria. Infected females lay unfertilized eggs and provide traF to their eggs that then develop as diploid females without a paternal genome. In contrast, sexually reproducing females without Wolbachia lay unfertilized haploid and fertilized diploid eggs and provide both types with non-sex-specific tra transcripts. The fertilized eggs rely on the paternal genome to initiate female development. This suggests that Wolbachia can manipulate host reproduction by altering the splice regulation of sex determination genes, but potentially also by substituting the early zygotic transcription of the paternal genome.

Role of gene polymorphisms in circadian and seasonal behaviour of Nasonia vitripennis

Authors: Beukeboom Leo W[1], Romeyer Pauline[1] and van de Zande Louis[1], University of Groningen, Netherlands

Abstract: The larger variation in daily cycles of light (photoperiod) and night with increasing latitude has led to the evolution of adaptive photoperiodic behaviour. Nasonia vitripennis is a parasitic wasp which has been used extensively as a model for studying photoperiodism response in insects because of its clear seasonal behaviour. Females can maternally induce diapause in stage L4 larvae, depending on the number of days of a critical day-length. Previous studies reported a latitudinal cline in diapause induction of natural European populations and allelic frequencies of the clock gene period correlated with this clinal variation. As the perception of the daily photoperiod (timer) and number of days with a critical day-length (counter) are essential for diapause induction, it is hypothesised that more clock genes are involved.

In this study we test the involvement of the circadian clock genes period, cryptochrome-2, clock and cycle in the timing of diapause induction. We identified non-synonymous single nucleotide polymorphisms (SNPs) in isogenic lines established from populations of three latitudes. We used sib-ship crosses between those lines to assess their effect on diapause induction timing. Additionally, we tested these polymorphisms for effect on circadian locomotor activity, to get insight in the overlap of seasonal and circadian timing regulation.

We found that the polymorphism in period was also associated with variation in free-running period. SNPs in cryptochrome-2 and clock, but not cycle, were found to be associated with both diapause inductions and free running period. Our results demonstrate the involvement of circadian clock genes in seasonal diapause induction and thus a partially overlapping genetic architecture between circadian and seasonal responses.

A new genus of Phlaeothripidae (Insecta, Thysanoptera) from a Neotropical Rainforest, Brazil

Authors: Bezerra Lima Elison Fabricio[3], Miyasato Elisa Aiko[2] and Eiras Marcelo[1], [1]Biological Institute of São Paulo, Brazil, [2]Federal Institute Southeast of Minas Gerais, Campus Barbacena, Brazil, [3]Federal University of Piauí, Campus Amílcar Ferreira Sobral, Brazil

Abstract: Brazil Conservation proposals require prior knowledge of the fauna. Despite the relevant role of thrips (Thysanoptera) in association with plants, their diversity and biology remain poorly known. Thrips can be predators of other arthropods (Arthropoda), act as pollinators, in addition to damaging plants by plant tissue feeding or pathogen vectoring. In this study, we described a new genus and species collected in the Neotropical rainforest, municipality of Santo Antonio do Pinhal, São Paulo State, Brazil, as part of "Aguas da Mantiqueira" Conservation Project. This project aims to restore 14 hectares of river basin springs around permanent preservation areas in this region. Adults of the new genus and species of Phlaeothripidae were collected in November 2017, associated with ferns. The specimens were prepared in permanente microscope slides in Canada balsam. The slides were deposited at Coleção Entomológica Adolph Hempel, Instituto Biológico, São Paulo (IBSP), Brazil, and Coleção de História Natural da Universidade Federal do Piauí (CHNUFPI), Floriano, Brazil. The new genus and species resembles Pueblothrips. This species belongs to a monotypic genus described from Mexico, probably associated with ground litter, that has been tentatively included in the Williamsiellina, based on the position of the maxillary stylets, low and wide apart in head. This classification, however, is probably artificial, as the only species of Pueblothrips that has two pairs of wing-retaining setae on abdominal tergites, three sense cones on antennal segments III and IV and fore wing with duplicated cilia and basantra absent. The new genus and species presented herein can be recognized by the following character states: pronotum distincltly sculptured with 2 circular irregular areas on anterior two thirds; anteromarginal setae short, epimeral sutures complete, anterior marginal setae as long as discal setae, epimeral and posteroangular setae fan-shaped, longer than anterior marginal setae. This new genus is distinct from Pueblothrips, specially, due to the presence of basantra, remarklable sculpture on pronotum, posteroangular setae fan-shaped and the color of legs, with fore coxa trochanter and femur brown. The discovery of this new genus with intermediate characteristics can help in clarifying Phlaeothrips-lineage classification. In future studies, phylogenetic analysis will be carried out as an attempt to trace possible relationships with this new genus and Phlaeothrips-lineage groups.

A new species of Frankliniella Karny, 1910 (Thysanoptera, Thripidae, Thripinae) from the Atlantic Rainforest in São Paulo, Brazil

Authors: Bezerra Lima Elison Fabricio[3], Miyasato Elisa Aiko[2] and Eiras Marcelo[1], [1]Biological Institute of São Paulo, Brazil, [2]Federal Institute Southeast of Minas Gerais, Campus Barbacena, Brazil, [3]Federal University of Piauí, Campus Amílcar Ferreira Sobral, Brazil

Abstract: Frankliniella is the most species-rich genus in the family Thripidae, with above 230 species. In South America there are about 74 species recorded, over a half in Brazil. In the Brazilian Frankliniella fauna, 21 species were described based on native material, and many other species remain to be identified. Only six Brazilian species are known as pests of plant production, either by vectoring Orthotospovirus or by causing feeding injuries to plant tissues. Members of this genus can be recognised especially by the postocular setae iii or iv directed posterolaterally and usually longer and stouter than the rest; antennae with eight or rarely seven segments; pronotum always with two pairs of posteroangular major setae and usually with one pair of anteroangular and one pair of anteromarginal major setae;, and between inner pair of posteroangular setae with five pairs of smaller, posteromarginal setae; ctenidia usually on abdominal tergites IV-VII and always on VIII; andspiracles on tergite VIII anterolateral to the ctenidia. In this study, we describe a new Frankliniella species collected in a remnant of Atlantic Rainforest, located in Fontes do Ipiranga State Park (PEFI), urban area in the municipality of São Paulo, São Paulo State, Brazil. Adults of Frankliniella sp. n. were collected during summer months of 2018-2019, associated with Solanum cernuum Vell. (Solanaceae) flowers. The specimens were prepared on permanente microscope slides in Canada balsam. The type material were deposited at "Coleção Entomológica Adolph Hempel", Instituto Biológico (IBSP), São Paulo, Brazil and at "Coleção de História Natural da Universidade Federal do Piauí" (CHNUFPI), Floriano, Brazil. The new species can be distinguished from other bicolored species, especially by: body yellow with antennal segments VI-VIII, wings and abdominal segments I-VIII brown; pedicel of antennal segment III simple; pronotal anteroangular and posteroangular setae longer than a half of pronotum length; posteromarginal comb on abdominal tergite VIII complete, but with short microtrichia medially.

Acknowledgments:

Exploration of white grub beetle, Lepidiota albistigma Burmeister (Coleoptera: Scarabaeidae) as human food in Assam, India

Authors: Bhagawati Sudhansu[1], Bhattacharyya Badal[1], Pathak Khanin[2], Sena Manpoong Nang[1], Pratim Gyanudoy Das Partha[3], [1]All India Network Project on Soil Arthropod Pests, Department of Entomology, Assam Agricultural University, India, [2]Department of Biochemistry and Agricultural Chemistry, Assam Agricultural University, India, [3]Department of Entomology, Assam Agricultural University, India

Abstract: Lepidiota albistigma B. is a white grub species belonging to the Scarabaeidae family under the order Coleoptera. Of late, this species has appeared as an emerging pest, posing a serious threat to many field and horticultural crops in Assam, India. L. albistigma possess annual life cycle where the adult lives for a very short period of 15-23 days. The adult emergence takes place during the evening hours (6.00-6.30 pm) which started from the 1st week of April and continued up to the 1st fortnight of May. Adult beetles mostly preferred to feed on mango, guava, ramie, citrus, arecanut, betel vine and black pepper etc. Grubs remain underground for a long period of 280-314 days infesting major field crops like potato, colocassia, green gram and sugarcane.

Considering the severity of damage, an effort was made for the mass collection and destruction of the beetles at Lower Brahmaputra Valley of Assam during 2014-2019. The beetles were collected through scouting and by using light traps as the beetles showed positive phototaxis. Approximately 40000 beetles were collected and killed at the endemic pockets and majority of them were relished as culinary delight by the tribal populace. Considering the possibilities of exploring the adult beetles as human food, extensive studies were conducted to analyze the complete nutritional profile of the beetles. Collected beetles were cleaned by removing wings and legs, keeping only the edible portion, which was then sun dried and ground to fine powder for further biochemical analysis. Proximate analysis of the sample estimated considerably higher amount of crude protein (68.54%) as compared to other proximate parameters viz., carbohydrate (11.84%), crude fiber (6.73%), crude fat (5.50%), total mineral (4.83%) and moisture (2.55%). The energy content was recorded to be 371.04 kcal/100g of sample. Elemental analysis of the samples revealed the presence of 7 nutrients in appreciable amount i.e., Na (29.57), K (144.33), Ca (29.94), Fe (1.41), Cu (2.01), Zn (2.38) and Mn (1.09) mg/100g. Both antioxidant and anti nutritional properties were also assessed. The phenol and flavonoid content of L. albistigma were recorded to be 6.42 mg catechol equivalent/g and 3.71 mg quercetin equivalent/g, respectively whereas DPPH activity was estimated to be 28.20 per cent. Tannin content was quantified to be 13.30 mg/g which was under acceptable limit. Fatty acid profiling registered relatively higher amount of saturated fatty acid (3.56%) as compared to mono (3.15%) and polyunsaturated fatty acid (1.11%). Palmitic acid content was maximum (2.85%) out of the ten fatty acids recorded. Amino acid profiling of the samples quantified 17 amino acids of which 8 were essential and leucine content was found in maximum amount (6.60%). Based on the nutritional value, a concerted effort has already been embraced for the further exploration of L. albistigma beetles as an alternate source of nutrition for human as well as animal feed in this region.

First evidence of CpGV and management of Codling moth in high altitude cold arid region of Ladakh, India

Authors: Bhat Barkat Hussain[1] and Yousuf Mir Waseem[1], [1]SKUAST-Kashmir, India

Abstract: Codling moth is menace and no solution was available in India for its management so all the fresh fruits from Ladakh is still banned due to quarantine regulations to prevent the 15000 Crore apple Industry of Jammu and Kashmir and Himachal Pradesh. The application of pheromone dispensers and two applications of insecticides throughout the year recorded less than one per fruit damage in apple orchard in Saliskoot Village. The application of pheromone dispensers alone reduced 50 % fruit damage in treated plots as compared to control plots at high density populations of codling moth.The area wide management for codling moth in Nurla/Nimoo villages, using pheromone dispensers showed promising results as compared to untreated plots. Among the treatments, SPLAT-Cydia and two applications of insecticides recorded lowest fruit damage (1.50%) as compared to other treatments and untreated plots recorded (58.75%) fruit damage. This is the first success story for the management of Codling moth in India. Therefore the ban on fresh fruits from Ladakh may not be considered as good rationale by using our management capsule. In addion to our targets, we reported codling moth Granulosis virus(CpGV), first time from India and the isolates were named as CpGV SKUAST-1 (Acc. No. MK801791) and CpGV SKUAST-2 (Acc. No.MK801792 and may be incorporated for the management of Codling moth. This native strain from India has a potential to manage the codling moth in Ladakh because toxic insecticides are neither sprayed and nor encouraged by the growers/policy makers because of socio-religious constraints. Though, major developed strains of CpGV from world, have developed resistance against codling moth and the new identified strain can be exploited globally for codling moth management.

The phylogeography of widespread Australian Cnestus (Curculionidae: Scolytinae) ambrosia beetles and their fungal symbionts

Authors: Bickerstaff James[1], Jordal Bjarte[2] and Riegler Markus[3], [1]Hawkesbury Institute for the Environment, Western Sydney University, Penrith, NSW, Australia, [2]University of Bergen, Norway, [3]Western Sydney University, Australia

Abstract: The comparative phylogeographic analysis of insects and their microbial symbionts can provide important information about host-symbiont interactions, transmission ecology and symbiont evolution. Previous co-phylogeographic analyses of xyleborine ambrosia beetles (Curculionidae: Scolytinae) and their fungal symbionts have shown that beetle and symbiont diversity are a manifestation of demographic processes (e.g. as a consequence of climatic change or human introduction of beetles into new environments), and higher diversity is generally found in native than invasive ranges. However, these studies were on a small number of ambrosia beetle species and their fungal associates, and were restricted to the northern hemisphere. We studied the genetic variation of the widespread Australian-endemic xyleborine ambrosia beetle genus, Cnestus Sampson 1911 and their symbiotic fungi of the genus Ambrosiella von Arx & Henneber 1965 (Ceratocystidaceae). In eastern Australia the beetles' distribution spans from Far North Queensland to Tasmania. This extensive range includes refugial habitats for mesic habitat-adapted ambrosia beetles and biogeographic barriers that may limit their dispersal. We used targeted multi-locus PCR approaches to characterise the genetic diversity of Cnestus and Ambrosiella across 2,500 km of their eastern Australian range. Cnestus is associated with at least two closely related cultivars of Ambrosiella which is indicative of either co-evolved fungal associations within this lineage, or alternatively a more recent sharing of the same fungus across different beetle lineages. More extensive characterisation of the genetic diversity of these beetle-fungus interactions will aid in deciphering their evolutionary ecology and provide taxonomic and diagnostic information for these potentially invasive ambrosia beetles and their fungi.

Evolutionary feedbacks between insect sociality and microbial management

Authors: Biedermann Peter[1] and Rohlfs Marko[2], [1]Forest Entomology and Protection, University of Freiburg, Germany, [2]Population and Evolutionary Ecology, University of Bremen, Germany

Abstract: Collaborative defenses against microbes have often been considered a by-product of social evolution in insects. Here, we take the view that both defense against microbial pathogens and promotion of beneficial symbionts are major drivers of social behaviours in many insect systems — ranging from aggregation to eusociality. By supporting our view with examples from a variety of taxa, we propose evolutionary feedbacks between the insect sociality and microbial communities. We identified variation in habitat stability — as determined by breeding site predictability and ephemerality — as a main ecological factor that constrains these feedbacks. To test this hypothesis we suggest following the evolution of insect social traits upon experimental manipulation of habitat stability and microbial consortia.

The chemical basis of symbiosis: Volatile interactions between conifer bark beetles and their fungal symbionts

Authors: Biedermann Peter[4], Kandasamy Dineshkumar[2], Andersson Martin[5], Hammerbacher Almuth[3], Gershenzon Jonathan[6] and Lehenberger Maximilian[1], [1]Department of Animal Ecology and Animal Behavior, University of Wurzburg, Germany, [2]Department of Biochemistry, Max Planck Institute for Chemical Ecology, Jena, Germany, [3]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, South Africa, [4]Forest Entomology and Protection, University of Freiburg, Germany, [5]Lund University, Sweden, [6]Max Planck Institute for Chemical Ecology, Department of Biochemistry, Jena, Germany

Abstract: Many insects exhibit symbioses with other organisms through signaling compounds which drive the evolutionary maintenance of mutualistic associations. Bark and ambrosia beetles are associated with a diverse species of symbiotic fungi which are vital for the successful colonization and development of these insects in their host trees. Fungi are able to mobilize/supplement nutrients for beetles by growing in the bark and wood, and also be able to detoxify the defense chemicals of trees which are toxic to beetles.

We investigated if volatile organic compounds emitted from different fungal symbionts could act as cues for bark beetles to recognize and distinguish their microbial community. Fungi associated with bark and ambrosia beetle emit a variety of volatiles comprised of simple aliphatic, aromatic alcohols and its esters, benzenoids, mono-, and sesquiterpenes. Using Ips typographus and its fungal symbionts as a model system, we showed that bark beetles were attracted to fungi in olfactometer assays and beetles preferred to feed on diet colonized by symbionts but not to commensals and pathogens. Testing these fungal compounds on beetle antennae using single sensillum recording revealed that beetles can detect many fungal volatiles and possess several new olfactory sensory neuron classes specialized for detecting the fungal volatiles. Additionally we showed that synthetic blend of fungal volatiles attracted bark beetles in olfactometer assays. These findings indicate that volatile compounds produced by fungi may act as recognition cues for bark beetles to maintain specific microbial communities that might have an impact on their fitness. These biologically active fungal volatiles might also have implications in pest management of bark and ambrosia beetles by deploying fungal volatiles as attractants or repellents alone or in combination with other types of semiochemicals.

New strains of predators to overcome challenges facing biocontrol in protected crops

Authors: Bielza Pablo[1], Rodríguez-Gómez Amador[1], Enrique Mendoza José[1] and Balanza Virginia[1], [1]BioControl Selection Lab. Universidad Politecnica de Cartagena, Spain

Abstract: Integrated pest management (IPM) based on arthropod biological control agents (BCAs) has definitely succeeded on many crops, especially crops grown under greenhouse conditions. Augmentative biological control has proven to be an efficient and robust pest control method, using generalist predators to control key pests.

However, there are serious limitations in the implementation of biological control in some crops, areas and periods of the year. There are constraints to the establishment and success of biological control protocols due to environmental conditions (low or high temperatures, low humidity), adaptation to crops (tomato, cucumber, ornamentals), compatibility with pesticides, etc. All crops, but particularly protected crops, grow under artificial conditions, sometimes very different from those in which natural enemies have evolved. BCAs must live on plants to which they are not naturally adapted, feed on new prey or hosts, thrive under extreme environments, or be exposed to pesticide residues. These stresses challenge the success and widespread adoption of biological control.

In the development of BCAs, interspecific variation has traditionally been used to select the most effective species of natural enemies. However, there is not always new species of BCAs that can perform better. Another source of selection is the variability between individuals and populations within a species. This intraspecific variability has shown potential for developing BCAs, but has barely been applied in the current commercial use of arthropod BCAs. This variation among individuals and populations within a species is what is intended to be explored and exploited through genetic improvement.

In this way, a real possibility of progress in biological control is the genetic improvement of natural enemies, responding to the challenges posed. As successfully achieved in the development of agriculture with plant varieties and animal breeds, the artificial selection of BCAs with certain traits can contribute decisively to a greater success of biological control.

In our opinion, the most important current challenges augmentative biocontrol is facing in protected crops are pesticide compatibility (synthetic or natural), continuous presence on the crop (prey-density dependence, adaptation to alternative food), non-suitable crops (plant defenses, lack of plant-provided food), and environmental conditions (extreme temperature and humidity).

Through a genetic improvement programme of omnivorous predators commonly used in horticultural protected crops, we have selected new strains to overcome these limitations in order to achieve a wider adoption of biological control and enhance its resilience.

Plant-Insect-Microbe interactions: summarizing thoughts

Authors: Biere Arjen[1], Tack Ayco[2] and Bennett Alison[3], [1]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [2]Stockholm University, Sweden, [3]The Ohio State University, United States

Abstract: Plant food webs include a stunning diversity of arthropods and microorganisms, and recent studies show that plant-insect-microbe interactions may be a major force structuring plant-based communities. Insect-associated microbes can strongly affect the ability of their host insects to exploit host plants and mitigate insect biotic and abiotic stress. Likewise, plant-associated microbes can strongly affect the quality of their host plants for phytophagous insects and their interactions with natural enemies and mitigate plant biotic and abiotic stress. However, environmental factors strongly modulate such interactions, limiting our ability to predict and apply these microbes in biocontrol. In closing this symposium, we will summarize some recent progress in this field and our understanding of the context-dependency in the outcome of these interactions.

The unusual reproductive ecology of tsetse and why it matters for disease control

Authors: Bierman Anandi, Stellenbosch University, South Africa

Abstract: Unlike most flies, tsetse have extreme maternal investment: females give birth to single larvae that equal their own size, and they do this continuously across their relatively long lifespan. There is no self-feeding by larvae and they are thus exclusively dependent on their mothers for the reserves which will see them surviving through the pupal stage and for the teneral period before they take their first bloodmeal. This is also the point at which they seem most susceptible to infection. Hence, understanding maternal investment has ramifications for predicting tsetse populations and disease spread.

Full-term pregnant tsetse, about to deposit a larva, are difficult to trap in the field, which makes it challenging to study mother-offspring interactions under natural conditions. Moreover, laboratory studies tend not to track the reproductive output of individual flies. Here, I present laboratory and field studies on how mothers allocate resources to their young under different conditions, using innovations in tsetse sampling and housing which alleviate these constraints.

I first describe a trapping method developed by members of our team which exploits the observation that, during the hot months of the year, savannah tsetse (Glossina morsitans morsitans and G. pallidipes) often larviposit in cooler warthog burrows. Using mother-offspring pairs caught using ‘artificial burrows’ at Rekomitjie Research Station, Zimbabwe, we show that mothers produce larger offspring when in better physiological condition themselves, and produce smaller offspring when they experience hotter temperatures during pregnancy.

We also used a new method of housing flies individually, developed at the Liverpool School of Tropical Medicine, to track how reproductive investment in the laboratory depends on maternal nutrition and age. We manipulated nutrition and showed that stressed females produce smaller offspring and, regardless of condition, females exhibit a similar age-dependent pattern of reproductive investment, reaching a peak around their third offspring and declining gradually thereafter. Maternal age can thus be important for offspring condition and life history. These matters are important in population and epidemiological modelling since they affect population responses to environmental change and, potentially, offspring susceptibility to disease.

Nutritional requirements for reproduction and survival in the blowfly, Lucilia sericata

Authors: Bierman Anandi[1], Al-Qurashi Shatha[2] and Wall Richard[3], [1]Stellenbosch University, South Africa, [2]University of Bristol, United Kingdom and University of Jeddah, Saudi Arabia, [3]University of Bristol, United Kingdom

Abstract: Insects with access to finite energy resources must allocate these between maintenance and reproduction in a way that maximises fitness. This will be influenced by a range of life-history characteristics and the environment in which any particular insect species lives. Here the allocation of resource between survival and reproduction is considered: females of the blowfly, Lucilia sericata (Diptera: Calliphoridae), were fed diets differing in protein and carbohydrate (sucrose) content, and the allocation of lipid to reproduction was quantified using a spectrophotometric method of analysis. Immediately after adult emergence, total body lipid, scaled for differences in body size, showed an initial decline as it was utilised to meet the metabolic demands of cuticle deposition, muscle maturation and then flight. When flies were denied access to sucrose, stored lipid then continued to decrease until flies died, usually within four days of emergence. However, flies given access to sucrose were able to increase body lipid content, demonstrating that carbohydrate is essential for homeostasis and that it can be used to synthesise lipid. Nevertheless, female flies fed sucrose only were unable to synthesise egg yolk. Only flies provided with protein were able to mature eggs. However, the rate of egg maturation and number and size of eggs matured were greater for female flies given liver compared to flies provided with pure whey protein powder. The results demonstrate the importance of different dietary components for different elements of the life-history of L. sericata, namely survival and reproduction.

Integrating more realistic tsetse biology into epidemiological models of human and animal African Trypanosomiases

Authors: Bierman Anandi[1], Beastall Molly[2] and Rock Kat[3], [1]Stellenbosch University, South Africa, [2]University of Bristol, United Kingdom, [3]University of Warwick Department of Mathematics, United Kingdom

Abstract: Classic epidemiological models of vector-borne diseases, based on the Ross-Macdonald framework, often make simplifying assumptions about vector biology, in part due to the lack of data or the need for mathematical tractability. Such models often assume that the biting rate is constant, or that vector mortality does not change with age. However, in the context of the African trypanosomiases, we have rich field and laboratory data on tsetse-trypanosome interactions that challenge these assumptions: for example, older flies have a higher probability of dying and young flies have higher infection rates (the teneral phenomenon).

Here, we present a partial differential equation model that incorporates this biological complexity to better compute the proportion of infected tsetse and infection transmission in vertebrate populations for a fixed vertebrate infection prevalence. Rather than assuming all flies in the population have equal mortality and behaviour, our model takes into account variation according to age and the hunger stage of flies. Young and old flies have a higher chance of dying and tsetse are obligate blood feeders that may die of starvation, which also influences their motivation to bite (depending on the time since their last blood meal). In addition, young flies have higher infection rates.

Overall, our model predicts that – depending on the species - infection prevalence in tsetse decreased up to five times with more biological realism in the model compared to classic models of human African trypanosomiases. Prevalence in tsetse decreased with the teneral phenomenon, starvation, and a more realistic parasite incubation phase but increased with mortality senescence. We use this model to assess the impact on predictions of disease elimination under different control scenarios for both human and animal African trypanosomiases, especially when considering the impact of vector control.

This approach could help improve current African trypanosomiases decision-making tools and could be generalised to other vector-borne diseases, which also stresses the need for further study of vector ecology and evolution.

Ecophysiology and biogeography in water beetles

Authors: Bilton David, University of Plymouth, United Kingdom

Abstract: The factors shaping the size and position of the geographical ranges of organisms remain poorly understood.

I will briefly summarize our recent work which has explored these issues, using water beetles as a model system, studying closely related species which often differ dramatically in the extent of their geographical distributions. Within a given habitat type physiological tolerance appears to be of fundamental importance in shaping both geographical range size and position, but shifts between habitats, whilst relatively rare, may drive dramatic changes in biogeography.

Wolbachia supplement biotin and riboflavin to enhance reproduction in rice planthoppers

Authors: Bing Xiao-Li[1], Anthony Hoffmann Ary[3], Zhao Dian-Shu[1], Hai-Jian Huang Hai-Jian[1], Ju Jia-Fei[1], Gong Jun-Tao[1], Zhang Kai-Jun[1], Hong Xiao-Yue[1], Zhang Xu[1], Guo Yan[1] and Xi Zhiyong[2], [1]Department of Entomology, Nanjing Agricultural University, China, [2]Department of Microbiology and Molecular Genetics, Michigan State University, East Lansing, Michigan, United States, [3]Pest and Environmental Adaptation Research Group, Bio21 Institute and the School of BioSciences, The University of Melbourne, Parkville, Victoria, Australia

Abstract: Symbiont-mediated nutritional mutualism are important in contributing host fitness of insects, especially for insects that feed exclusively on nutritionally unbalanced diets. Here, we elucidate the functional importance of two plant-sap feeding insects' association of Wolbachia, which is known for manipulating host reproduction as a facultative symbiont. We found the brown planthopper Nilaparvata lugens (Stål) and the small brown planthopper Laodelphax striatellus (Fallén) laid significantly more eggs than uninfected planthoppers, regardless of temperature. Furthermore, experimental transfer of Wolbachia into the uninfected lines rescued their fecundity deficit. Genomic analysis showed Wolbachia strains from both planthoppers encoded complete biosynthesis operons for biotin and riboflavin. And metabolic analysis revealed Wolbachia-infected planthoppers had higher titers of biotin and riboflavin. A series of ecological experiments further verified that supplementation of a mixture of biotin and riboflavin could recover the fecundity deficit of Wolbachia-uninfected planthoppers. In addition, comparative genomic analysis suggests that the riboflavin synthesis genes are conserved among Wolbachia supergroups. However, though being rare in Wolbachia, the biotin operons of all Wolbachia strains share a recent ancestor that may have been horizontally transferred from Cardinium. Our results demonstrate a type of mutualism that involves facultative Wolbachia and plant-sap feeding insects via vitamin Bs and may lead to improved strategies for integrated pest management.

What's Amata with this moth? Aposematic variation in an Australian lepidopteran

Authors: Binns Georgina[4], Mappes Johanna[1], Hart Nathan[2], Rowland Hannah[5], Umbers Kate[6] and Herberstein Marie[3], [1]Helsinki University, [2]Macquarie University, [3]Macquarie University, Australia, [4]Macquarie University, Australia, [5]Max Planck Institute for Chemical Ecology, Germany, [6]Western Sydney University, Australia

Abstract: Aposematism is an anti-predator strategy where defended prey species advertise their defence with conspicuous warning signals. Predators learn to recognise these warning signals after an initial unpleasant experience and associate the signals with unprofitability. Aposematism incurs selective benefits to the prey, such as increased survival rates, and warning signals are thought to be honest indicators of the strength of the defence. To be effective, warning signals need to be recognisable, memorable and consistent. However, variation in warning signals has been reported in most aposematic taxa, contradicting the theoretical assumption that warning signals are under stabilising selection.

The day-flying aposematic wasp moth Amata nigriceps (Erebidae: Arctiinae) is thought to be a complex of subspecies, which is yet to be taxonomically and ecologically defined. They are conspicuous fliers and are chemically defended by pyrazines and preliminary trials with naïve predators (Blue tits) indicate that the moths are indeed distasteful to birds. The warning signal consists of conspicuous orange spots and stripes against a black background, which varies between 10-30% proportionally, in both males and females. The aim of this study is to quantify and explain the observed variation in Amata moth warning signals. We compared colour patterns of moths from museum collections and our own collections spanning 123 years and related this to climatic variables and bird predator diversity. We found an increase in the warning signal wing spots with increasing temperatures over 90 years and across populations spanning 746kms from across the Australian east coast, but no effect of predator diversity or precipitation. We also conducted a controlled full-sibling laboratory experiment with different developmental temperatures and found no evidence of temperature-driven pattern plasticity, but high heritability (70%) of the warning signal.

We also found a distinct difference in colour pattern between males and females – females are proportionally more red than males, which may reflect sexual selection or an increased need for conspicuousness. These results help us to predict how prey populations may evolve in response to future climate and diversity impacts.

Role of fruit odors in attraction and oviposition behaviors of peach fruit fly, Bactrocera zonata Saunders

Authors: Binyameen Muhammad[1] and Afzal Imran[2], [1]Bahauddin Zakariya University, Pakistan, [2]Department of Entomology, FAST, Bahauddin Zakariya University, Multan, Pakistan

Abstract: Several tephritid species are native to South and South-east Asia, and severely affect horticulture productions. Targeting female fruit flies using techniques that rely on the olfactory sensitivity of the flies, may support direct and more selective ways to control fly populations. This study used Y-tube olfactometer to test the physiological response of economically important pest specie, Bactrocera zonata to host fruits odors and gas chromatography mass spectrometry for the detection of major compound found in whole fruit odor. Three fruit species and their varieties; Guava (Gola, Larkana Small Surahi (LSS) Larkana Large Surahi (LLS),Mango (Sufaid Chaunsa, Black Chaunsa, Fajri Kalan, Aman Dusehri, and Anwar Ratol) and orange (Kinnow, Musami and fruiter) were used to test different behavioral and fitness parameters. Female flies showed significantly higher levels of attraction to both un-infested and infested fruit odors compared to control (blank). In pairwise comparisons of guava fruit varieties, female flies were significantly attracted towards un-infested Gola compared to un-infested LSS, while in the case of intra-varietal comparisons, significantly higher number of flies were attracted to un-infested fruits compared to infested fruit in all three tested varieties of guava. In pair-wise comparisons of un-infested mango varieties, female flies showed significantly higher level of attraction towards the S. Chaunsa compared to B. Chaunsa, A. Dusehri and A. Ratol, while in case of intra-varietal comparisons, significantly more flies were attracted to un-infested fruits compared to infested fruit in all tested mango varieties. In two-choice oviposition bioassays, B. zonata females made significantly more visits, greater numbers of oviposition, spent a significantly longer time, and larger numbers of pupae and adults developed on Gola fruits compared to LSS fruits. While in case of two-choice oviposition bioassays on mango fruit, B. zonata females made significantly more visits, greater numbers of oviposition, spent a significantly longer time, and larger numbers of pupae, average pupal weight and adult emergence on S. Chaunsa variety compared to other tested varieties. In no-choice bioassays, female flies made more visits and spent a significantly longer time on LSS compared to Gola and LLS. However, in case of no-choice oviposition bioassays on mango fruit, no significant difference was observed among the tested varieties. Orange results are in progress and hopefully, will present in congress. GC-MS analysis of guava headspace revealed presence of aliphatic and aromatic esters as a dominant group of compounds in both un-infested and fruit-fly-infested fruits, with a higher quantity mostly occurring in fruit-fly-infested fruits. Role of fruit volatiles is discussed in an ecological context of attraction and oviposition behaviors of adult females and fitness of their offspring.

Key words: Headspace, GC-MS, plant volatiles, behavior,

The Search for Invertebrate Consciousness

Authors: Birch Jonathan, London School of Economics, United Kingdom

Abstract: There is no agreement on whether any invertebrates (e.g. insects, spiders, worms, octopuses, crabs) are conscious and no agreement on a methodology that could settle the issue. How can the debate move forward? If we rely on a specific theory of consciousness, our inferences will only be as secure as that theory - and all general theories of consciousness are speculative and controversial. If we try to do without theory all together, our inferences are unconstrained. I aim to plot a middle path between these extremes that I call the “theory-light” approach. At the core of the theory-light approach is a minimal theoretical commitment about the relation between consciousness and cognition: the hypothesis that conscious perception of a stimulus facilitates, relative to unconscious perception, a cluster of cognitive abilities in relation to that stimulus. This “facilitation hypothesis” is commitment that is compatible with many specific theories of consciousness, and it can productively guide inquiry into invertebrate consciousness. What’s needed? At this stage, not more theory, and not more undirected data gathering. What’s needed is a systematic search for consciousness-linked cognitive abilities, their relationships to each other, and their sensitivity to masking. I illustrate the “theory-light” approach using the example of bees.

Intra-species diversification using resistant “elite plants” reduces strawberry herbivory

Authors: Birge Traci[1], B Amby Daniel[3], Andreasson Erik[2], Stenberg Johan[2], de Jong Sanne[2] and Koski Tuuli-Marjaana[2], [1]Biodiversity Unit, University of Turku, [2]Swedish University of Agricultural Sciences, Sweden, [3]Univerisity of Copenhage, Denmark

Abstract: Minimizing the use of harmful pesticides is a key step towards reaching sustainable food production. However, the transition towards more sustainable plant protection with less pesticide use is difficult, because no “silver bullet” exists among the available non-chemical tools. Recently, increasing genetic diversity of plantation via cultivar mixing has been shown to be a promising method to reduce pest damage. Combining cultivar mixing with functional plant traits (“elite plants”) may thus be a safer pathway to functional Integrated Pest Management (IPM). Here, using a full-factorial experiment with 60 strawberry plantations, we show that reductions in chewing herbivore damage can be achieved through increased use of resistant “elite plants” either alone, or as mixture with susceptible plants. Importantly, the lowest herbivory was found in plantations where high diversity was achieved by cultivar mixing using multiple genotypes of “elite” plants or by using elite plants alone, whereas the highest herbivory was found in plantations with low diversity consisting of susceptible genotypes. Therefore, increasing the genetic diversity and resistance of plantations via “elite plants” likely reduce pesticide dependency.

Effects of drought and invertebrate herbivore communities on plant performance along a European latitudinal gradient

Authors: Birge Traci[2], Vandegehuchte Martijn L.[3] and Stenberg Johan A.[1], [1]Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Alnarp, Sweden, [2]Biodiversity Unit, University of Turku, [3]Terrestrial Ecology Unit, Department of Biology, Ghent University, Belgium

Abstract: Plant populations are often locally adapted to the particular herbivores present in the community and the particular set of local climate conditions. However, climate change is causing multiple changes in both the abiotic and biotic environment of plants. Temperatures as well as the frequency and intensity of droughts are increasing across Europe. Simultaneously, several species adapted to a southern climate are shifting their ranges northward. As dispersal abilities differ among organisms, e.g. among plants and their different herbivores, this results in novel or no-analog communities.

The success of some non-native plants is often attributed to release from specialist herbivores, enabling plants to divert resources from defenses to growth and reproduction. However, several plant species actually increase their defense levels if herbivore species are lost. A proposed explanation is that multiple herbivores often exert interfering selection pressures on defense traits, and that escape from community complexity lifts the constraints imposed by this interference, enabling the plant to optimally defend against the remaining herbivores.

So far, however, we have limited empirical understanding of how changes in herbivore communities interact with climatic changes to affect selection on plant traits including defenses. Latitudinal gradients can be used as a space-for-time approach, with southern ecosystems representing more northern systems of the future. We set up five common gardens of woodland strawberry along a continental latitudinal gradient from southern Spain to northern Finland. Each garden consists of 16 plant genotypes from across this gradient. Per garden, half of the plants of each genotype have incoming precipitation experimentally reduced by 50%. We here present the first results on how different woodland strawberry genotypes perform along the gradient, with and without drought, and how invertebrate herbivores, local climate, and drought interact to shape the evolution of plant resistance and tolerance.

Beetles disperse viable spores of a keystone wood decay species

Authors: Birkemoe Tone[1], Lunde Lisa Fagerli[1], Boddy Lynne, Sverdrup-Thygeson Anne, Jacobsen Rannveig Margrete and Kauserud Håvard, [1]Norwegian University of Life Sciences, Norway

Abstract: Wood decay fungi are considered to be dispersed by wind, but dispersal by animals may also be important, and more so in managed forests where dead wood is scarce. We investigated 1) the arthropod community visiting sporocarps of the keystone fungi Fomitopsis pinicola by use of time-laps cameras 2) whether viable spores of F. pinicola could be found in the faeces or exoskeleton of beetles collected on the sporocarps or 3) whether viable spores of F. pinicola could be found on beetles collected from newly felled spruce logs nearby, a favorable habitat for spore deposition. We found that Coleoptera was the most numerous order caught by the camera, followed by Diptera and Aranea. Coleoptera longer than 5 mm could be identified to species. Viable spores were found on the exoskeleton and in the faeces of all beetle species collected from sporulating sporocarps and nine beetle species transported viable spores to recently felled spruce logs. Our results demonstrate that beetles can provide directed dispersal of wood decay fungi and that a larger group of arthropods might have the potential to do so.

The macroecology of ant thermal traits

Authors: Bishop Tom[3], Parr Kate[4], Robertson Mark[5], Boyle Mike[1], Nowrouzi Sara[2] and Law Steph[4], [1]Imperial College London, United Kingdom, [2]James Cook University, Australia, [3]University of Liverpool & University of Pretoria, United Kingdom, [4]University of Liverpool, United Kingdom, [5]University of Pretoria, South Africa

Abstract: Life on Earth walks a thermal tightrope. Too hot, or too cold, and organisms cannot survive. To maintain thermal balance, organisms have evolved a range of different thermal traits. First, physiological traits set hard thermal boundaries on the functioning of animals. Different proteins and membranes can maintain their integrity at across different temperature ranges. Second, morphological and behavioural traits can act to help keep body temperatures within these physiological boundaries. Traits such as colour and body size play critical roles in the gain and loss of heat – particularly for ectotherms who largely cannot generate their own heat. Darker colours absorb heat faster than reflective, pale colours do, while larger bodies gain and lose heat at a much slower rate than small bodies. Finally, the thermal advantages offered by these traits can be maximised through behavioural regulation: consider a dark coloured butterfly basking in the sun to heat its flight muscles, or a reptile seeking shade to avoid overheating.

Do these thermal traits distribute across geography in predictable ways? The answer to this question will not only reveal how animals have evolved and spread across the planet, but will also suggest the ways in which the biosphere might change in the face of rising temperatures.

Here, I will synthesise a body of work showing how ants (Hymenoptera: Formicidae) respond to a diversity of thermal gradients via a suite of physiological, morphological and behavioural traits. We use thermal gradients ranging from seas to summits, the understory to the canopy, and from disturbed to pristine ecosystems. Together, they are helping us build a predictive picture about why different ants live where they do, and where they might be going next.

Insecticidal Properties of the Main Components of Trachyspermum ammi (L.) Fruits Against the Small Hive Beetles, Aethina tumida (Murray)

Authors: Bisrat Daniel[2], Jung Chuleui[1], [1]1Agricultural science & technology research institute, Andong National University, Andong, GB, Korea 2 Department of Plant Medicals, Andong National University, [2]Agriculture Science and Technology Research Institute, Andong National University, GB 36729, Republic of Korea, South Korea

Abstract: Small hive beetles (SHB) (Aethina tumida Murray, Coleoptera: Nitidulidae) are native to sub-Saharan Africa where they exist as scavengers in colonies of western honey bees (Apis mellifera L.). They feed on pollen, honey and larvae of honey bees. However, SHB within their native range rarely inflict severe damage on strong bee colonies. In the current study, contact, fumigant and repellent toxicities of the main constituents derived from Trachyspermum ammi (Linn.) Sprauge fruits were evaluated against the small hive beetles (SHB). Hydrodistillation of T. ammi fruits grown in Ethiopia yielded a light pale yellow essential oil (3.5% v/w) with a strong aromatic odor. Analyses by gas chromatography-mass spectrometry (GC-MS), twenty-two compounds, accounting 98.68% of the total oil were identified. The oil was dominated by monoterpenoids such as gamma-terpinene (32.72%), p-cymene (27.92%) and thymol (24.36%). The essential oil showed strong contact and fumigation toxicities against the small hive beetle adults, with LD50 value of 66.64 µg/adult and LC50 value of 89.03 mg/L Air, respectively. Among the main constituents, thymol was the most toxic component found in both contact (LD50=41.79 µg/adult) and fumigation (LC50=52.66 mg/L Air) toxicities. The other two components, gamma-terpinene and p-cymene, were less effective in both contact and fumigant toxicities testing. The results showed that T. ammi essential oil and thymol could serve as potential alternatives to synthetic insecticides for the control of SHB.

Genus Hydrovatus Motschulsky, 1853 - a pantropic enigma with focus on the taxonomy of the species in Japan (Coleoptera, Dytiscidae, Hydroporinae)

Authors: Biström Olof[2] and Vahtera Varpu[1], [1]Biodiversity Unit Zoological Museum University of Turku, Finland, [2]Visiting scientist of Finnish Museum of Natural History, Entomology Unit, University of Helsinki, Finland

Abstract: The genus Hydrovatus Motschulsky, 1853 is one of the most species-rich diving beetles genera with currently about 210 valid species. Together with its sister-group, the genus Queda Sharp, 1882, with only three recognized species, Hydrovatus forms a monophyletic tribe Hydrovatini, which is placed in the subfamily Hydroporinae. Monophyly of Hydrovatini is based on morphological and molecular characters. Closest relatives on tribe-level are Hyphydrini and Hygrotini. Hydrovatus is distinguished from Queda by having visible labrum (in part) and by deep metacoxal incisions (corresponding characters in Queda are labrum concealed and metacoxal incisions shallow). Hydrovatini has an extensive pantropic distribution. Distribution of Queda is restricted to northeastern part of Neotropical region while Hydrovatus is pantropical, being most diverse on both side of Equator between the Tropic of Cancer and the Tropic of Capricorn. Hydrovatus extends, however, its distribution outside the tropics, generally being less diverse there.
Japan is located north of the Tropic of Cancer. Eight species of Hydrovatus have been recorded from the country. All of them belong to four different species groups, the main distribution of which is between the tropics. Accordingly, we assume that the origin of the species recorded in Japan is also to be located between the tropics. Our studies have thus far revealed one new species, H. remotus Biström & Watanabe 2017, distributed in the southernmost islands of the Ryukyus. DNA analysis has been undertaken in critical cases of species delimitation. Moreover our studies of various material including types will contribute to a more exact and reliable species list of Hydrovatus in Japan.

Investigating how conservation measures affect pollinator communities – implications for ecosystem services and insect conservation

Authors: Blackmore Lorna[1] and Davies Richard[2], [1]PhD student from the University of East Anglia, United Kingdom, [2]Primary supervisor. Lecturer in Biodiversity at the University of East Anglia, United Kingdom

Abstract: Efforts to mitigate declines in pollinators on farmland include use of field margins that are florally enhanced with wildflower seed mixes. These have mainly targeted bumblebees and honeybees, yet uncertainty remains over their effectiveness for other pollinating insects. Adult hoverflies (family Syrphidae), despite being highly abundant and important crop pollinators in temperate agricultural ecosystems and showing long-term declines, are a relatively neglected group in studies of plant-pollinator interactions and conservation effectiveness of agri-environment schemes.

The questions we aim to answer are, does floral enhancement of field margins: (i) affect dietary niche parameters of hoverflies; and (ii) influence the functional diversity of the visiting hoverfly community?

It is not known how florally enhanced field margins influence dietary niches (including breadth and specialism) in hoverflies at either the individual insect or the species level. Determining this is important for pollinator assemblages for two reasons: (i) greater individual specialism in plant species visited is thought to result in greater pollinator effectiveness; and (ii) greater average generality of pollinator species is thought to increase stability of pollinator networks, hence pollination services. Ecological generalist species are often found to consist of heterogeneous collections of specialised individuals. Optimal foraging theory predicts that an increase in resource availability will lead to an increase in dietary specialism of individuals. However, alternative mechanisms mean that net effects of floristic enhancements on specialism/generalism of individual hoverflies and species remain uncertain without dietary analysis. We measured ecological resource-use and diet using DNA metabarcoding, which has better taxonomic resolution than traditional light microscopy for the identification of pollen from key plant families such as Asteraceae.

A functional trait-based approach focused on resource use can aid our understanding of causal links between pollinator conservation interventions, pollinator diversity, and pollination services. Trait variables such as body size, tongue length and morphology influence pollinator preferences for particular floral morphologies. Species-specific functional trait values can be used to calculate multi-species functional diversity metrics for pollinator assemblages under different management regimes. Functional diversity is known to be a better predictor, hence index, of the rates and resilience of ecosystem processes and functions (e.g. pollination) than simple species richness.

Our work tests the effect of field margin floral enhancement on the functional diversity of whole hoverfly assemblages with intra-specific dietary composition and diet breadth for a subset of common hoverfly species.

Compiling and summarising the evidence for effective conservation action for butterflies & moths

Authors: Bladon Andrew[1], Sutherland William[2] and Smith Rebecca[1], [1]Conservation Evidence Department of Zoology University of Cambridge, United Kingdom, [2]University of Cambridge

Abstract: Lepidoptera (butterflies and moths) are the second most speciose group on the planet, and play a vital role in many terrestrial ecosystems as pollinators and primary consumers. Butterflies in particular are probably the most popular and well-known group of insects, and in an era of increasing concern about global declines in insect abundance, much of the best evidence comes from butterflies and moths. Despite facing a wide-range of threats, from habitat loss and conversion, to pollution and climate change, only around 1,500 species of Lepidoptera (of ~180,000 described) have been assessed for the IUCN Red List, the majority of which are butterflies. From these assessments, around 30% of species are thought to be in decline, and 5-10% are threatened with extinction. Conservation management is required to reverse these declining population trends, and to recover species that have suffered local extinctions.

Evidence-based knowledge is key for planning successful conservation strategies and for the cost-effective allocation of scarce conservation resources. Targeted reviews may be carried out to collate evidence on the effects of a particular conservation action, but this approach is labour-intensive, expensive and ill-suited for areas where the data are scarce and patchy. The evidence for the effectiveness of conservation actions aimed at insects is scarcer than for vertebrate taxa, and accordingly, only a small number of targeted reviews on butterflies and moths exist. Assembling the existing evidence for butterfly and moth conservation actions in one place, alongside information for other taxa, facilitates easy-access for both conservation scientists and conservation practitioners.

We used a subject-wide evidence synthesis approach to simultaneously summarise the evidence for all actions dedicated to the conservation of butterflies and moths. By simultaneously targeting the entire range of potential actions, we were able to review the evidence for each action cost-effectively. The resulting synopsis can be updated periodically and efficiently to incorporate new research. I will present the theory behind the Conservation Evidence approach, and discuss the findings from our recently published synopsis. The synopsis will be freely available online and, alongside the Conservation Evidence online database, will be a valuable asset to the toolkit of practitioners and policy makers seeking sound information to support butterfly and moth conservation.

The evolutionary demise of a social interaction: social partners differ in the rate at which interacting phenotypes are lost

Authors: Bladon Eleanor[2], Mashoodh Rahia[2], Bird Nancy[1], Kilner Rebecca[2] and Pascoal Sonia[2], [1]University College London, United Kingdom, [2]University of Cambridge, United Kingdom

Abstract: Phenotypic plasticity enables animals to flexibly adjust their behaviour to their social environment – sometimes through the expression of adaptive traits that have not been exhibited for several generations. We investigated how long social adaptations can usefully persist when they are not routinely expressed by using experimental evolution to document the loss of social traits associated with the supply and demand of parental care. Populations of burying beetles Nicrophorus vespilloides were evolved over 48 generations - in ‘Full Care’ populations traits associated with the supply and demand of care were expressed, whereas in ‘No Care’ populations we prevented expression of these traits experimentally. We then revived trait expression in the No Care populations at generations 24, 43 and 48 by allowing parents to supply post-hatching care, and compared these social traits with those expressed by the Full Care populations. We found that offspring demands for care decayed in the No Care populations more rapidly than a parent’s capacity to supply care. Furthermore, male care decayed faster than female care. We suggest that this reflects differences in the strength of selection on offspring, males and females, for the expression of alternative traits which are more likely to enhance fitness when post-hatching care is disrupted.

Evolution of Aposematic Coloration in Xylocopa: An Unsupervised Machine Learning Approach

Authors: Blaimer Bonnie[1], Willadsen Peter[2], [1]Museum für Naturkunde Berlin, Germany, [2]North Carolina State University, United States

Abstract: Large carpenter bees (genus Xylocopa), are a species-rich, easily recognizable genus resembling bumble bees in size and appearance. Carpenter bees are found on every continent except Antarctica, and display a diverse array of color patterns. In some lineages, aposematic coloration, often consisting of brightly colored bands or patches of pubescence on the dorsum of the bee, is displayed by many species. Some species also exhibit sexual dichromatism, in most cases the female is the brightly colored sex while the male is often drab and covered in yellow or brown pubescense. As part of this study, I am imaging the dorsum of a variety of aposematic carpenter bees species from museum collections and using an unsupervised machine learning approach to cluster species with similar aposematic patterns. Each image will also be overlaid onto a standardized bee template, both the original photographs and templates will be run separately and compared. The evolution of color patterns will then be investigated by testing for the presence of phylogenetic signal based on a phylogeny of Xylocopa constructed as part of this project. In addition, color pattern clusters will be correlated with Xylocopa species distributions to test whether the ranges of members within a cluster overlap, and co-occurring species may have converged on similar color patterns to reinforce the warning signal to predators through Mullerian mimicry. This study’s ultimate goal is to identify potential drivers underlying the evolution of color patterns across Xylocopa and lay the groundwork for future studies on additional factors influencing present patterns.

Key innovations and the diversification of Hymenoptera

Authors: Blaimer Bonnie[3], Santos Bernardo[4], Cruaud Astrid[1], Gates Michael[6], Kula Robert[6], Mikó István[7], Rasplus Jean-Yves[1], Smith David[6], Talamas Elijah[2], Brady Seán[5] and Buffington Matthew[6], [1]Centre de Biologie pour la Gestion des Populations, INRAe, [2]Florida State Collection of Arthropods, [3]Museum für Naturkunde Berlin, Germany, [4]Muséum national d'Histoire naturelle, [5]National Museum of Natural History, Smithsonian Institution, [6]Systematic Entomology Laboratory, ARS-USDA, [7]University of New Hampshire

Abstract: Hymenoptera (wasps, ants and bees) are one of the most diverse animal lineages, but whether specific key innovations have contributed to their diversification is still unknown. We assembled the largest phylogenomic framework for Hymenoptera to date and tested if particular morphological and behavioral innovations influenced diversification in the order: the wasp waist of apocritan wasps; the stinger of aculeate hymenopterans; parasitoidism, a specialized form of carnivory; and secondary phytophagy, a derived plant-feeding strategy. Our time-calibrated phylogenies indicate that a parasitoid regime in Hymenoptera originated in the Late Triassic and remained dominant until the Early Cretaceous. We found strong evidence that transitions to secondary phytophagy (from parasitoidism) had a major influence on hymenopteran diversification rate. Support for parasitoidism, the stinger and the wasp waist as key innovations remains equivocal, but there is indication that these traits laid the anatomical and behavioral foundations for adaptations more directly associated with diversification.

Unraveling diversity patterns and endemism in Malagasy ants: a phylogenomic approach

Authors: Blaimer Bonnie[2], Carolina Loss Ana[1], Fisher Brian[1] and Camacho Gabriela[3], [1]California Academy of Sciences, United States, [2]Museum für Naturkunde Berlin, Germany, [3]North Carolina State University and California Academy of Sciences, United States

Abstract: The first step in preserving biodiversity and its associated ecosystem functions is assessing and quantifying measurable units of this diversity. Two key elements of measuring biodiversity across space and time are species diversity and endemism. In the past, most survey efforts have been focused on using taxonomic species as the unit of diversity and endemism, but over the last decade it has become more common practice to assess phylogenetic (or lineage) diversity alongside taxonomic species richness. Measuring arthropod diversity based on either of these units is challenging, given that surveys are often too limited in geographic scope to capture the magnitude and breadth of arthropod species distributions and diversity, and timely identification of collected samples is difficult. Arthropods are thus often excluded from conservation planning decisions. Here we outline the goals and first results of our project MAMI (Malagasy ant microendemism), which aims at a synthesis of survey efforts for ants in Madagascar spanning two decades. We use a phylogenomic approach to investigate regional patterns of phylogenetic diversity, endemism, and community structure across more than 1,200 species of ants in Madagascar based on ~2,200 loci of ultraconserved elements. We analyze phylogenetic patterns of community structure, diversity and endemism of ants in Madagascar across several different habitat types and along climatic and primary productivity gradients. Our island-wide community analyses uncovers general patterns of species richness, lineage diversity and endemism across ant communities in Madagascar, allowing us to draw broad, widely applicable conclusions about the importance of these patterns for conservation planning.

Eradication of Ips typographus from the UK: progress 18 months from the first finding

Authors: Blake Max[1] and Straw Nigel[1], [1]Forest Research, United Kingdom

Abstract: Ips typographus is one of the most significant pests of spruce throughout its native range in Europe. Though the UK relies on spruce (primarily Sitka and Norway) for a large portion of its forestry industry, Ips typographus has never managed to establish here, and for over 25 years detailed surveys as part of the EU Protected Zone against invasive Ips in the UK had never found the species established and breeding here, until 2018.
Several hibernating adults were found in Kent (the most south easterly part of England, closest to France) in November 2018, and a follow up survey revealed that there was an established breeding population in a restricted woodland setting. Other surveys in spruce woodland in south east England have failed to pick up any additional Ips typographus populations, and one year on from the initial finding no other breeding populations have been located.

The woodland is now part of an eradication program, led by Forestry Commission England and Forest Research, which aims to eradicate Ips typographus from the UK and prevent any potential spread of the species further through the UK. Following significant works to reduce any breeding substrate on the woodland, work over the following seasons has attempted to trap out adults from the site, as well as monitoring other areas using pheromone traps. The success of the eradication actions will be indicated following pheromone trapping in 2020, although eradication itself won't be declared, if successful, until at least 2022. Pheromone trapping data will be presented alongside insights from molecular and host-choice experiments to indicate how such research has helped inform the decisions surrounding the management of Ips in the UK.

Successful eradications of bark beetles are rare, therefore this eradication attempt will serve as a case study highlighting areas of success (and failure) with the aim of helping inform other bark beetle eradication attempts. The on-ground work will be presented as a case study discussing what went well and what didn't, highlighting recommendations for any future eradication attempts. Wider findings of Ips typographus will also be discussed with a long-term view of Ips typographus establishment in the UK. Is it possible that this species will recolonise the UK, and if so are there any management practices that could help prevent or slow establishment?

Elevated carbon dioxide concentration impacts the semiochemically-mediated plant-insect interactions

Authors: Blanchard Solène[3], Boullis Antoine[1], Detrain Claire[2], Verheggen François[1] and Lognay Georges[2], [1]Functional and Evolutionary Entomology, Gembloux Agro-Bio Tech, University of Liege, Belgium, [2]Unity of Social Ecology, University of Brussels, Belgium, [3]Unity Social Ecology, University of Brussels and Functional and Evolutionary Entomology, Gembloux Agro-Bio Tech, University of Liège, Belgium

Abstract: The impact of global change on ecosystems has received growing scientific attention during the last decades. Numerous studies are now suggesting that abiotic environmental factors will modify plant physiology with cascade effect on higher trophic levels.
In this study, we tested the hypothesis that the predicted raise of carbon dioxide concentration will modify the semiochemically-mediated interactions in a multitrophic model including plants, aphids, aphid-tending ants, and aphid natural enemies. To do so, we raised all plants and insects under two contrasted carbon dioxide concentrations.
Due to the pest status of aphids and the dispersal ability of their winged morphs, we investigated the host plant choice of black bean aphids under changing environment and found positive impact of elevated CO2 concentrations for the winged morphs, but not for the apterous ones. These modifications of behaviors were not led by modifications of Vicia faba plant volatile emissions under elevated carbon dioxide concentrations. Because aphid honeydew volatiles are mediating the prey location behavior of aphid-natural enemies, we characterized the volatile profile of honeydew and found qualitative and quantitative modifications under elevated CO2 concentrations. These changes were not linked with a modification of hoverfly attraction and oviposition site selection. The raise of CO2 concentrations also increased the number of physical interactions between ants and aphids, leading to the reinforcement of the aphid-ant mutualism. Sugar composition of aphid honeydew is now investigated for a more comprehensive understanding of the impact of abiotic factors on aphid-ant mutualism.
We conclude that carbon dioxide concentration impacts these semiochemically-mediated interactions. New studies on the effect of warming on the same multitrophic interactions revealed quantitative impacts of elevated temperatures on the emission of plant volatiles and behavioral impacts on the aphid-ant mutualism.

Field assessments of the effects of elevated ozone and diesel exhaust emissions on insect pollination and natural enemy recruitment

Authors: Blande James[4], Girling Robbie[5], Ryalls James[1], Langford Ben[2], Pfrang Christian[3], Nemitz Eiko[2] and Mullinger Neil[2], [1]Centre for Agri-Environmental Research, School of Agriculture, Policy and Development, University of Reading, United Kingdom, [2]Centre for Ecology and Hydrology, Edinburgh, United Kingdom, [3]School of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, United Kingdom, [4]University of Eastern Finland, Finland, [5]University of Reading, United Kingdom

Abstract: Common atmospheric pollutants such as nitrogen oxides (NO and NO2, collectively NOx) released from diesel vehicle exhausts and tropospheric ozone (O3) are capable of disrupting the volatile organic compounds (VOCs) that many insects utilise for communication during critical stages of their life cycles, such as locating hosts. The disruption of these odour signals may have wide ranging, yet unquantified, impacts on insects and the important ecosystem services they provide (e.g. pollination and plant pest management), which are critical for the functioning of terrestrial ecosystems. While laboratory-based behavioural studies have demonstrated that air pollution may reduce the foraging efficiency of pollinators and herbivore natural enemies (e.g. predators and parasitoids), to-date there has been limited field-scale validation.

Using eight Free-Air Diesel and Ozone Exposure (FADOE) rings, we investigated the impact of diesel and ozone pollution, individually and in combination, on insect pollination services and natural enemy recruitment. Both pollutants had clear negative effects on insect counts and flower visitation by major pollinator groups, which coincided with decreases in yield metrics of our study plant (Brassica nigra). Numbers of true bugs, beetles and parasitoids, however, tended to increase under some pollution treatments. These results provide evidence of significant negative field-scale effects of air pollution on insect-derived pollination services. The complex nature of pest-natural enemy interactions, however, makes broad field-scale assumptions about natural enemy responses to air pollution difficult, requiring a more mechanistic understanding that targets individual ubiquitous species to maximise pest control.

Revival of the larch budmoth (Zeiraphera griseana) cycles in the European Alps

Authors: Blaser Simon, Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Switzerland

Abstract: The regular cycles of the larch budmoth (LBM) in the European inner alpine valleys are a famous example for cycling population dynamics. Extensive investigations in the middle of the last century have shown that several mechanisms are involved in driving, stabilizing and synchronizing the population cycles across the alpine arch. Mechanisms include regulation by natural enemies, negative feedback of food quality, different performance of caterpillar ecotypes, and dispersal across landscapes.

While, by means of tree ring analyses, the regular LBM outbreaks could be dated back more than thousand years, no mass outbreaks were observed during almost four decades after 1981. Population cycling, however, continued with the same frequency as before, but with lower amplitudes and without visible discoloration of the larch stands. Starting in 2016, in accordance with the previous periodicity, large LBM outbreaks started in the Western Alps of France. They then travelled across the Alps affecting Switzerland in 2017 and 2018. The extent and intensity, however, did not quite reach the levels of the outbreaks in the middle of the last century. It is supposed that this resurrection of outbreaks was brought about by altered winter temperatures affecting egg survival and by improved synchrony of budburst and egg hatching.

Trends in bark beetle outbreaks and sanitation felling of spruce in Switzerland

Authors: Blaser Simon[2], Stroheker Sophie[2], Blaser Simon[3], Bader Martin[1], Elderry Robert M.[2], Queloz Valentin[2] and Brockerhoff Eckehard G.[2], [1]Linnaeus University, [2]Swiss Federal Institute for Forest, Snow and Landscape Research WSL, [3]Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Switzerland

Abstract: The European spruce bark beetle (Ips typographus) represents an ongoing threat to Norway spruce across Europe. In Switzerland, Norway spruce represents the most common tree species covering approximately one quarter of the total forest area. Especially in mountainous regions, this tree species often fulfils important protection functions against natural hazards such as rockfalls or avalanches. Besides forestry losses, bark beetle disturbances can therefore directly influence the security of humans and infrastructure. In order to formulate appropriate management strategies, the understanding of infestation dynamics is crucial. Since 1984, the volume of Norway spruce killed by I. typographus as well as the results from pheromone trap monitoring have been yearly registered for the different forest districts of Switzerland. In our current work, we analyze this dataset for the first time in an in-depth manner, focusing on effects of climate factors (mean temperature, drought, storms, etc.) and comparing the infestation dynamics among the different geographic forest regions. Moreover, we assess the relationship between trap catches and the volume of infested Norway spruce. Our findings present the trends of the infestation dynamics in Switzerland over the last 37 years and provide important information for sustaining the various forest functions in the long run.

Biorational pest management in arable crops using semiochemicals and egg parasitoids

Authors: Blassioli Moraes Maria Carolina[4], Birkett Michael[1], Borges Miguel[3], Fernandes Furtado Michereff Mirian[2] and Alberto Laumann Raúl[2], [1]Biointeractions and Crop Protection Department, Rothamsted Research, United Kingdom, [2]Embrapa Genetic Resources and Biotechnology, Brazil, [3]Laboratório de Semioquímicos, Embrapa Recursos Genéticos e Biotecnologia, Brazil, [4]Semiochemicals Laboratory, Embrapa Genetic Resources and Biotechnology, Brazil

Abstract: During the last 30 years, changes in agricultural systems, such as non-tillage and keeping soil occupied all year-round, have improved crop production significantly. However, they have also provided food in abundance for insects, thus provoking insect outbreaks and increased crop losses. A recent study on stink bugs and their adult parasitoid populations in nine soybean production regions in Brazil showed there was a very low level of parasitoid and predator communities due to overuse of pesticide application. To minimize insecticide application, studies are being conducted to develop more sustainable technologies for pest control. Semiochemicals applied synthetically or naturally, using companion plants that can repel pest or attract natural enemies, are among the critical tools that have been evaluated. Field experiments conducted in Brazil on soybean parcels treated with dispensers releasing the sesquiterpene (E,E)-a-farnesene attracted higher numbers of Platygastridae parasitoids, resulting in higher levels of parasitized stink bugs eggs compared to parasitism levels of non-treated soybean parcels. Another field experiment with maize cultivated with companion plants, such as Cajanus cajan and Napier grass (Pennisetum purpureum), showed that these areas attracted higher numbers of egg parasitoids and Braconidae wasps compared to areas with only maize or maize combined with Crotalária spectabilis. The results of these experiments and the underlying chemical ecology involved will be presented, and possible applications will be discussed.

Sesquipiperitol as stink bugs pheromones' constituent and biosynthesis intermediate

Authors: Blassioli Moraes Maria Carolina[2], Khrimian Ashot[3] and Borges Miguel[1], [1]Laboratório de Semioquímicos, Embrapa Recursos Genéticos e Biotecnologia, Brasilia, Brazil, [2]Semiochemicals Laboratory, Embrapa Genetic Resources and Biotechnology, Brazil, [3]USDA-ARS, NEA, BARC, Invasive Insect Biocontrol and Behavior Laboratory, United States

Abstract: Sesquipiperitol (2,10-bisaboladien-1-ol, or 3-methyl-6-(6-methylhept-5-en-2-yl)cyclohex-2-en-1-ol) is a plant-produced sesquiterpene alcohol, a putative biological role of which in plants is still unknown. This compound can exist in eight stereoisomeric forms, yet absolute configurations of sesquipiperitols occurred in plants remained unidentified. It was reported that (+)-trans-sesquipiperitol occurred in roots of Argyranthemum adauctum spp. jacobaeifolium, and (-)-trans-sesquipiperitol was isolated from the foliage of Fitzroya cupressolides. Two Zingiberaceae plant species, Alpinia densibracteata and Zingiber officinale have also been reported to contain sesquipiperitol of undisclosed stereochemistry. Recently, (1S,6S,7R)-1,10-bisaboladien-1-ol (SSR-sesquipiperitol) had been found for the first time in animals as an intermediate in the harlequin bug, Murgantia histrionica, pheromone biosynthesis.1

We found that two more stink bug species, Tibraca limbativentris and Glyphepomis spinosa, known as rice pests in Brazil, produce sesquipiperitols. In case of the former, sesquipiperitol was shown as a pheromone component but it could possibly serve as a biosynthetic precursor to pheromones of both species. For precise stereochemical identifications of these and other naturally-occurring sesquipiperitols, we synthesized all eight stereoisomers starting from commercially available (S)- and (R)-citronellals. We exploited two synthetic strategies: a rhodium-catalyzed enantioselective addition to carbonyl group, and a Robinson annulation to prepare stereodefined sesquipiperitones. Reductions of each of these ketones (total four) produced two epimeric sesquipiperitols, the stereochemical assignment of which was conducted by preparations of Mosher ester and analyses thereof by NMR.

Use of vibratory signals for stink bugs monitoring and control

Authors: Blassioli Moraes Maria Carolina[3], Laumann Raúl[3], Moreira Dias Aline[4], Cokl Andrej[1], Borges Miguel[2], [1]Department of Organisms and Ecosystems Research National Institut of Biology, Slovenia, [2]Laboratório de Semioquímicos, Embrapa Recursos Genéticos e Biotecnologia, Brasilia, Brazil, [3]Semiochemicals Laboratory, Embrapa Genetic Resources and Biotechnology, Brazil, [4]Zoology Post-Graduation Programme, University of Brasilia, Institute of Biology, Brasília, Brazil

Abstract: Many species of stink bugs, mainly those of Pentatominae and Edessinae, are serious pests in crops such as legumes, grasses, grains, vegetables and fruit and nut trees. Their impact on agriculture has been increased by some invasive species affecting crops around the world. It is necessary develop management strategies for stink bugs based on integrated pest management (IPM) practices with efficient monitoring systems and alternatives for population control. In this way application of knowledge related to sexual communication and vibratory signals may contribute to some birational control alternatives. Applied biotremology offers a strong potential to contribute to reach this goal. The general pattern of reproductive behaviour of stink bugs starts at long range with the emission of aggregation or sexual pheromone by the males. Pheromones triggers emission of the female substrate-borne signals (calling signals) on the plant, at medium range. Female calling signals, transmitted through the plant, provide information on signaler identity and location. The calling phase of reproductive behaviour is followed by the courtship phase, at short range, which is characterized by duetting with courtship song vibratory signals, antennation and butting at close range. It is possible to interfere in stink bug communication at any of these phases. Some recent advances of applied biotremology for stink bugs management will be presented. Attention will be place on three principal areas of applications: 1- the use of vibratory signals in monitoring systems, 2- the disruption of stink bug mating by interference of vibratory communication and 3- applications in biological control.

Effect of green cover management on arthropods predation in Mediterranean vineyards

Authors: Blaya Romane[3], Bischoff Armin[2], Mazzia Christophe[2], Blight Olivier[1] and Ponel Philippe[2], [1]Institut of Mediterranean Biodiversity and Ecology, [2]Mediterranean Institute of marine and terrestrial Biodiversity and Ecology, France, [3]Mediterranean Institute of marine and terrestrial Biodiversity and Ecology, France

Abstract: Green cover has been identified as an alternative management of vineyard soil to improve biodiversity and ecosystem services. We explore here the relationship between vegetation cover and arthropod predation, hypothesising that inter-row vegetation provides habitat and resources for generalist predators, improving pest regulation. We selected 26 vineyards located in south-eastern France with three different green cover managements: tillage, one inter-row of two tilled and complete inter-row vegetated vineyards, and evaluated both ground and canopy predation. In each vineyard, we set 96 for eight hours during the day living sentinel preys (Lucilia sp. larvae), 48 on the ground and 48 in the vine canopy. Larvae were then renewed for an 11 hours night session. Regular visual checking during the day allowed us to identify predators at preys. We found a clear and significant increase in larvae predation from tilled to complete vegetated vineyards. We observed spiders, harvestmen, and beetles but ants were by far the primary predator. They were responsible for more than 75% of larvae predation, with two key species, Camponotus vagus in the vine canopy and Cataglyphis cursor on the ground. These results highlight the underestimate role of ants as generalist predators and their likely role in pest regulation that is directly related to green cover management in vineyards. Therefore, the use of green cover in Mediterranean vineyards promotes predation by generalist arthropods and may be key to provide pest regulation services.

A multi-dimensional quantitative approach to study the evolution of social complexity

Authors: Bloch Guy[1] and Greenbaum Gili[1], [1]The Hebrew University of Jerusalem, Department of Ecology, Evolution and Behavior, Israel

Abstract: The current approach for research on the evolution of insect sociality is based on a qualitative and crude classification and suffers from several limitations: (i) It assumes that social traits always evolve together and in synchrony, which may falsely imply that social evolution always progresses along a single linear stepwise trajectory; (ii) It limits our ability to test the association between the level of sociality and quantitative "omics" molecular, physiological, and behavioral parameters. We are developing a novel approach that is based on quantitative indices for social complexity using bees as a model. As a first step, we compiled a comprehensive database of social traits for 70 species. Next, we performed data-driven statistical analyzes, which account for phylogenetic relations between species. Our approach enables quantification and mapping of sociality in species based on multiple types of data. Our results indicate a spectrum of sociality types in bees, which is wider than appreciated with the classical approach. We identified multiple axes that characterize regions of interest in the multidimensional trait space, suggesting non-trivial relations between different social complexity traits. Moreover, we discovered potential trajectories for social evolution by calculating the molecular evolutionary rate of focal genes.

Cues mediating social entrainment of circadian rhythms in honey bees

Authors: Bloch Guy[1] and Seihler Oliver[1], [1]Department of Ecology, Evolution and Behavior, The Alexander Silberman Institute of Life Sciences, The Hebrew University of Jerusalem, Israel

Abstract: Honey bees (Apis mellifera) show task-related plasticity in circadian rhythms. Forager worker bees have strong circadian rhythms that are necessary for sun-compass orientation and for timing visits to flowers whereas "nurse" bees tend brood around the clock with attenuated or no activity rhythms. Nevertheless, nurses that are removed from the hive, show strong circadian rhythms that are in phase with ambient day-night cycles. These observations indicate that at least some pacemakers in their brain continue to measure time in the constantly dark and tightly thermoregulated nest environment. This premise is supported by immunocytomemistry analyses showing that clock gene protein expression similarly cycle in pacemaker neurons in the brains of foragers with, and nurse without, circadian rhythms in locomotor activity. The nurse clock is entrained by social cues, that can even override photic entrainment, but the nature of these social cues remain elusive. We hypothesize that surrogates of bee activity generate daily oscillations in the nest microenvironment, which in turn, entrain circadian rhythms of other bees to a common colony phase. Here we tested whether direct contact, substrate-borne vibrations, and nest volatiles can entrain circadian rhythms in honey bee workers and can mediate social synchronization. We manipulated the cues passing among bees and used circadian analyses and circular statistics to assess the degree of phase synchronization. We further used our new ICON pipeline to calculate the coupling function between the rhythms of pairs of bees. Our findings show that both direct contact between pairs of individually-isolated bees and activity-induced changes in the common environment can entrain circadian rhythms of young bees. Substrate-borne vibrations and changes in nest volatiles entrain circadian rhythms and can mediate social synchronization of honey bees to a common colony phase. These findings are consistent with a self-organization model for circadian rhythms synchronization in complex social insects colonies composed of dozens thousand individuals.

Side-effect testing of pesticides on beneficial organisms - the IOBC-WPRS approach

Authors: Blümel Sylvia, Austrian Agency for Health and Food Saftey (AGES), Austria

Abstract: Integrated Pest Management combines diverse preventive and curative measures including pesticides to protect plants from pest organisms. These pesticides should not affect natural enemies or antagonists of plant pests and therefore reliable information about their potentially adverse effects on non-target organisms is necessary. In this context, the International Organisation for Biological and Integrated Control, West Palearctic Regional Section (IOBC-WPRS) had started in the 1970ties to develop a sequential pesticide side-effect testing concept to identify pesticides selective for beneficial organisms. Indicator species of beneficial organisms from different taxonomic groups against major pests in important crops were selected and species-specific standardized side-effect testing methods were developed. These methods follow a stepwise approach from a worst-case study in the laboratory with the most sensitive developmental stage of a beneficial exposed to pesticide residues on different substrates, to semi-field tests on plants with all beneficial developmental stages under controlled conditions up to field studies with naturally occurring or released populations of the target organisms. Pesticides are applied at the highest recommended field rate as commercial formulations. Main end- points of the laboratory tests include primary direct (lethal) and indirect (sublethal) effects such as mortality and decreased oviposition. All effects are combined to so-called efficacy values. The efficacy values are classified in four categories from harmless to harmful and were published in IOBC-WPRS Bulletins and in the online database (https://www.iobc-wprs.org/ip_ipm/IOBC_Pesticide_Side_Effect_Database.html). Between 1983 and 2000, nine Joint Testing Programmes with about 200 pesticides for up to 25 different beneficial indicator species were carried out. Over time, the methods partly had to be adapted for pesticides with new mode of actions. When the provision of data about side effects of pesticides on non-target organisms became obligatory for the authorization of pesticides in the EU, a „Joint Initiative for the validation of beneficial arthropod testing" with participants from the European Plant Protection Organisation (EPPO), pesticide industry, contract test laboratories and IOBC-WPRS was established to validate and standardize existing side-effect testing methods (mainly those of IOBC-WPRS) in ring-test groups for 12 relevant indicator species. The first tier tests for assessments of the effects of Plant Protection Products on Non-target Arthropods for regulatory purposes (EEC/91/414, EC 1107/2009) are based on these jointly established side-effect testing methods.

Microbial metabolites as key elements in the life cycle of entomopathogenic nematodes

Authors: Bode Helge, Molecular Biotechnology, Department of Biosciences, Goethe University Frankfurt, Germany

Abstract: Entomopathogenic nematodes of the genera Steinernema and Heterorhabditis live in symbiosis with bacteria of the genera Xenorhabdus and Photorhabdus, respectively. Genome analysis of these bacteria as well as their chemical analysis have revealed the presence of several specialized metabolites and their biosynthetic gene clusters that might be involved in the tripartite interaction of nematode host, bacterial symbionts and insect prey.
The talk will highlight recent methods to obtain and modify these metabolites in order to apply the metabolites themselves or the engineered bacteria in medicine or agriculture.

Spittlebugs in vineyards: influence of plant community characteristics on the abundance of Xylella fastidiosa vectors

Authors: Bodino Nicola, Fogliatto Silvia, Demichelis Stefano, Saladini Matteo, Vidotto Francesco, Ottati Sara and Bosco Domenico

Abstract: The bacterium Xylella fastidiosa (Xf) has been identified in Europe for the first time less than ten years ago. In Southern Italy, a strain of Xf subsp. pauca is the causal agent of the Olive Quick Decline Syndrome (OQDS) on olive, a destructive disease that killed millions of trees and is still spreading. Xylella fastidiosa is also a potential major threat to the European wine sector, as it is known as the causal agent of Pierce's disease of grapevine. Insect vectors of this bacterium, i.e. spittlebugs (Hemiptera: Aphrophoridae), can reach high populations in vineyards, hence the risk of X. fastidiosa outbreaks in wine-producing areas is significant. However, current knowledge on drivers of insect vector presence and abundance in the vineyard agroecosystem is scarce. The aim of this study was to investigate the influence of vegetation community characteristics and management strategy on presence and abundance of spittlebug nymphal and adult stages in the vineyard agroecosystem. A two-year field survey of spittlebug populations was carried out in six vineyards (three organic and three IPM) in North-western Italy. Nymphal samplings were carried out in April, at the time of nymph population peak. Randomly selected sampling units (n = 15, 0.25 m2) were performed in each vineyard. Vegetation characteristics were recorded within each insect sampling unit. Adult stage was sampled by sweeping net in June and September from three vegetation compartments of the vineyard: i) grapevine plants ii) ground cover herbaceous vegetation iii) spontaneous woody plants. All samplings were conservative. Our results show that spittlebug nymph abundance is negatively correlated with i) high values of mean Ellenberg indicator value of nitrogen, ii) high herbaceous cover percentage and iii) high herbaceous biomass. Also, the abundance of Philaenus spumarius (the main European vector of Xf) was negatively influenced by high cover percentage of monocots. Spontaneous woody plants host high numbers of adult spittlebugs (P. spumarius and Aphrophora alni) in summer, and density of P. spumarius adults on grapevine was similar to those observed on the other vegetation compartments – at least in vineyards with high spittlebug population. New insights on associations between plant community characteristics and density level of spittlebugs may pave the way to the design of environmentally-sound strategies to lower vector populations in X. fastidiosa susceptible agroecosystems, e.g. by promoting herbaceous cover not suitable to spittlebug nymphal development or by developing trap cropping systems at the plant community level.

Intergeneric imprinting and the impact of early experience on nest affiliation in hornets

Authors: Bodner Levona, Israel

Abstract: Social insects spend the first couple of days following eclosion inside their nests. During this time, they incorporate the odor signature (i.e., the cuticular hydrocarbon template) of their nest and nest members, and are practically being “imprinted” on their colony. We examined the potential plasticity of colony imprinting in the Oriental hornet (Vespa orientalis) by transferring newly-emerged hornets onto larvae-containing combs of German wasps (Vespula germanica). The hornets nursed the foster brood and exhibited the regular set of social behaviors in the heterospecific colony, including trophallactic interactions with their adult foster sisters. This result prompted us to investigate the impact of early exposure on nest imprinting in both behavioral and chemical levels. We tested the hornets' comb preferences in a T-maze and analyzed their cuticular hydrocarbon profiles, following one week in a foster German wasp colony, and compared both results with a control group (i.e., their biological sisters that were reared in their biological colony). We found that hornets from the foster colony showed stronger affiliation to the foster (German) nest, while exhibiting a chemical profile that resembled their biological sisters' and differed from that of their foster sisters. Our results exemplify the effect of early environmental and social exposure on nest affiliation, as well as the potential plasticity of recognition and colony imprinting in social insects.

Population dynamics of winter moth in the northeastern United States before and after the establishment of the parasitoid Cyzenis albicans.

Authors: Boettner George[2] and Broadley Hannah[1], [1]Department of Environmental Conservation, University of Massachusetts, Amherst MA & USDA APHIS Plant Protection and Quarantine, Science and Technology, United States, [2]University of Massachusetts, United States

Abstract: Winter moth, Operophtera brumata L. has recently invaded the northeastern United States and caused widespread defoliation. We embarked on a 14 year project to collect life table data which involved estimating densities of different winter moth life stages at multiple research plots on two different tree species.. We also began introduction of the tachinid parasitoid, Cyzenis albicans, which has controlled winter moth at other locations in North America. An analysis of 14 years of life table data collected from outbreak populations of this species has revealed that populations are regulated by direct density-dependent mortality primarily in the larval stage. This mortality is mainly due to density dependent dispersal of larvae. Mortality of pupae in outbreak populations is not density-dependent. These dynamics contrast strongly with classic analyses of low-density populations of this insect. Introductions of the parasitoid Cyzenis albicans have resulted in successful establishment at several locations and sharp reductions in winter moth density at multiple locations. Once winter moth populations decline, mortality of pupae becomes density dependent, as it has in multiple previous studies.

Sawflies containing toxic peptides

Authors: Boevé Jean-Luc[1] and Rozenberg Raoul[2], [1]Royal Belgian Institute of Natural Sciences, Belgium, [2]Universite´ Catholique de Louvain, Belgium

Abstract: From the 1970’s, toxic peptides were detected and identified in the larvae of some Argidae (genus Arge) and Pergidae (Lophyrotoma, Perreyia) sawfly species (Hymenoptera: Symphyta). They caused the death of livestock in Australia, Denmark and South American countries. The chemicals were studied, here, to elucidate their involvement in ecology, evolution, physiology and behavior of the sawflies. Liquid chromatography–tandem mass spectrometry of extracts from single larvae revealed that the peptides occur commonly in the two sawfly families. A phylogenetic approach pointed to evidence that the peptides may have driven the evolution of these sawflies by allowing frequent “defense shifts”, that is, switches between cryptic and conspicuous appearances, and levels of gregariousness. The toxic peptides proved to vary in quality and quantity across species, and in quantity across populations. Such results led to canceling the use of a pergid (Heteroperreyia hubrichi) as a biocontrol agent of an invasive weed. In Arge berberidis the chemicals were detected not only at larval stage but also in the prepupal and adult stages. By isolating organs from larvae of Lophyrotoma zonalis and Arge pagana, the chemicals were detected mainly in the hemolymph and integument, and little or none in the digestive tube. Finally, bioassays revealed that Pergidae and especially Arge larvae are well defended against ants, with ant responses determined by the body size and behavior of the larva such as raising the abdomen. Thus, combined with other antipredator defense mechanisms, the toxic peptides seem to constitute an essential element in the biology and ecology of Argidae and Pergidae sawflies.

Are non-native mud dauber wasps (Hymenoptera: Sphecidae) dangerous for people and for their native European relatives?

Authors: Bogusch Petr, University of Hradec Kralove, Faculty of Science, Department of Biology, Czech Republic

Abstract: Three non-native species of the family Sphecidae have been recorded in various parts of Europe. In particular, Sceliphron curvatum has spreaded to many parts of the continent. Studies have investigated their potential threats to other hymenopterans and also to people. S. curvatum originates from India and surrounding countries and was first reported from Europe in 1979, with a record from south Austria. Recently it has been recorded in most of the continent except the northernmost parts and it has also been recorded in other parts of the world (Mexico, Argentina). The presence of this species is not welcomed by humans because it places its nests mainly inside buildings. The nests can make a mess in rooms and people may be fearful, especially of the insects’ provisions of paralyzed spiders. However, S. curvatum does not represent an important danger as the nests are usually placed on or in unused matter (paper boxes, old clothes, books, behind pictures or furniture) and the species is not aggressive. The specific nesting habits can help this species to spread very fast in various parts of the world, but it does not compete well with other species, which place their nests differently. Sceliphron caementarium and Chalybion californicum have their origins in North and Central America and they place their nests mainly on the surface of buildings, while the latter usually uses old nests of Sceliphron species and re-builds them for its own nesting purposes. They nest similarly to the native Sceliphron destillatorium. In several regions of South Europe (especially coastal regions of Slovenia, Croatia and Italy), S. caementarium is very numerous and has forced out the native S. destillatorium, which has become very rare or has locally disappeared. The second species, C. californicum is rare and its presence probably does not harm native species. Since these species negatively influence people (in the case of S. curvatum) or native species (S. caementarium) they must be considered to be invasive.

What are the main pollinators of almond trees and is the role of native solitary bees important?

Authors: Bogusch Petr[3], Hlavackova Lucie[3], Alins Georgina[2] and Bosch Jordi[1], [1]CREAF, Barcelona, Spain, [2]IRTA Fruitcentre, PCiTAL, Park of Gardeny, Fruitcentre Building, Lieida, Spain, [3]University of Hradec Kralove, Faculty of Science, Department of Biology, Czech Republic

Abstract: Almonds are fruit trees, which are planted in south Europe in high numbers. The production is highly dependent on the effectivity of the pollination done especially by various species of bees. We have studied the insects present on flowers of almond trees in 12 orchards in the vicinity of the town Lleida in NE Spain in March 2019, when the trees were in flower. In each orchard, one person was capturing and observing all visible bees on the flowers. Additionally, we have captured other bees present in the orchard. The numbers of species recorded and dominances differed among the orchards, as well as the total number of specimens recorded. The honeybee (Apis mellifera) was most numerous in all orchards except those, where nesting blocks with horned mason bees (Osmia cornuta) were installed and this bee species was most numerous. We have recorded additional 15 species of bees and two species of hoverflies pollinating almond flowers, of which only Andrena nigroaenea was quite numerous. Capturing the bees in the surroundings of the trees, we have recorded that most of the wild bees occurring in almond orchards do not pollinate almond trees or only males sporadically gather nectar on the flowers. Most of the species were recorded on plants of the family Brassicaceae, which were numerous in herb layer. Almond trees are then dependent on mason bees and the honeybee and keeping these species in the orchard is very important for good pollination. The presence of species-rich communities of wild bees are not necessary for almond pollination but the bees are important for the biodiversity and natural character of the landscape in the vicinity of the orchard.

High doses of the attractant indole repel mosquitoes

Authors: Bohbot Jonathan[1], Dekel Amir[1], Ruel David[1] and Yakir Esther[1], [1]Department of Entomology, The Hebrew University of Jerusalem, Israel

Abstract: N,N-Diethyl-meta-toluamide (DEET) is an effective mosquito repellent used for personal protection. However, this synthetic compound suffers from a several disadvantages, including plasticizing effects, oily feel and low user acceptability. More significantly, DEET exhibits a limited range of action due to its low volatility. New repellents with higher volatility and longer range of action are therefore desirable. Based on its chemical structure and known modulatory effects on odorant receptor (OR) function, we have hypothesized that indole may act as an OR modulator. We show that high indole concentrations not only inhibits OR function, but also elicit avoidance behavior in mosquitoes. These findings confirm that a structure-activity approach can lead to the discovery of potential mosquito repellents. In this study, using indole as a mosquito repellent may offer greater volatility and spatial repellence than DEET.

Seeing a Lot With a Little: Visual specialization in the miniaturized eyes of thrips (Thysanoptera)

Authors: Bok Michael[2] and López Reyes Karla[1], [1]Lincoln University, [2]Lund University, United Kingdom

Abstract: Thrips (Thysanoptera) are an order of tiny, yet economically important insects. Several species are major agricultural pests, including Frankliniella occidentalis, the Western Flower Thrips (WFT), which causes severe economic impacts. There has been extensive research testing the response of WFT to visual cues to improve lures for pest management strategies. However, little is known about the fundamental aspects of WFT visual systems. Here we present data about the structure, optics, and visual genes present in WFT eyes. Despite possessing a mere 60 ommatidia in each eye, WFT display a tremendous degree of regionalised retinal specialization. They express five visual opsins, have putative spectral filters in a mosaic of enlarged ventral ommatidia, and display anatomical specialization in dorsal rhabdoms that may be analogous to a dorsal rim, which is used for orientation using celestial polarization patterns in many flying insects. Furthermore, we use 3D synchrotron µCT reconstructions of WFT eyes to model their visual system in simulated light environments. Using this approach, we can combine information about regionalized spatial, color, and polarization sensitivity in order to inform the design of improved trapping strategies utilizing visual lures that will be increasingly salient and attractive to WFT in agricultural settings.

Selection of natural enemies for augmentative biological control: sense and nonsense of ecological selection criteria

Authors: Bolckmans Karel[2] and Wackers Felix[1], [1]Biobest Group NV, Belgium, [2]Biobestgroup

Abstract: The selection of natural enemies species for augmentative biological control is based on answering three basic questions: 1. is the natural enemy able to significantly contribute to managing the population of the target pest in the target crop?; 2. are there any undesired side-effects on the crop, or on other natural enemies that are used in the same crop, or, in the case of non-native species, are significant effects on non-target species expected?; 3. can the natural enemy be economically mass-reared?

Insect ecology is the scientific study of how insects, individually or as a community, interact with the surrounding biotic and abiotic environment or ecosystem. Based on natural enemy species that are either successfully used in augmentative biological control programs and species that did not make it through the screening process, we will discuss the sense and nonsense of different ecological selection criteria.

Insight in ecology also informs how to optimally deploy specific species or combinations of species of natural enemies in crop specific biocontrol-based IPM programs.

The How and Why of insect air flows

Authors: Bomphrey Richard, Royal Veterinary College, United Kingdom

Abstract: Traditionally there have been substantial practical challenges in recording insect wing kinematics, describing aerodynamic force generation and understanding how insects monitor their own state within the physical environment. More recently, a suite of genetic, videography and computational methods have been used to explain the elusive links between form and function. I will describe how some of these innovations have opened new research avenues in fundamental aerodynamics, functional ecology and robotics.

Exploring the link between viral integrations and the piRNA pathway in Aedes mosquitoes

Authors: Bonizzoni Mariangela[1], Crava Cristina[2], Pischedda Elisa[1], Marconcini Michele[1] and Palatini Umberto[1], [1]Department of Biology and Biotechnology, University of Pavia, Italy, [2]Universitat de València, Spain

Abstract: Arthropod-borne viruses such Dengue, Zika and Chikungunya are (re)-emerging public health threats. Despite having different genome structures and replication strategies, these viruses are all nonretroviral RNA viruses, thus they lack reverse transcriptase and integrase and complete their life cycle in the cytoplasm of their host cells. Arboviruses belong to large viral families which include additional viruses able to replicate exclusively in insect cells and are thus called Insect-Specific Viruses (ISVs).

Unexpectedly, we, and others, detected hundreds of ISV sequences integrated into the genome of the main arboviral vectors, Aedes spp. mosquitoes. These Nonretroviral Integrated RNA virus Sequences (NIRVS) are enriched in piRNA clusters and produce piRNAs. This observation and the physical contiguity between NIRVSs and transposable elements (TEs) in piRNA clusters, led to the hypothesis that NIRVSs contribute to mosquito immunity through piRNA-targeted processing of cognate viruses and are adaptive.

If NIRVSs behave like TE fragments of piRNA clusters, their distribution within mosquito genomes should diversify according to previous pathogen encounters. Alternatively, viral integrations may represent ancient viral relicts, among which only few may have been co-opted for antiviral functions.

We developed a computational approach to probe the genome of wild-collected mosquitoes and test for differences in the landscape of viral integrations in and outside piRNA clusters. We also applied computational and molecular approaches to probe the evolution of viral integrations in field mosquitoes and their activity after viral integration. We identified novel viral integrations in the genomes of both Aedes aegypti and Aedes albopictus wild-collected mosquitoes. We also showed that a limited number of viral integrations are adaptive and produce piRNAs following arboviral infection. Overall our results indicate that like TEs, not all viral integrations are the same, and they are organized through a redundant system that influence mosquito response to arboviruses, primarily through the piRNA pathway.

Safety Education is Critical for Grain Fumigation

Authors: Bonjour Edmond[1] and Jones Carol[1], [1]Oklahoma State University, Stillwater, Oklahoma, United States

Abstract: Fumigation is an important part of an integrated pest management strategy for keeping stored grain in good condition. The stored grain environment may cause concern for the safety of fumigant applicators who need to enter the structure because of unsafe atmospheric conditions, possible grain entrapment, and the use of a potentially dangerous insecticide. Instructions and equipment for testing the atmosphere, knowledge about how entrapment occurs and how to avoid it, and safety precautions for using a severely toxic insecticide will be discussed. Atmosphere and phosphine monitors needed to test the air and keep applicators aware of the amount of fumigant in the area are needed for all fumigations. Being aware of the condition of the grain in storage and knowing whether any grain has been previously removed are important aspects to help prevent entrapment from occurring. Many steps must be taken and included in a fumigation management plan to keep applicators and workers safe from exposure to toxic insecticides. Education of applicators and employees is essential to keep everyone safe.

Historical plant flows predict current insect invasions

Authors: Bonnamour Aymeric, University of Lausanne, Switzerland

Abstract: Thousands of insect species have been introduced outside of their native range, causing important damage on ecosystems and human societies. Many insects are tightly associated with plants as they feed or live on plants. Consequently, the plant trade is one of the main pathways of alien insect introductions. Alien plants also facilitate the establishment and spread of alien insects, in particular of those that use these plants as hosts. Here, we tested the hypothesis that plant invasions precede insect invasions. If such time lag exists, recent plant invasions might be useful to predict future insect invasions.

We tested the predictive power of historical and current alien plant flows and of potentially confounding socioeconomic drivers on alien insect invasions. We found that alien insect flows were best explained by alien plant flows of 1900. We then used the observed time lag between plant and insect invasions to estimate the insect “invasion debt”. Based on recent plant flows, we found that alien insect invasions are expected to increase in Asia, Africa and South America.

Evolution of novel receptors and peripheral inputs in the olfactory system

Authors: Bontonou Gwénaëlle[1], Arguello Roman[3], Baticle Tess[1], Auer Thomas[1], Álvarez-Ocaña Raquel[1], Cruchet Steeve[1] and Benton Richard[2], [1]University of Lausanne, [2]University of Lausanne, Center for Integrative Genomics, Switzerland, [3]University of Lausanne, Switzerland

Abstract: Chemoreceptor gene families are characterized by extensive between-species copy number changes, but how these genomic changes relate to modifications in the neural circuitry in which they are expressed remains mysterious. Drosophila's Odorant receptor (Or) family is particularly useful for addressing this question because most Ors are expressed uniquely in single olfactory sensory neuron (OSN) types. Between-species changes in Or copy number, therefore, may indicate OSN diversification or reduction. We focus on a rapidly duplicated/deleted subfamily (named Or67a) in the D. melanogaster species group. Genomic analyses have uncovered a dynamic recent history involving many parallel receptor gains and losses, likely related to an increased mutation rate promoted by repeat-rich sequences surrounding Or67a genes. Physiology, expression, and molecular evolutionary analyses have revealed a previously unappreciated adaptive mechanism involving Or co-expression. These experiments have also identified an evolutionary "birth" of a young OSN population. Together, our Or67a results shed light on the early steps of olfactory system evolution and the intriguing relationship between chemoreceptor family turnover and sensory neuron diversification.

Strepsipteran Parasitism of White Leafhopper, Cofana spectra (Distant) in Lowland Rice Fields

Authors: Boonsa-nga Kunlayaa[1], Kunawong Chattraporn[1] and Jaikeang Unchalee[1], [1]Chiang Rai Rice Research Center, Division of Rice Research and Development, Rice Department, Thailand

Abstract: White leafhopper, Cofana spectra (Distant) (Hemiptera: Cicadellidae) is considered as a minor insect pest of rice in Thailand. Nymph and adult of White Leafhopper suck the sap in rice plants resulting in tiller reduction, stunting and yellowing from leaf tip downwards. Severe damage finally causes rice death. Recently, the survey of insect pest of rice in the North revealed important information that White leafhopper was found abundantly in the light traps, rice fields particularly those nearby the lights, and wheat fields. Concurrently, Halictophagus spectrus Yang (Strepsiptera: Halictophagidae) was also found as an endoparasitoid of the White leafhopper. Although Strepsiptera has been recorded as possible biocontrol agents, there was no information on the effective use of H. spectrus as the endoparasitoid for controlling White leaf hopper. The objective of this study was to investigate the population dynamic of White leafhopper and it's relative number infected by H. spectrus in the fields at Chiang Rai Rice Research Center from February 2017 to February 2018. Sampling and monitoring in the rice fields were conducted on a weekly basis by sweeping net. During the study, two peaks of White Leafhopper population were recorded i.e April-June and October-December. The highest percentage of stylopization of the White leafhopper by H. spectrus being 34.6 % was recorded in June 2017. The result indicated that the effect of parasitization by H. spectrus may be one of the factors suppressing the population levels of White leafhopper in the rice field. However, indepth study should be carried out further to gather information adequately for developing efficient biological control of White leafhopper by the endoparasitoid H. spectrus.

Solving the taxonomy of dacine fruit fly larvae (Diptera: Tephritidae) with the help of morphology and adult morphometrics

Authors: Boontop Yuvarin, Plant Protection Research and Development Office, Department of Agriculture, Bangkok, Thailand

Abstract: The tribe Dacini includes some of world's prime economic and quarantine pests. Larvae infest fruit and vegetables, causing serious production losses and widespread, phytosanitary barriers to global trade. Larval stages are most commonly encountered by regulatory officials certifying exports or performing quarantine inspections of imported goods, but these stages are notoriously difficult to identify using morphological characteristics. In this study, dacine fruit flies were surveyed in diverse, fruit orchards throughout Thailand. Adults were collected by lure trapping; larvae were collected for morphological study and rearing. Larvae of six species (all major pests) were re-described from reliably associated material: Bactrocera correcta, B. dorsalis, B latifrons, B. umbrosa, Zeugodacus cucurbitae and Z. tau. A dichotomous key was prepared to enable rapid identification of third instar larvae by using a combination of morphological features. Wing morphometrics were studied in these species and an additional four: B. carambolae, B. cilifera, B. tuberculata and B. zonata. Centroid sizes (calculated from xx wing metrics) differed significantly among sampled species ($P > 0.05$), with B. latifrons smallest (5.533 ± 0.401 mm) and B. tuberculata largest (6.377 ± 0.306 mm). Canonical variate analysis of the dataset revealed a clear pattern in which species of Zeugodacus clustered together and separated from the cluster comprising species of Bactrocera. This study provides a basis for ongoing molecular analysis to clarify the distinction among species and establish criteria for confirmatory, molecular diagnosis of larvae.

Pheromone-based products for the monitoring and management of tomato leafminer (Tuta absoluta) on tomatoes

Authors: Booysen Petrus Johannes Gerhardus[1], Schlemmer Marie-Louise[1], van Tonder Aletta Johanna[1], Liebenberg Jessica[1], Schlemmer Marie-Louise[1] and M Steyn Vernon[1], [1]Insect Science (Pty) Ltd, South Africa

Abstract: The tomato leafminer, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) is an economically important pest of tomato (Solanum esculentum L.), potato (Solanum tuberosum L.) and various other solanaceous crops. If not controlled in tomatoes, T. absoluta can cause severe crop damage leading to losses of up to 80 - 100%. With international markets enforcing lower chemical residues and increased resistance to various insecticides, the need for more sustainable management of T. absoluta is critical. Monitoring of T. absoluta is essential to enable growers to detect its presence and population growth to ensure timely management interventions. The Insect Science (Pty) Ltd pheromone lure (T.A. PheroLure®), loaded with T. absoluta female sex pheromone, was developed to monitor T. absoluta in South Africa. T.A. PheroLure® caught a mean of 53 moths/trap/week over six weeks in five trials located throughout South Africa and can therefore be used for effective monitoring of tomato leafminer. Two pheromone-based control products (attract-and-kill and mass trapping) were developed for the management of T. absoluta. The Insect Science (Pty) Ltd attract-and-kill product (Last Call™ T.A.) at 2000 droplets/ha effectively controlled (reduced by > 80%) T. absoluta moths for three weeks and suppressed (reduced by > 60%) T. absoluta moths for five weeks compared to a standard insecticide programme. Last Call™ T.A. at 4000 droplets/ha extended control of T. absoluta with one week. No fruit damage occurred for eight weeks in both the 2000 and 4000 droplets/ha treatment blocks. The Insect Science (Pty) Ltd mass trapping product (TrapAll™ T.A.) at 30 water traps/ha effectively suppressed tomato leafminer over a period of six weeks. Both Last Call™ T.A. and TrapAll™ T.A. can be used effectively in an integrated pest management programme to manage tomato leafminer in tomatoes.

Elucidating the mechanisms of aphid resistance in Triticum monococcum L. (Poaceae)

Authors: Borg Alexander, Rothamsted Research, United Kingdom

Abstract: The aim of this study is to characterise the antibiotic mechanisms underlying aphid resistance in T. monococcum MDR049, focusing on its secondary metabolites (SMs). Two hypotheses were tested: (i) induction of aphid resistance in MDR049 is aphid density-dependent and (ii) aphid resistance mechanisms are systematically induced upon aphid feeding.

MDR049 leaf extracts were antibiotic against S. avenae after 24hrs and 48hrs, reducing adult survival and number of nymphs. MDR049 has a threshold of 5 aphids to induce a significant antibiotic activity at the aphid feeding site. This activity is reversed at the same leaf as the feeding site and not affected at a different leaf of the feeding site. LCMS analysis shows MDR049 leaf SMs change in trends compared to Solstice with increasing aphid density with signs of a systemic reaction to aphid feeding in MDR049, confined to the same leaf as the feeding site. Bioassay guided fractionation has identified peaks potentially responsible for the antibiotic activity observed in MDR049.

In conclusion, SM changes in MDR049 are aphid-density dependent and may be related to its aphid resistance mechanisms. MDR049 shows signs of a systematic response to aphid feeding. The SMs potentially responsible for this aphid antibiotic activity have been isolated.

Migration pattern of diurnal Lepidoptera populations under a rural-to-urban gradient

Authors: Borges da Silva Elsa[1] and Ramos Ana Paula[2], [1]Forest Research Centre, Instituto Superior de Agronomia, Universidade de Lisboa, [2]Laboratório de Patologia Vegetal “Veríssimo de Almeida”, Instituto Superior de A

Abstract: The influence of the urban gradient on the abundance and richness of diurnal Lepidoptera was studied in three sites located in the perimeter of the School of Agriculture of Lisbon (rural area) and in a public garden (urban garden) in Lisbon, from spring to fall of 2018. The objectives were: 1) evaluate the impact of human activity (frequency of people and vehicles) on lepidopteran abundance and richness populations and the pattern of migration; 2) relate the abundance and richness of Lepidoptera with the floristic composition.

The results show the existence of an inversely proportional significant relationship between the abundance and richness of Lepidoptera and human presence, following a rural-to-urban gradient, depending also on the species. A seasonal pattern of abundance and richness of Lepidoptera population’s species was also observed with the increase in the urban garden suggesting the establishment of a migration pattern under a rural-to-urban gradient. The migration from the rural to the urban area, together with the existence of small private gardens with abundant flowering plant species in the interstices between these two zones, thus constitutes a green corridor, which acts like a food repository and/or shelter for Lepidoptera at the urban area of Lisbon.

Host-seeking behavior of ticks toward resistant and susceptible animals: identification of repellent compounds and their use for tick control

Authors: Borges Ligia, Federal University of Goias, Brazil

Abstract: We are working on tick-host interactions with a goal to identify behavior-modifying compounds that can be used for tick control. Two breeds of dogs, English cocker spaniel and beagle, were compared for susceptibility to the tick Rhipicephalus sanguineus sensu lato. Beagles were found to have lower tick infestation than cockers due the production of two repellents, benzaldehyde and 2-hexanone. Slow-release formulations containing those repellents reduced the number of R. sanguineus on dogs. We further examined the odor profiles of three dog breeds: beagles, cockers, and the miniature pinschers (putative resistant). The mean amounts of benzaldehyde and 2-hexanone were similar for beagles and miniature pinschers and higher than that observed for cockers. Furthermore, 6-methyl-5-hepten-2-one was significantly higher in miniature pinschers than for the other breeds and repelled R. sanguineus in a bioassay. Those results support the hypothesis that miniature pinschers are a tick-resistant dog breed. We also tested and compared semiochemicals produced by horses (susceptible) and donkeys (resistant). One compound, (E)-2-octenal, was detected exclusively in donkey extracts, displaying repellency against Amblyomma sculptum. (E)-2-octenal slow-release formulations were found to reduce A. sculptum numbers in humans in a naturally infested field. This volatile also repelled Rhipicephalus microplus Amblyomma dubitatum and Lutzomyia longipalpis.

Staying in the club: Exploring criteria governing metacommunity membership for obligate symbionts under host–symbiont feedback

Authors: Borges Renee[1], Venkateswaran Vignesh, [1]Centre for Ecological Sciences, Indian Institute of Science, India

Abstract: Metacommunity membership is influenced by habitat availability and trophic requirements. However, for symbiont metacommunities consisting of herbivores and their predators, symbiont-host interactions can curtail membership criteria in novel ways. Understanding such host–symbiont feedback effects on symbiont community membership is crucial for understanding symbiont community structure and function.

We investigate symbiont community colonizing host inflorescences during specific host developmental stages. By modelling Inflorescences as habitat microcosms and accounting for the various symbiont-host we demonstrate two factors uniquely constraining symbiont membership criteria. 1) Host–mutualistic symbiont feedback ensured that no other symbiont had higher persistence than the mutualists, thereby constraining membership for non-mutualists. 2) Larger symbiont colonization windows, in part driven by host inflorescence development, increased overall colonization success and symbiont persistence. We also determine that predators required a larger number of hosts than that of their prey for persistence in the community with valuable implications for top–down predator-aided symbiont community stability. Our study clearly demonstrates that factors influencing symbiont community membership can be fundamentally different from those of non-symbiont metacommunities owing to host–symbiont feedback effects and impacts on host microcosm development and these constraints governing symbiont community membership, function and structure require special attention. Finally, through my talk, I will justify the utility of natural insect microcosms to test theories in metacommunity ecology.

Releases of native and exotic natural enemies to control main apple pests

Authors: Borowiec Nicolas[1], Hance Thierry[2], [1]INRAE Sophia-Antipolis, France, [2]UCLouvain, Belgium

Abstract: Research in agricultural entomology must face the challenge of radically reducing the use of pesticides in the coming years. Different alternative techniques to pesticides are already in use, but a combination of methods is often required to achieve sufficient reductions in pest population levels. The releases of natural enemies in the frame of biological control is one of these techniques. In order to control the two main pests in apple orchards, the rosy apple aphid Dysaphis plantaginea (RAA) and the codling moth Cydia pomonella, we tested three different strategies: (i) the releases of the exotic parasitoid Mastrus ridens for its permanent establishment, (ii) the inundative releases of the native predator Forficula auricularia and (iii) the inundative releases of the native parasitoids Aphidius matricariae and Ephedrus cerasicola.

The first releases of Mastrus ridens in Europe were done during summer 2019. A total of 6 900 M. ridens were released in 23 sites from North-West to South-East France. Since post-release surveys will be done next summer, the success of establishment of the parasitoid is still unknown. However, progeny of released M. ridens have been already sampled in some sites in South-East France.

We performed earwig releases in spring and then follow RAA infestation as well as potential sides effects on other beneficials arthropods. This predator appeared to be very efficient at the colony level but failed to control aphid population at the tree scale.

When the release of aphid parasitoids was carried out at a low density of aphids, an effective control of the density of aphid populations is observed, that is similar to the level of control obtained when spraying chemical products authorized in organic farming. However, if the release was done at a high density level of aphids, the parasitoid failed to reduce the density of the pest. The implementation of this technique in the field needs nevertheless to be improved particularly with regard to the significant costs associated with it.

The intercompatibility of these three techniques in experimental orchards and the feasibility of their combined use in commercial orchards will be discussed.

Does acquisition of resistance to entomopathogenic virus influence the outcome of a host-parasitoid interaction? A case-study with the codling moth Cydia pomonella and its parasitoid Mastrus ridens.

Authors: Borowiec Nicolas[4], Moiroux Joffrey[1], Perrin Marie[2], Dib Hazem[3] and Delattre Thomas[3], [1]Avignon University, France, [2]Avignon University, France, [3]INRA, PSH Unit, Team Biological Control by Conservation, Avignon, France, [4]INRAE Sophia-Antipolis, France

Abstract: A wide range of tools is used for pest control, such as pesticides, pheromones, microorganisms or natural enemies. Repeated application of a method may result in the acquisition of resistance to this method, as commonly observed in the rapid appearance of resistance to insecticides in pest insects. Such acquisition of resistance to a given method may however be traded-off against, or, on the contrary, increase resistance to another control agent. The codling moth Cydia pomonella is a worldwide-distributed species which causes major losses in orchards. Among pest control methods, Cydia pomonella granulovirus (CpGV) has been successfully used for 15 years as a bioinsecticide until some insect populations with low susceptibility to the virus were detected for the first time in 2004 in southeast France. More recently, in 2019, the parasitoid Mastrus ridens was released in experimental fields to study its efficiency to control the codling moth in France. In this study, we compared in the lab a Cydia pomonella sensitive and resistant line with the CpGV to investigate how acquisition of resistance to this entomopathogenic virus shaped life history traits of this pest species, and how it influenced its resistance to chemical and biological insecticides and to the newly introduced parasitoid Mastrus ridens. Implications for pest management will be discussed.

Ants do drugs to fight disease

Authors: Bos Nick[1], Freitak Dalial[2] and Sundström Lotta[3], [1]University of Copenhagen, Denmark, [2]University of Graz, Austria, [3]University of Helsinki, Finland

Abstract: Defence against pathogens and parasites is extremely important for organisms in order to maintain their fitness. Immune responses can take on many forms, which can be divided between behavioural and physiological responses. One of these behavioural responses is self-medication, which occurs when an organism consumes or contacts biologically active compounds in order to clear or inhibit the infection. Here, we show that upon exposure to a fungal pathogen, ants (Formica fusca) change their diet preference to include Reactive Oxygen Species (ROS). This leads to higher resistance against fungal infection. Furthermore, we show that only infected ants benefit from feeding on ROS, as when healthy ants feed on the same diet, they show increased mortality. Thus, by showing a cost of medication in the absence of pathogens, we rule out the possibility of compensatory diet choice, and provide conclusive evidence for the first time, that ants engage in therapeutic self-medication.

Where do all the fungi go?

Authors: Bos Nick[1], Thomas-Poulsen Michael[1], Guimeraes Leandro[1], Kone N'golo[2], Palenzuela Romen[1] and Silue Simon[2], [1]University of Copenhagen, Denmark, [2]Nangui Abrogoua University, Ivory Coast

Abstract: Fungus-growing termite colonies are rarely infected by antagonistic fungi, and their fungus gardens are essentially free of other fungi with 99% of amplicon reads belonging to their Termitomyces symbiont. However, foraging for food is expected to open the way for antagonistic fungi to enter the nest and exploit the termites' fungal crop, raising the question as to how the termites achieve such a sterile environment while raising their monoculture.

Several potential barriers to diseases entering the nest have been suggested. First, as termites normally forage underneath self-built soil sheets, they could sterilize the foraging substrate they are foraging on. Furthermore, any returned food could potentially be sterilized by the workers through a gut passage. This is a feature unique to the fungus-growing termites, where all food first passes through their gut, before being deposited by defecation on the fungus comb.

To test these two potential barriers, we first analysed the diversity of fungi growing in termite foraging sites. To test whether fungal diversity in the foraged material decreases during the gut passage, we dissected worker guts and divided them into three compartments, and used a culture-based approach to identify fungal genera present in each of the compartments.

Foraging material did not appear sterilized, and fungal diversity did not decrease during gut passage. We therefore conclude that any sterilization of substrate is likely to happen after it has been deposited on the fungus comb, likely through an interplay between defences originating from the termites as well as those from the crop itself.

Gene tree symmetry in the age of genomics– a case study on Nomiinae

Authors: Bossert Silas[1], Danforth Bryan[2] and Brady Sean[3], [1]Cornell University Smithsonian National Museum of Natural History, United States, [2]Cornell University, United States, [3]National Museum of Natural History, United States

Abstract: Modern gene tree approaches that aim to solve notoriously difficult nodes of large-scale phylogenies suffer from uninformative genes and poorly resolved gene trees. The resulting gene tree estimation error, coined the 'Achilles' heel' of coalescent methods, can substantially distort the process of finding the true species tree. I present research on establishing a metric to identify suitable and less suitable loci, and provide first-hand suggestions to improve gene tree-based phylogenetic reconstruction of species trees.

The control of Tuta absoluta tomato leafminer in the region of Mostaganem (Algeria).

Authors: Boualem Malika[1], Ghelamallah Amine[1], Krache Farial[1], [1]University Abdelamid Ibn Badis of Mostaganem, Algeria

Abstract: Since 2008, the tomato leafminer Tuta absoluta (Meyrick, 1917) (Lepidoptera: Gelechiidae) has been considered in the Mediterranean basin and Algeria as a serious threat to greenhouse and field tomato production. This microlepidoptera attacks all the phenological stages of the crop and causes significant damage to leaves, stems and fruits, its damage can reach 100% losses. A number of research has been carried out to develop control strategies that can help mitigate the extent of this pest on glasshouse tomatoes in the Mostaganem region. Two plants (Urtica membranacea Poir.) and (Juniperus oxycedrus L.) have been used as bioinsecticides for their richness in bioactive substances (essential oil, aqueous and hydroalcoholic extracts). A biological control based on the use of predatory or parasitoid auxiliaries with the enhancement of the species of auxiliary insects identified as such under the bioclimatic conditions of the study area. The combination of all these regulatory factors has made it possible to control this pest to an interesting degree.

The Multi Target Method (MTM) for the control of stable, horse and tsetse flies in the FlyScreen project

Authors: Bouhsira Emilie[9], Lienard Emmanuel[9], Salou Ernest[2], Gimonneau Geoffrey[3], Rayaisse Jean-Baptiste[2], Ouma Johnson[1], Thaisungnoen Kornkanok[7], Desquesnes Marc[6], Franc Michel[9], Jacquiet Philippe[9], Chalermwong Piangjai[7], Guillet Pierre[1], Masmeatathip Roungthip[5], Jittapalapong Sathaporn[8], Onju Sathaporn[7], Shukri Sharif[9], Shah Viral[1] and Grimaud Yannick[4], [1]AtoZ Textile mills l.t.d., Arusha, Tanzania, [2]CIRDES, Bobo-Dioulasso, Burkina Faso, [3]CIRDES/CIRAD, UMR InterTryp, Bobo-Dioulasso, Burkina Faso, [4]GDS, La Reunion Island, Réunion, [5]Kasetsart University, Department of Entomology, Faculty of Agriculture, Kamphaeng Saen, Thailand, [6]Kasetsart University, Faculty of Veterinary Medicine, Bangkok CIRAD, UMR InterTryp, Bangkok, Thailand, [7]Kasetsart University, Faculty of Veterinary Medicine, Bangkok, Thailand, [8]Kasetsart University, Faculty of Veterinary Technology, Bangkok, Thailand, [9]Veterinary School of Toulouse, France

Abstract: Facing increasing needs to feed human populations requires, more than ever, to enhance quantity, quality, safety and security of agricultural products, and, at the same time, to reduce environmental contamination. Thus, in livestock production, it is required to control blood-feeding flies such as Tabanids and stable flies which are responsible of annual losses estimated at 130Kg of milk/cow and 25Kg of meat/ox. To the huge blood spoliation are added stress, loss of appetite and energy, immunosuppression and mechanical transmission of viruses (equine infectious anaemia, ovine catarrhal fever), bacteria (Q fever, anthrax) and parasites (Besnoitia, Trypanosoma), with dramatic medical and economic consequences. Control of hematophagous flies is most often neglected or occasional, since insecticide spraying on walls or animals (spray, pour on) is expensive, of short term efficacy and meets increasing chemo-resistance problems. Moreover, residues contamination of animal products and environment is unacceptable, for biological agriculture.

Tsetse fly control using insecticide impregnated fabric targets proved to be efficient in Africa, because Glossina spp. are low prolific and very sensitive to insecticides. Unfortunately, this does not apply to other hematophagous flies such as Tabanids (> 4,400 species present in all types of landscapes and climates), Stomoxys (one species is cosmopolite) and other hematophagous insects such as Haematobia and Musca crassirostris, which are highly prolific, and may develop early chemo-resistance to insecticides.

FlyScreen project aims at the development and optimization of efficient, low cost and low or non-polluting methods for the control of hematophagous insects. It consists in (i) design and optimize specific hematophagous colour baited attractant screen (excluding pollinators) (ii) Develop and evaluate in laboratory conditions various toxic systems including encapsulated (slow release) insecticides, UV-protection and attractants (iii) Evaluate and validate these screens in semi-natural and natural conditions to measure efficacy and safety (environmental contamination) and (iv) Promote low-cost and low-polluting control methods.

FlyScreen project was coordinated by CIRAD and supported by the French Research Agency (FlyScreen project ANR-15-CE35-0003). It has been carried out by a Consortium in partnership between France [CIRAD (UMR InterTryp), National Veterinary School of Toulouse (ENVT) (UMR IHAP), Montpellier 3 University (CEFE)], Thailand [Kasetsart University (Bangkok)], Burkina Faso [CIRDES, Bobo-Dioulasso] and Tanzania [AtoZ Textile Mills l.t.d.].

During this project, new insecticide impregnated plastic screens have been developed and give very good results for tsetse flies, and good results for stable and horse flies when populations are still sensitive to pyrethrinoides. Ecotoxicological tests have been performed by an independent start-up showing very low release of insecticide in the environment.

Improving the efficacy of two Metarhizium species combined with Spinosad to control two species of wireworm (Agriotes lineatus and Agriotes obscurus).

Authors: Bourdon Pierre-Antoine[3], Baxter Ian[1] and Butt Tariq[2], [1]Certis Europe, United Kingdom, [2]Swansea University, United Kingdom, [3]Swansea University, France

Abstract: Following the withdrawal of registration of neonicotinoid and mocap in 2018, wireworm management is challenged. Spinosad, a bioinsecticide, is one of the only products still registered for wireworm control; however, its efficacy is limited. Entomopathogenic fungi (EPF) are another option, but the time to kill the larvae do not prevent damage. A stress and kill strategy combining an insecticide with an EPF can reduce the time to death and increase the mortality. Two Metarhizium strains were tested against wireworm in combination with three sublethal doses of spinosad. Metarhizium brunneum Met52 and Metarhizium 16P alone were unable to kill any Agriotes lineatus and Agriotes sordidus larvae. The addition of sublethal doses of spinosad could increase significantly the mortality of the wireworm larvae; however, synergies were dose dependant and species dependant. Met52 combined with spinosad produced higher mortality and was faster to kill than Metarhizium 16P against both species of wireworms. Control of wireworm could be possible to achieve in the field, but the right combination between an EPF, the appropriate dose of stressing agent and the right wireworm species.

The utilization of the fungal volatile organic compounds 1-octen-3-ol and 3-octanone against wireworm, corn rootworm and garden chafer: toxicity and semiochemicals activity

Authors: Bourdon Pierre-Antoine[3], Myrta Arben [1], Midthassel Audun[1] and Butt Tariq[2], [1]Certis Europe, [2]Swansea University, [3]Swansea University, France

Abstract: New pest management solutions are needed to control soil insects. Fungal volatile organic compounds (VOCs) such as 1-octen-3-ol and 3-octanone could be part of the solution as these have fumigant properties and semiochemicals properties affecting various insects or mollusks. We tested the fumigants properties of these two volatiles against three soil pests: wireworm (Agriotes lineatus), corn rootworm (Diabrotica virgifera virgifera) and garden chafer (Phyllopertha horticola) in closed tubes with or without soil. The insects differed in their sensitivity to these VOCs. The lowest doses (1.25 and 2.5µl) were sufficient to kill corn rootworm and garden chafer but not wireworms which required a threshold of 5µl or more to die. The semiochemicals properties of the VOCs were assessed in 5L bucket with a choice trial (untreated vs treated maize). Low doses (100 or 200µl) of VOCs could influence the movement of the insects in the soil but not kill them. Corn rootworm and garden chafer were mostly attracted by low doses VOCs while wireworms were repelled by these. Fumigation in the field seemed unrealistic as it will require huge amount of VOCs; however, attract and kill or push pull strategies could be develop against soil insects to reduce crop damage.

Dietary preferences of Heteromurus nitidus (Collembola) among wheat phytopathogenic fungi of crop residues: implications for bioregulation

Authors: Bourgeois Thomas[2], Salmon Sandrine[1], Suffert Frédéric[3], Dupont Joëlle[1], Prado Soizic[1], Lacoste Sandrine[1], Biau Gwenola[1], Dury Gérard[1], [1]Muséum national d'Histoire naturelle, [2]UMR 7179 CNRS, France, [3]Université Paris-Saclay - INRAE

Abstract: Soil arthropods play a key role in agrosystems through several ecosystemic services. Among these services, they regulate fungal communities and could play a role in mitigating the impact of deleterious fungi overwintering in crops. In this study, we investigated the preferences of a springtail, Heteromurus nitidus, between two phytopathogenic fungi, Zymoseptoria tritici and Fusarium graminearum, and eleven fungi present on wheat plants by placing springtails in presence of fungi grown in vitro in pairs. We also tested the impact of long-term consumption of the phytopathogenic fungi on springtail populations and fungal development by feeding populations with the fungi for ten weeks. Our first results show that Z. tritici was more often preferred to other fungi offered than F. graminearum . During the long-term experiment, springtail populations fed on either Z. tritici or F. graminearum had a better growth than control populations. Moreover fungal cover at the end of the experiment was reduced by springtail presence. These results seem to highlight a potential capability of H. nitidus as a biological control agent against the pathogenic fungi tested and open the way to new tests in situ.

Peer Community In Entomology: a free recommendation process of unpublished scientific papers in Entomology based on peer reviews

Authors: Bourguet Denis[1], Guillemaud Thomas[2], Facon Benoit[3], [1]CBGP, Inra, France, [2]INRA, ISA (INRA/UNSA/CNRS), France, [3]PVBMT, Inra, France

Abstract: Peer Community in Entomology has been launched in 2019. It already counts 90 recommenders and has already received submissions of preprints for evaluation and recommendation. It is part of the global Peer Community in (PCI, https://peercommunityin.org) project.
In order to offer an alternative to the current system of publication - which is particularly expensive and not very transparent - we have initiated PCI: a non-profit scientific organization that aims to create specific communities of researchers reviewing and recommending, for free, unpublished preprints in their field (i.e. unpublished articles deposited on open online archives like arXiv.org and bioRxiv.org). Each PCI is a group of several hundred recommenders playing the role of editors who recommend such preprints based on peer-reviews to make them complete, reliable and citable articles, without the need for publication in 'traditional' journals (altough the authors can submit their recommended preprints afterwards). Evaluations and recommendations by a PCI are free of charge. When a recommender decides to recommend a preprint, he/she writes a recommendation text that is published along with all the editorial correspondence (reviews, recommender's decisions, authors' replies) by PCI Evol Biol. The preprint itself is not published by PCI: it remains in the preprint server where it has been posted by the authors.
The first Peer Community in has been launched in 2017: Peer Community in Evolutionary Biology (PCI Evol Biol). More than 700 recommenders have already joined PCI Evol Biol, PCI Paleontology, PCI Ecology, PCI Animal Science and PCI Entomology.

Sterile Insect Technique and population management of insect pests: success and challenges

Authors: Bourtzis Kostas, Insect Pest Control Laboratory, Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, Vienna, Austria

Abstract: Insects represent the most abundant and speciose group of animals on our planet. The great majority of them are beneficial or harmless. However, a small fraction of them are considered major pests for agriculture or transmit devastating diseases to animals and humans. The populations of these insect pests and disease vectors have so far mainly been controlled with broad spectrum insecticides. However, insecticides pose major threat to the health of ecosystems and humans while insecticide resistance evolves and has been frequently reported and therefore there is an urgent need of alternative methods for the management of these insect pests and disease vectors. The sterile insect technique (SIT) is an environment-friendly birth-control method, which has been successfully implemented for the last 70 years as a component of area-wide integrated pest management to suppress or locally eradicate populations of insect pests and disease vectors worldwide. In this presentation, we will outline the basic principles of SIT and will report on recent R&D activities at the FAO/IAEA Insect Pest Control Laboratory, Seibersdorf, Austria. We will also present a few SIT success stories and will discuss the major challenges for its large-scale implementation against insect species of agricultural, veterinary and human health importance.

Potential use of Coccinellids as predator of Bagrada hilaris (Hemiptera: Pentatomidae) in Chile

Authors: Bout Alexandre[3], A. Gonzales C.[2], A. Verdugo Jaime[4], Fernanda Flores M.[1] and V. Albornoz Marta[2], [1]Agroadvance, Chile, [2]centroceres, Chile, [2]Centroceres, Chile, [3]INRAE, France, [4]University of Talca, Chile

Abstract: Bagrada hilaris (Burmeister) (Hemiptera: Pentatomidae), the painted bug, is a native species of Africa and one of the most invasive pentatomid pests in the world. In South America, B. hilaris was recently reported, for the first time, in the Santiago Metropolitan Region, Chile, in 2016. Despite the control measures adopted in Chile, which include reiterative applications of conventional insecticides, the populations of B. hilaris have been growing and have been recently found in all central regions of the country, mainly associated with horticultural crops of the Brassicaceae family. Although entomopathogenic fungi, several parasitoids (Scelionidae) and predators such as Bochartia sp. have been described, there have been no reports of efficient strategies using them in the field. This study reports for the first time the predation of coccinellids on immature Bagrada hilaris (Burmeister) (Hemiptera: Pentatomidae) in South America. In Chile, B. hilaris was found in association with three genera of coccinellid predators: Harmonia, Hippodamia and Eriopis. Therefore, we study i) the diversity of Coccinellidae species associated with B. hilaris on brassica and ii) predatory behavior assays of these Coccinellidae species on nymphs of B. hilaris. The evaluations were done using a General Linear Model (GLM) with a quasibinomial error distribution and logit link function. The results are discussed to explore new alternatives for controlling this pest.

Physiological consequences of climate change on the performance and metabolism of the eastern spruce budworm (Choristoneura fumiferana, Clemens)

Authors: Bowden Joe[1], Moise Eric[1], Spicer Heather[2] and Thomas Raymond[3],

[1]Canadian Forest Service, Atlantic Forestry Centre, Corner Brook, Memorial University (Grenfell Campus), School of Science and Environment, Corner Brook, Canada, [2]Memorial University (Grenfell Campus), Boreal Ecosystems and Agricultural Sciences program, Corner Brook, Canadian Forest Service, Atlantic Forestry Centre, Canada, [3]Memorial University (Grenfell Campus), Boreal Ecosystems and Agricultural Sciences program, Corner Brook, Canada

Abstract: Climate change is projected to have significant consequences for forest ecosystems, including for irruptive forest insects, such as the spruce budworm. Despite current knowledge that temperature affects insect performance (e.g., reproduction, body mass, feeding), the underpinning physiological mechanisms are not yet fully understood. Using environmental chambers, we established six temperatures (n=6) to simulate a range of historical and projected growing season temperatures for Newfoundland, Canada. We monitored growth, development, feeding and metabolic rate (using an infrared gas-exchange analyzer). Our results indicate that temperature significantly decreased development times for both pupae and adults (p <2.2 x10-16), but there was marginal consequence for pupal (p= 0.054) and none for adult mass (p= 0.952). At both fifth-instar and adult stages, an increase in temperature resulted in a significant increase in metabolic rate (L5: p= 0.043, and Adult: p= 0.014). Feeding assay results suggest that despite shorter maturation periods and greater metabolic losses, the lack of an effect on budworm mass can likely be attributed to the positive relationship observed between warming and compensatory feeding (p= 0.019 for net growth efficiency and p= 0.045 for growth rate). We will also present the results of compositional changes to the storage- and mitochondrial membrane specific- lipids. It is imperative to understand the physiological basis of the relationship between warming and performance on irruptive insects to comprehend how climate change continues to influence these economically, and ecologically, important species.

Molecular regulation of diapause initiation in the solitary bee Megachile rotundata

Authors: Bowsher Julia[1], Yocum George[3], Brar Gagandeep[1], Signor Sarah[1], Torson Alex[3] and Rinehart Joseph[2], [1]North Dakota State University, United States, [2]United States Department of Agriculture Agricultural Research Service, United States, [3]USDA-ARS

Abstract: Environmental cues regulate diapause initiation in facultatively diapausing insects. In the alfalfa leafcutting bee, Megachile rotundata, diapause seem to have a maternal component to its regulation. The goal of this work was to test whether methylation influences gene expression at the point of diapause initiation, and which genes were differentially expressed at that decision point. We compared prepupae that were diapause-destined and nondiapause-destined with whole genome bisulfite sequencing and RNAseq. Samples were collected early in the field season and late in the field season. We found that methylation rates were low across the genome regardless of diapause status. There was a significant overlap between genes that were differentially expressed and genes that were differentially methylated, but the direction of differential expression did not always correspond with methylation status. We identified differentially expressed genes involved in oxidative stress and other diapause-related pathways. Methylation may be important for the regulation of specific genes involved in diapause, but is not likely to be a general regulator of gene expression prior to diapause.

Telomere dynamics during development and overwintering in solitary bees

Authors: Bowsher Julia[2], Grula Courtney[2], Heidinger Britt[2] and Yocum George[1], [1]Edward T. Schafer Agricultural Research Center USDA-ARS, United States, [2]North Dakota State University, United States

Abstract: Adult insects have relatively short lifespans but show declines in performance with age. The mechanisms that underlie these age-associated declines in performance are not well understood. Decreasing telomere length is positively associated with aging in various organisms. Telomeres are repetitive sequences of non-coding DNA located at the end of chromosomes, which protect coding DNA during replication. Telomere attrition is associated with increasing age in many animals. Insects that go through metamorphosis can spend different lengths of time in each life stage. Cellular aging may depend on life stage and time spent in that stage, especially if that life stage is extended, as during diapause. This study aimed to determine the telomere dynamics throughout development, and overwintering in solitary bees, Osmia lignaria and Megachile rotundata. Bees from differing stages of development including prepupae, pupae, and multiple adult stages were collected and their DNA was extracted. Telomere length was measured using qPCR. Our results show a contradictory trend in telomere attrition, with telomeres elongating with age. Telomere length did not change during diapause, but increased only in emerged adults. These data can be used to demonstrate how bees age, and to determine if telomere loss is a driving mechanism of aging in solitary bees.

A new DNA metabarcoding approach to describe the diet of social wasps and evaluate their impact on biodiversity

Authors: Boyer Stéphane[3], Lefort Marie-Caroline[4], Saunders Thomas[2], Beggs Jaqueline[5] and Glare Travis[1], [1]Lincoln University, [2]Plant and Food, [3]Tours University, [4]UNITEC Institute of Technology, [5]University of Auckland

Abstract: For most invertebrates, it is difficult to access 'historical' samples such as older faeces due to the small size of the animals and the absence of permanent dejection sites. This project aimed at developing a method to study the diet of social wasps and provide an overall picture of their diet using the leftover prey DNA recovered from their nests.

By applying our method to the nests of two Polistine wasps (Polistine chinensis and P. humilis) in urban and sub-urban areas in New Zealand, our analysis provided an outline of the resource partitioning between these species and their potential impact on New Zealand native inverterbrates.

Our method allowed the amplification and sequencing of 96 samples collected from 48 wasps' nest, with on average 80,334 DNA reads (±6,435 sem) per sample. For both wasps species the main prey taxa detected comprised Thysanoptera, Lepidotera, Diptera, Coleoptera and Acariformes. Among these, a significant number of reads corresponded to pest species, which supports the hypothesis that wasps can have positive effect on the control of other insect pests. On the other hand, our study also revealed the presence of New Zealand native and endemic species, which highlights the ambivalent impact of these generalist predators.

The IMAgHO project: Increasing the Multifunctionality of Agroecosystems by Harnessing fOod webs

Authors: Boyer Stéphane, Institut de Recherche sur la Biologie de l'Insecte (IRBI), Tours, France

Abstract: In a context of ever-increasing demand for food, the future of farming requires to develop sustainable agricultural practices. The IMAgHo project aims at harnessing naturally-occurring trophic interactions to maximise regulatory services in agroecosystems and thus maintain or increase yield while reducing chemical inputs. Key regulatory services (biological control and pollination), will be studied in oilseed rape crop through the deciphering of food web dynamics at very fine temporal scale (monthly sampling), and wide spatial scale (from plot to landscape) in a setting that allows the testing of critical environmental and management gradients. Three work packages have been developed to reach the projects' goal. First the dynamics of selected food webs will be described over two years with samples collected every month during the crop growing season (WP1). Massively parallel DNA sequencing and environmental DNA samples will be used to decrypt food webs and quantify regulatory services of carabids feeding on pests and weeds, parasitoids attacking aphids and domestic and wild bees collecting pollen. The structure, stability and other connectedness descriptors of these webs will then be analysed in relation to environmental gradients, as well as existing long term historical data on agricultural practices, agrochemical input and biodiversity (WP2). Finally, modelling and field experiments will be implemented to predict and test how modifications of food webs can cascade into increased ecosystem services and greater yield (WP3). Results from the project will lead to better management of monoculture and overall lower use of pesticides. This will have a substantial impact in economic term (less buying of pesticides) and in ecological term. The more ecological growing practices may also give a market edge or lead to higher resale value as customers are constantly demanding for production processes that are environmentally friendly.

Within and beyond stick insect evolution: trait evolution and historical biogeography based on an extremely comprehensive taxon sampling

Authors: Bradler Sven[2], Bank-Aubin Sarah[1], [1]Dept. Animal Evolution and Biodiversity, University of Göttingen, Germany, [2]Johann-Friedrich-Blumenbach-Institute of Zoology and Anthropology, University of Göttingen, Germany

Abstract: Stick and leaf insects (Phasmatodea) are nocturnal herbivorous arthropods characterised by masquerading as plant parts. Despite their morphological diversity and worldwide tropical distribution, their traditional taxonomy is unstructured and lacks a solid basis for sensible classification. It was only until recently that Phasmatodea was considered one of the lesser-studied insect lineages. However, due to efforts of the past years, molecular phylogenies have begun to shed light on the phylogenetic relationships and raised doubt on the validity of the traditional classification. Using a set of seven nuclear and mitochondrial markers, we aim to revise the traditional concepts that were mainly based on morphological characters. We inferred the so far largest phasmatodean molecular phylogeny comprising over 1000 stick and leaf insect species. We are not only covering almost a third of the described species, but also presenting a vast amount of hidden and undescribed phasmatodean diversity. In combination with geographical data, we reconstructed the historical biogeography, which allows us to draw conclusions about distribution patterns of an insect group with rather low dispersal capability. Furthermore, our extensive taxon sample provides the optimal framework to discuss evolutionary relevant traits such as reproduction strategies and the capability of flight. We suppose that wings and ocelli were lost and possibly regained in several instances and that similar evolutionary processes may have shaped the evolution of organismic lineages beyond the stick and leaf insect clade.

From ancestral states to ancestral ecological networks

Authors: Braga Mariana P[1], Nylin Sören, Janz Niklas, Ronquist Fredrik and Landis Michael, [1]Swedish University of Agricultural Sciences

Abstract: Intimate ecological interactions, such as those between parasites and their hosts, may persist over long time spans, coupling the evolutionary histories of the lineages involved. Most methods that reconstruct the coevolutionary history of such associations make the simplifying assumption that symbionts have a single host. We developed a Bayesian approach for inferring coevolutionary history based on a model that allows symbionts to use multiple simultaneous hosts and to preferentially colonise new hosts that are phylogenetically similar to other hosts in it's host repertoire. These features reveal the entire distribution of ancestral states at any given point in time, allowing us to build networks of all inferred interactions at different times in the past. By reconstructing ancestral networks, we show how specific host shifts, host-range expansions, and recolonisations of ancestral hosts have shaped the network of interactions between Pieridae butterflies and their angiosperm host plants over time, creating an evolutionarily stable modular and nested structure. Our approach can be used to test ideas about the evolution of ecological networks in many other systems besides herbivorous insects.

Behavior, freedom of choice, flexible niches and their link to the ecological resilience and stability debate

Authors: Branco Leote Pedro Nuno[1], RubbmarkRennstam Oskar[1], Sint Daniela[1], [1]University of Innsbruck, Austria

Abstract: Despite that we need a clear hypothesis for how animals can stably coexist when conditions are adverse (e.g. to support diversity, the resilience of endangered ecosystems, or ecosystems services that we rely on for food), we have so far struggled to identify the core mechanisms that enable this ability. Consequently "how resilience is promoted" has become listed as one of the most important fundamental questions that remain to be answered in ecology. However, despite that we know that behavioral responses to natural (e.g. seasonal variation) or human-made habitat changes (e.g. agriculture) are common, we have barely addressed that the ability of individuals to behaviorally "choose" to step out of competitive dynamics when conditions are adverse could be the key to answering this question.

Such choices could, for example, be when individuals change their behavior in response to the resources available (e.g. per optimal foraging theory) or to avoid negative encounters, and we here present a novel network-based approach where we use the level of "freedom of choice" to approximate ecological response and recovery rate. Using this approach we conceptually show how behavior is likely to buffer competition and community dynamics before diversity effects have time to emerge. Furthermore, we also empirically use this approach to show how management manipulations, such as a switch to organic fertilization, immediately can change both functional redundancy and resilience within the available diversity. In our case, the reason for this was arguably that unstable prey communities (induced by inorganic fertilization) constrained predators' choices and made functioning depend on early competitive and community settings. Whereas, stable prey communities (induced by organic fertilization) on the other hand lead to an increased adaptability, reduced the influence of "the ghost of competition past", and made functioning reliable.

In summary we show that behavioral mechanisms are key measurements that needs to be incorporated into resilience and coexistence hypothesis. Not the least because our hypothesis for how diversity is regulated both implies that species niches are flexible and that their dynamics are preceded by a behavioral "sorting by competition", that we believe could lead to a paradigm shift in our understanding of how competing species co-exist. Furthermore, by allowing effects that are occurring within the available diversity to be assessed, we hope to enable a leap a towards a gaining more detailed understanding of how ecosystems could be managed. This is important, not the least because diversity effects often are slow to emerge and difficult to survey during the short time frame allowed by most funding schemes.

Converting molecular data to trophic networks: what needs to be considered and why

Authors: Branco Leote Pedro Nuno[5], Jonsson Mattias[4], Neidel Veronika[5], Saska Pavel[2], Daouti Eirini[4], Carbonne Benjamin[3], Bohan David[3] and Foffová Hana[1], [1]Crop Research Institute, Czech Republic, [2]Functional Diversity group, Crop Research Institute, Czech Republic, [3]INRAE French National Institute for Agriculture, Food and Environment, Dijon, France, [4]Swedish University of Agricultural Sciences, Sweden, [5]University of Innsbruck, Austria

Abstract: DNA-based approaches are widely used for assessing trophic interactions. In trophic networks of arthropod communities one of the major challenges is the high complexity they harbour: multiple consumer species are interacting with a wide range of prey taxa. But how do we translate the results from molecular screenings of different consumers into meaningful trophic networks?

We want to address this question in relation to a recently produced, large molecular dataset. In the framework of the BioAware project, molecular gut content samples of carabid beetles (Coleoptera: Carabidae) have been collected to assess their role as natural pest control agents in arable land. This unique dataset of over 10.000 individual samples of over 100 carabid species collected in 60 cereal fields across four European countries in two synchronized sampling sessions will be examined to assess carabid food choices in relation to environmental conditions.

Our findings suggest that consumer traits are important to be considered when translating molecular into trophic data. This adds highly needed methodological and conceptual considerations to how molecular data sets should be used for studying trophic networks.

Examining the reliability of biological control by assessing the season-wide trophic dynamics between pests, generalist predators and alternative prey

Authors: Branco Leote Pedro Nuno[2], Rennstam Rubbmark Oskar[1] and Traugott Michael[1], [1]University of Innsbruck, [2]University of Innsbruck, Austria

Abstract: Modern food production often involves using pesticides and while this constant input is unsustainable, natural methods of pests control have yet to be refined. Among these, conservation biological control is the ecosystem service most likely to enable reductions in pesticide use. Despite this, current knowledge on what drives its efficacy has been insufficient to make it reliable. Because most research within crop-pest systems has been restricted to limited time points, we lack an understanding of season-wide dynamics between pests, predators and alternative prey. Knowing how predators adapt their behaviour to changing conditions is crucial to understanding how biological control could be managed. Such adaptations affect the redundancy of pest consumption, and increasing redundancy is likely to enhance the resilience of biological control. We investigated the temporal dynamics in trophic interactions between predators, pest and alternative prey, by molecularly analysing the gut content of several thousand predator individuals. Using cereal fields naturally infested by aphids, we experimentally manipulated pest and alternative prey availability, to assess how turnover in community structure affects predator diets and niche overlap. This allowed a high temporal resolution of interactions occurring throughout the entire season, to determine critical time points to maintaining a reliable biological control.

Reducing wireworm damage in potato: assessing trap crops and entomopathogenic fungi

Authors: Branco Leote Pedro Nuno[3], Grabenweger Giselher[1], Reinbacher Lara[1], Zeisler Christiane[2], Rotondo Claire[2], Neu Diane[2] and Writz Marijan[2], [1]Agroscope, Zurich, Switzerland, [2]Mountain Agriculture Research Unit & Department of Ecology, University of Innsbruck, Innsbruck, Austria, [3]University of Innsbruck, Austria

Abstract: Wireworms pose a serious problem in potato production in Central Europe and elsewhere as they damage tubers and make them vulnerable to attack of pathogens. Due to the ban of insecticides for wireworm control in many countries, there is a great need to develop alternatives for the control of elaterid pests. One such alternative control approach is the deployment of trap crops and ento-mopathogenic fungi. Whilst the former is intended to lure the larvae away from the crop, the latter should infect and kill wireworms to reduce their population densities. To test this approach under field conditions, two field experiments were conducted in Tyrol (Austria) where we tested the combination of trap crops (a mixture of six plant species) and Metarhizium brunneum to reduce the feeding pressure Agriotes larvae exert on potato tubers. The treatments involved the application of the fungus in the preceding crop and the main crop as well as trap crops and combinations thereof. Wireworm densities were monitored within and between potato ridges throughout crop development and collected larvae were tested for plant DNA to assess their food choices. Moreover, potato yield and damage to tubers was examined. We found that the combination of trap crops and the application of the fungus in potato reduced wireworm-induced damage by one third whilst wireworm densities seemed to be unaffected in the different treatments. Molecular gut content analysis showed that potatoes represent the most attractive host plant when comparing plant DNA detection frequencies between the crop and the trap crop species. These findings provide important implications for the refinement of a novel attract and kill approach to reduce wireworm damage in potato crops.

Redundancy and climate resilience of generalist predator food webs in Swedish barley crops

Authors: Branco Leote Pedro Nuno[3], Jonsson Mattias[1], Feit Benjamin[1], Straub Cory[4] and Bluethgen Nico[2], [1]Swedish University of Agricultural Sciences, Sweden, [2]TU Darmstadt, Germany, [3]University of Innsbruck, Austria, [4]Ursinus College, United States

Abstract: In general, increased biodiversity is expected to provide more resilient ecosystem processes. This is largely because in diverse communities there are more species that can contribute to the functions (functional redundancy), and because different species are likely to respond differently to environmental variation (response diversity). Unfortunately, attempts to empirically assess resilience of ecosystem processes in relation to relevant disturbances are few, not least in agricultural landscapes. We will here present results from a study investigating functional redundancy and climate resilience of generalist predators predating on pest aphids and a range of other prey types in Swedish barley crops. To assess functional redundancy we developed a new method linking interaction metrics with metabolic theory that allows for a quantification of redundancy at the level of ecosystem processes. Applying this method to our generalist predator food webs, we found that redundancy of aphid predation significantly increased with the complexity of landscapes surrounding the barley fields. To assess response diversity in relation to global warming we have investigated the activity niches of a large number of actively hunting generalist predators in relation to temperature. By combining these activity niches into a metric of climate resilience at the predator community level and applying it to existing datasets we are now assessing how climate resilience varies with landscape complexity and in field management. Results from this work will be presented at the congress.

First record in Europe of Psyllaephagous blastopsyllae associated to the eucalypt psyllid Blastopsylla occidentalis: a new case of fortuitous biological control

Authors: Branco Manuela[2], Afonso Catarina[1], Valente Carlos[4] and Carlos Franco José[3], [1]Forest Research Centre (CEF), ISA, University of Lisbon & RAIZ, Aveiro, Portugal, [2]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [3]Forest Research Centre, School of Agriculture, University of Lisbon, Portugal, [4]RAIZ Forest and Paper Research Institute, Eixo, Aveiro, Portugal

Abstract: The psyllid Blastopsylla occidentalis Taylor (Hemiptera: Aphalaridae) is an Australian species that is invasive in Africa, South America and Europe. The species was first detected in Portugal in 2009. This psyllid use different Eucalyptus species as hosts, in particular E. camaldulensis, E. globulus, E. rudis and E. tereticornis. These Eucalyptus species occur in Portugal on urban and peri-urban areas for amenity and leisure purposes. Eucalyptus globulus is an economically important species widely used in plantations. Here we present the most recent geographical distribution of B. occidentalis in Portugal, and data on its abundance and potential impact. Field surveys conducted in four years, showed low population levels of B. occidentalis. On average, less than 20% of eucalypt buds were attacked. In 2019, the endoparasitoid Psyllaephagous blastopsyllae (Hymenoptera: Encyrtidae) was found associated to B. occidentalis. This is the first report in Europe of P. blastopsyllae. This parasitoid was first reported from Camaroon and was later introduced into South Africa and South American countries.

How critical are insect pests for Eucalyptus plantations in Iberia and how biological control may alleviate it?

Authors: Branco Manuela[2], Valente Carlos[3], Afonso Catarina[1] and Gonçalves Catarina[3], [1]Forest Research Centre (CEF), ISA, University of Lisbon & RAIZ, Aveiro, Portugal, [2]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [3]RAIZ Forest and Paper Research Institute, Eixo, Aveiro, Portugal

Abstract: The area planted with Eucalyptus in the Iberian Peninsula has increased about 4-fold during the last 40 years, reaching around 1.4 million ha at present. The first Australian invasive pest species affecting Eucalyptus plantations was reported in early 70's. Since then, the number of invasive pest species of Eucalyptus increased exponentially following global trends. During the last decade, almost every year one new species has been reported. Biological control has been a major aid to reduce the economic impact of these invasive species. More than 60% of the Eucalyptus invasive species are currently under complete or partial classical biological control. Significant positive benefit: cost ratio was demonstrated for the case of Gonipterus platensis under control by the egg parasitoid Anaphes nitens in Portugal. Although the success was incomplete, benefit estimates may have exceed 2000 million Euros. Further, an anticipation of the establishment of this parasitoid by just one year provided a benefit: cost ratio of 67. No negative impacts were registered whatsoever on non-target native insects for any of the introduced parasitoids. Interestingly, 85%, 6 out of 7 species of biological control agents currently present in Portugal arrived unintentionally, most of them following releases in other regions or other continents. Once a classical biological control is launched in one region it may originate significant positive externalities by natural spreading to other regions. In the case of A. nitens, further augmentative releases were conducted. Research programs are under way with the aim of introducing new control agents in Portugal and Spain, namely for the control of G. platensis and Thaumastocoris peregrinus. These include biological control organisms already released in other continents, such as Cleruchoides noackae, and new ones, never released outside Australia, such as the larval parasitoid Anagonia sp.. However, the process has been slow and the cost and time needed to complete all the studies required by legislation may hinder the initiatives. The current strict legislation for the introduction of new biological agents in many European countries is probably one of the most important constrains to biological control programs. We defend that present European regulations and countries legislation should be reviewed. In particular, the requirements for programs for which biological control was demonstrated to be safe and efficient in other regions of the world should be lessened.

The interplay of habitat composition and configuration on ant communities: effects at distinct landscape matrices

Authors: Branco Manuela[1], Zina Vera[2], Fonseca André[2], Carlos Franco José[2], Rosário Fernandes Maria[2], Teresa Ferreira Maria[2] and Conde Sofia[2], [1]Forest Research Centre (CEF), ISA, University of Lisbon, Portugal, [2]Forest Research Centre (CEF), School of Agriculture (ISA), University of Lisbon (ULisboa), Portugal

Abstract: Ants (Hymenoptera, Formicidae) have been widely used as bioindicators of habitat loss and fragmentation due to their sensitive and rapid response to environmental changes and human impacts. Moreover, ants play a key role in ecosystem functioning and provide valuable ecosystem services (e.g., nutrient cycling, decomposition, seed dispersal, biological control).

In the scope of the CERES project – Connectivity of forest and riparian ecosystems of the SUDOE space, this work aims to show how forest and riparian habitat composition and configuration affects ant abundance and diversity, and how ant communities may be used to identify and prioritize the reestablishment of landscape connectivity. The study was conducted in two Mediterranean areas, in Portugal: the Sorraia and Tagus valleys. Ants were surveyed in June and July 2019, both inside Ecological Relevant Units (ERU), i.e., forest and riparian vegetation habitats, and within the three distinct dominant landscape matrices, i.e., Intensive Agriculture, Forest Production, and Extensive Agriculture systems. Samples were collected using pitfall traps in 280 sites. In each site, five pitfall traps were installed and left in the field for approximately 48 hours. Ant specimens were preserved and identified at the species level in the laboratory, under a stereomicroscope. ERU patches were mapped using World Imagery layer (RGB, 50cm, flyover 2018) and classified based on the location and vegetation attributes, leading to the following types of habitats: 1) Riparian Woody (rw); 2) Riparian Non-Woody (rNw); 3) Non-Riparian Woody (Nrw); and 4) Non-Riparian Non-Woody (NrNw). Landscape metrics related to connectivity and shape configuration were calculated for each ERU class, at the distinct dominant landscape matrices.

Results showed higher ant abundance in the ERU patches than in matrices for the Intensive Agriculture and Forest Production types. Ant abundance was particularly low in the agricultural areas. Large and complex riparian woody patches seem to be particularly relevant for ant communities, especially in Forest Production areas. In agricultural dominated matrix small forest patches and isolated trees play an important role in the maintenance of ant structural community. Ant functional traits and diversity metrics will be discussed in view of better understanding the functional importance of landscape features that appear to be of high connectivity value.

Evolution of alternative reproductive systems in Bacillus stick insects

Authors: Brandt Alexander[1], Lavanchy Guillaume[1] and Schwander Tanja[1], [1]Department of Ecology and Evolution, University of Lausanne

Abstract: Stick insects of the genus Bacillus feature a variety of reproductive strategies including canonical sex, parthenogenesis and hemiclonal reproduction (hybridogenesis). The different parthenogenetic and hybridogenetic lineages were suggested to be of interspecific hybrid origin between the same two sexual species, but it remains unknown whether they derive from independent hybridization events or whether a single event was followed by secondary diversification of reproductive modes. Here, we revisit the different species and hybrid lineages within the genus Bacillus using a de novo chromosome-level reference genome and RADseq data of > 500 wild-caught individuals. We corroborate that two hybridogenetic lineages and two parthenogenetic lineages show the genomic signatures of diploid or triploid F1 hybrid species with the maternal genome coming from the facultative sexual species B. rossius. We then phased the haplotypes in each hybrid lineage to infer the separate evolutionary history of each parental genome. Our preliminary phylogenomic analyses suggest that sex was lost after a single historical hybridisation event, followed by (multiple) transitions between parthenogenesis and hybridogenesis, subsequent hybridisations and ploidy changes. These findings indicate transitions between unorthodox modes of reproduction previously unknown to occur, suggesting that loss of sex per se can be a driver of reproductive mode diversification.

Deciphering the role of pollen-borne microbes in the development of Megachile rotundata

Authors: Brar Gagandeep Singh[1], Bowsher Julia[1], Floden Madison[1], Rajamohan Arun[3], Yocum George[4] and McFrederick Quinn[2], [1]North Dakota State University, [2]University of California, [3]USDA-ARS

Abstract: The alfalfa leaf cutting bee, Megachile rotundata F. is an important field crop pollinator. The females provision their offspring with pollen having diverse microbial community that can contribute to the health and survival. The Apilactobacillus clade is the most abundant microbe in the gut and provisions helping bees to digest pollen. Despite the apparent importance of the microbial community, evidence concerning the effects of provision microbes on M. rotundata physiology are lacking. To test this, M. rotundata larvae were reared on the pollen with antibiotics, sterile pollen, sterile pollen + Lactobacillus micheneri, natural pollen + Lactobacillus micheneri, and natural pollen (control). Results showed that there was no significant difference in larval and prepupal weight when fed on sterile pollen, sterile pollen + Lactobacillus micheneri and natural pollen + Lactobacillus micheneri as compared to control. Larvae spun significantly heavier cocoons and showed delayed development when fed with sterile pollen and as compared to control. As a follow up, we used 16S rRNA gene sequencing to assess whether the bee-microbiome interaction and quality of diet can shape the fitness of M. rotundata. This study will improve the understanding of the microbiome-bee symbiotic relationship in the field of bee health and nutrition.

The genetic mechanism of polyphagy in Noctuidae

Authors: Breeschoten Thijmen[1], Simon Sabrina[1] and Eric Schranz M[1], [1]Biosystematics Group, Wageningen University, Netherlands

Abstract: Many species within the butterfly family Noctuidae are generalists and form notorious pests on various plant species. Yet, most insect herbivores show a degree of host specialisation, likely driven by co-evolutionary forces. Host-plant specialisation seems to be the rule rather than the exception. Still numerous insect species –as in the Noctuidae- have evolved the ability to feed on a large range of host plants from distant related families. The ability to do so seems to be dependent of a broad digestion and detoxification system due to the diversity and flexibility of genes involved in these processes.

How is a polyphagous insect able to cope with the variation of plant material and defences encountered during feeding? We studied how generalist cutworm moths are able to feed on a broad host plant range. By linking herbivore success with gene expression data we studied and compared the transcriptional response within Noctuidae species. We did so within an evolutionary framework, allowing us to study the evolution of (polyphagous) herbivory on a molecular, genetic scale.

Linking genomic loci with behavioral variation in Ixodes scapularis

Authors: Brinkerhoff Jory[2], Gulia-Nuss Monika[1] and Otalora-Luna Fernando[2], [1]University of Nevada-Reno, [2]University of Richmond United States,

Abstract: Ixodes scapularis, the principal vector vector of the Lyme disease bacterium in eastern North America, can be divided into two primary lineages through single- and multi-locus genetic analysis. These lineages are broadly linked with variation in Lyme disease risk but specific associations between genomic loci and behavioral variation have yet to be identified. We describe variation among tick populations in Virginia across nearly 25,000 polymorphic loci in the context of variation in tick density, Lyme disease incidence, and observed differences in tick behavior. We found that ticks from different Virginia populations where Lyme disease risk varies substantially engage in different host-seeking behaviors and in their propensity to parasitize rodent hosts. Genomic analyses of ticks form these populations revealed functional differences in genes related to metabolism, development, and external stimulus response, suggesting that differences in tick behavior and heterogeneity in host use may be related to physiological processes and organism function. Although preliminary, our analyses shed light on the genetic underpinnings of host seeking and host use behavior in an important disease vector.

Military roles in vector control

Authors: Breidenbaugh Mark, Northwest Mosquito and Vector Control District, United States

Abstract: The United States Department of Defense employs advanced-degreed entomologists as Preventative Medicine and Public Health Officers in the Army, Navy, and Air Force. While the primary function of these scientists is service member health, military entomologists can also provide support to vector control operations following natural disasters. Each of the services has various specialties and the Air Force maintains a capacity to conduct large-area aerial sprays to control disease vectors in combat zones and in response to declared emergencies. This talk will touch on the various capabilities of the individual services and highlight Air Force aerial spray operations, using recent responses to natural disasters as case studies.

Acoustic communication of bark and ambrosia beetles

Authors: Brockerhoff Eckehard[2], Hofstetter Richard[1], Bedoya Carol[3], Hayes Michael[3] and Nelson Ximena[4], [1]Northern Arizona University, United States, [2]Swiss Federal Research Institute WSL, Switzerland, [3]University of Canterbury, Christchurch, New Zealand, [4]University of Canterbury, New Zealand

Abstract: Bark and ambrosia beetles including pinhole borers (Coleoptera: Curculionidae: Scolytinae and Platypodinae) are among the smallest wood- and bark-boring insects. They spend much or most of their lifetime inside plant tissue, a dark and chemically over-saturated environment, and hence acoustic communication appears to be widespread; however, sound production in these taxa is sorely understudied, perhaps because monitoring individuals communicating inside woody tissue is somewhat difficult. We collected the largest dataset to date of bark and ambrosia beetle sounds, consisting of distress calls of 55 species within 15 subtribes of both the Scolytinae and the Platypodinae. Based on this we analysed the presence and absence of acoustic communication and characterised the temporal, spectral, and amplitude features of the calls across these multiple tribes and genera. Depending on the species, either both sexes stridulated or only one. Some species had calls with different acoustic morphotypes (e.g., one, two, or three notes), and when both sexes stridulated, the sounds generally differed. We also performed a literature review and combined both acoustic and metadata to investigate the effects of the type of mating system - and its interactions with body size and phylogeny - on the use of acoustic communication. We found that the interaction between size and mating system plays a fundamental role in determining the presence and sex-dependence of acoustic communication in a species. Furthermore, we studied the context-dependence of the spectro-temporal parameters of the stridulatory sounds and the effect of the physical presence/absence of other individuals in the variability of such parameters. Physical interactions between individuals rather than acoustic stimulation from nearby males appeared to be a causative factor in the variability of stridulatory sounds.

Bridgehead effects in forest insect and pathogen invasions

Authors: Brockerhoff Eckehard[5], Bertelsmeier Cleo[6], Yamanaka Takehiko[3], Nahrung Helen[2], Turner Rebecca[4] and Ollier Sébastien[1], [1]Ecology, Systematics and Evolution Lab, Department of Biology, University Paris-Sud XI, France, [2]Forest Industries Research Centre, The University of the Sunshine Coast, Queensland, Australia, [3]Research Center for Agricultural Information Technology, NARO, Japan, [4]Scion, New Zealand, [5]Swiss Federal Research Institute WSL, Switzerland, [6]University of Lausanne, Switzerland

Abstract: Invasions of insects and pathogens are a major threat to forest ecosystems. Invasions typically originate in the native range of species; however, some successful invaders become very abundant in the invaded range which may lead to further invasions originating in the invaded range. This is known as the “bridgehead effect”. In this presentation, I will review the bridgehead effect concept and present some evidence for the existence of the effect based on interception and establishment data and population genetic studies of selected insects and pathogens (including some new results). Finally, as bridgehead invasions are likely to become more frequent, I will discuss potential measures to counter their occurrence.

Human transport networks drive global alien species flows

Authors: Brockerhoff Eckehard[5], Bertelsmeier Cleo[6], Yamanaka Takehiko[3], Nahrung Helen[2], Turner Rebecca[4] and Ollier Sébastien[1], [1]Ecology, Systematics and Evolution Lab, Department of Biology, University Paris-Sud XI, France, [2]Forest Industries Research Centre, The University of the Sunshine Coast, Queensland, Australia, [3]Research Center for Agricultural Information Technology, NARO, Japan, [4]Scion, New Zealand, [5]Swiss Federal Research Institute WSL, Switzerland, [6]University of Lausanne, Switzerland

Abstract: Since the Industrial Revolution increased international trade and human movement have resulted in the accidental movement of many species worldwide at an unprecedented scale. There has been much interest in identifying which regions have acted as major donors of invasive species and why. Darwin proposed that more species from the Northern hemisphere have invaded the Southern hemisphere than vice versa because “the northern forms have existed in their own homes in greater numbers, and have consequently been advanced through natural selection and competition to a higher stage of perfection or dominating power, than the southern forms”. More recently, it has been suggested that Old World plants have more frequently invaded the New World than vice versa because they share traits for quick colonization of disturbed habitats and are pre-adapted to invade. These are two examples of the many species trait hypotheses that have been proposed to explain historical patterns of global invasions. Alternatively, these patterns may simply reflect the direction and level of human transport. Here, we evaluate the extent to which global species flows are best explained by the biodiversity of donor regions or the worldwide network of human transport, using ants (Formicidae) as model system. To test if global flows of the 241 species of alien ants are simply driven by the available species pools of the donor regions, we compared the observed species flows to expected flows based on the native species richness of each region. Observed species flows differed significantly from expected flows based on native species richness. For example, Australia and North America have exported less species than expected and Europe has exported more species than expected. To test if these patterns can be explained by the level and direction of human transport, we analysed flows of transported species representing the level of species introductions through human transport before the establishment stage, using border interceptions from air and maritime ports in five countries on three different continents. We found that expected species flows based on human transport were consistent with observed species flows (establishments) to these countries. Our results imply that the direction of human-mediated transport is able to generate the observed species flows in contrast to species trait hypotheses based on the evolutionary superiority of regional faunas.

Impacts of prescribed burns on the nesting communities of ground-nesting bees in tallgrass prairies in Minnesota, USA

Authors: Brokaw Julia[1], Cariveau Daniel[1] and Portman Zachary[1], [1]University of Minnesota, United States

Abstract: Nearly all wild bee conservation efforts focus on mitigating the effects of habitat loss by enhancing foraging resources like floral diversity, floral abundance and nectar quality. Tallgrass prairie restoration provides an ideal system in which to mitigate against wild bee declines and support their conservation efforts. Prescribed fire is a common management tool in tallgrass prairie systems because many plants require burning to persist in the landscape. While ground-nesting bees nest deep enough below the soil surface to avoid detrimental impacts of burning, it is unknown how the resulting changes to the vegetation structure and microhabitat of the soil surface influence their nesting choices. To determine if nesting by ground-nesting bees are influenced by burning, we used emergence traps to make direct measurements of areas used by bees for nesting. We placed twenty-one hand-designed and commercially available emergence traps in burned and unburned areas of four remnant prairie sites that were patch burned in the spring of 2019. Traps were rearranged weekly from June to August and collected 507 bees of 52 different species. The bee nesting abundance of actively nesting females was greater in the burned areas than the unburned areas, but species diversity of bee nesting was not significantly different. The results of this research demonstrate that patch burning in prairies supports ground-nesting bee nesting preferences and documents an often overlooked life history trait of ground-nesting bees.

Economic and socio-environmental impacts of insect resistance technology in Brazil: historical analysis, perspectives and future challenges

Authors: Brondani Adriana[1], [1]Biologist, MSc and PhD in Molecular Biology Director at Biofocus Hub Professor at the MBA of Agribusiness at the University of São Paulo (USP), Brazil

Abstract: The advent of GMO crops has been one of the main technological advances in the agricultural sector in the last two decades. The insertion of genes that enable plants to produce proteins with insecticidal activity against major pests has provided farmers with an additional tool to deal with the complex process of integrated pest management. In Brazil, the introduction of this technology occurred in 2005, with the approval and launch of a cotton variety. Insect resistant (IR) maize was approved in the country in 2007 and soybeans in 2010. Due to its efficiency, there was intense adherence by farmers to technology. Today, the rate of IR crops adoption in the country are 65% for soybeans, 82% for maize and 85% for cotton (data from the 2018/19 harvest). Currently, the area cultivated with insect resistant varieties reaches 39 million hectares, making Brazil one of the largest global players in the adoption of such technology. The factors that best explain the success of the technology are those observed directly on farms. Taking the gains obtained in the field as a starting point, we have quantified the benefits that GMO plants resistant to insects have provided to the Brazilian agribusiness, from the authorization of its planting until the last harvest (2018/19 harvest), emphasizing its impacts in the economic, social and environmental areas. In addition, based on the agricultural growth scenario expected for the next ten years, the future impact of that technology on the control of target insects is also estimated. The discussion over the next few years is especially relevant because we are at a time when there are reports of population growth of insects resistant to Bt proteins, which would decrease the efficiency of the technology. In light of the risks pointed out, the importance of coordinated actions among farmers, the industry and the government is discussed so that the technology remains sustainable in medium and long terms. It is vital to preserve the efficiency of Bt plants so that they continue providing gains in the productive sector and maintain positive externalities in terms of wealth generation, job creation, more efficient use of resources and reduction of environmental impacts.

Urban hardwood forest diversity and structure drive carabid beetle assemblages

Authors: Brosius Tierney[1] and Reisner Michael[1], [1]Augustana College, United States

Abstract: Urbanization impacts native ecosystems directly through replacement of native communities with urban infrastructure and indirectly through habitat fragmentation and degradation. Understanding how and to what extent urbanization has impacted forest composition and structure is vital because these forests continue to provide a diverse array of ecosystem services. We sampled 38 sites across an urbanization gradient. Cluster analysis revealed four groups of forest sites that differed in understory and overstory plant diversity structure and diversity (MRPP, $A = 0.14$, $p < 0.0001$) and abiotic factors (MRPP, $A= .19$, $p < .0001$). The first group consisted of closed canopy forests with depauperate understory dominated by native mesophytic species such Acer saplings & Virginia creeper and high levels of bare soil. Woodland-specialist carabids (Chlaenius emarginatus & Calathus gregarious) dominated these sites. The second group consisted of open-canopy forests with relatively intact native understory and overstory communities dominated by oak and hickory species. A mix of forest edge and open area carabids (Cyclotrachelus sodalis & Galerita janus) dominated these sites. The third and fourth groups consists of sites located in the smallest remnant forest patches that were also most disturbed. They were characterized by the highest levels of invasive plant species and differed primarily in Lonicera spp. (honeysuckle) dominance. Generalist and forest edge carabids dominated these sites. Our findings suggest that despite being degraded these remnant urban forest ecosystems serve as a refuge for native flora and fauna.

Airborne cues accelerate and enhance flowering without cost to growth and defence.

Authors: Brosset Agnès[1], Yu Hao[2] and Blande James[2], [1]Department of Environmental and Biological Sciences, University of Eastern Finland, Kuopio, Finland, [2]University of Eastern Finland, Finland

Abstract: Volatile cues can induce and/or prime plant defences, but it is less well known if plants also respond by altering growth and reproduction-related parameters. Here we evaluated whether plant volatile cues can elicit changes in growth, flower production, net photosynthesis rate and defences in receiver plants and whether those responses are similar to those elicited in response to direct herbivore-feeding. Our results demonstrate that exposure to volatiles emitted from damaged neighbours accelerated the time to first flowering, and increased the number of flowers produced, net photosynthesis rate, without altering the fresh harvested plant biomass and volatile defences, compared to non-exposed plants. Earlier flowering was also observed for plants exposed to volatiles from undamaged plants. These responses differed from those of plants exposed to actual herbivore-feeding for which feeding enhanced net photosynthesis rate but reduced growth and had no effect on reproduction and defence in response to subsequent herbivory. These findings document that plant airborne cues can influence reproductive traits of receiver plants. In particular, the flower phenology is modulated, and photosynthesis is enhanced, suggesting that carbon allocation is directed toward reproduction.

Global phylogeography of the Bemisia tabaci cryptic species group by mitochondrial COI and nuclear ortholog sequence analyses, and niche-modeling to unravel phenotypic plasticity

Authors: Brown Judith[1] and Paredes-Montero Jorge[1], [1]The University of Arizona, Tucson, United States

Abstract: The whitefly Bemisia tabaci cryptic/sibling species group consists of important pests and plant virus vectors corresponding to geographically structured phylogenetic clades. Here, the mitochondria cytochrome oxidase (mtCOI) sequences from whitefly individuals (n=1,923) was used to infer a global phylogeny, and the intragroup nucleotide (nt) divergence (corrected nt distances) was estimated, imposing 12.5% to establish species boundaries. Based on matrix correlation and niche modeling methods, respectively, whitefly 'occurrence' records were overlaid to determine if phylogenetic breaks were structured based on geographical affiliations or sharp transitions across environmental gradients i.e. indicative of geographic isolation. To determine if intra-clade genenic variation could be explained by spatial distribution, intra-clade divergence estimates and geographical distances for each clade were compared using a simple mantel test. To account for predicted environmental factor influences a partial mantel test was carried out in which fourteen agro-environmental variables were considered. Finally, climatic suitability, as a potential driver of diversification among endemic members to the major clades, was assessed by ecological niche modeling that considers environmental-, ecological-, and agricultural-related factors that could influenced ecological processes that may in turn delimit distribution and/or phenotypic plasticity of the cryptic species. Distance analysis resolved 14 lineages within and/or basal to the five recognized species clades (delimited by 2184 nuclear orthologs): American Tropics (AM-TROP) (1), Asia (ASIA) (3 lineages), Asia-Pacific-Australia (AS-PAC-AU) (6), North Africa-Mediterranean-Middle East (NAF-MED-ME) (1), or Sub-Saharan Africa (SSA) (1), plus the 'undefined' sweet potato-Uganda (UGswpot) (1) and Italian highlands-T mitotype (1). Well-supported patterns of geographic isolation ($rM=0.61$, $p<0.05$) influenced primarily by seasonal temperatures ($rM=0.4702$, $p=0.00001$) appeared to best explain extant diversification of species lineages. Similarly, niche predictions resolved an isolation-by-distance model of speciation, at >0.9 AUC support values in test and training datasets, with annual mean temperature and precipitation of the driest month explaining up to 80% of the variation in the model, suggesting these factors best explain the distribution of B. tabaci worldwide. Remaining challenges include increased overall sample size of certain represented species, better representation of non-agricultural species exemplers, validation of predicted habitat with genotype-phenotype character state associations, and analysis of effective gene flow within and between species and predicted sister groups within a species e.g. sibling or cryptic species status.

Disruption of targets at the psyllid-Ca.Liberibacter interface to abate early stages of the infection cycle leading to circular, propagative transmission

Authors: Brown Judith[1], Gang David[3], He Ruifeng[4], Rast Timothy[1] and Fisher Tonja[2], [1]The University of Arizona, Tucson, AZ, United States, [2]Agricultural Science Center North Lexington, KY, United States, [3]Washington State University, Pullman, WA, United States

Abstract: 'Ca. Liberibacter asiaticus' (CLas) is the obligate, fastidious bacterial pathogen that causes citrus greening disease, or Huanglongbing. The bacterium is transmitted in a circulative, propagative manner by Asian citrus psyllid (ACP) Diaphorina citri Kuwayama adults. Using the surrogate study system involving the potato psyllid Bactericera cockerelli Sulc. and the analogous bacterial pathogen of tomato/potato plants,' Ca. Liberibacter solanacearum' (CLso). The identification and functional characterization of effectors involved in invasion of the psyllid gut and blood, with presumed entry into the salivary glands was investigated using combined transcriptomic, proteomic, yeast-2 hybrid (Y2H) and co-immunoprecipitation (Co-IP) analyses. In silico annotation and differential expression analysis of contigs from ACP and/or PoP nymphs and adults, and adult midgut and salivary gland tissues identified transcripts and proteins with altered expression in response to CLas/CLso infection. Several differentially expressed transcripts were selected as bait for Y2H-detection in protein-protein interactions studies. Those positive by Y2H were subjected to verification by bait to prey co-transformation and Co-IP. Proteins positive in one or both assays were tested in 'knock down' experiments using dsRNA to induced RNA-interference (RNAi), with quantification by qPCR. Candidates of the greatest interest were those with a predicted role in entry, gut /salivary gland invasion, virulence, and systemic infection, that if disrupted by RNAi could abate Liberibacter accumulation in and exit from the gut, circulation in hemolymph, and acquisition in the salivary glands. Collectively, the results suggest a model for invasion in which Liberibacter- and prophage-encoded effectors that exploit psyllid cellular pathways, including membrane ruffling for entry into the gut, followed by cytoskeletal remodeling, and exocytosis leading to bacterial exit into the hemocoel. Following systemic invasion of the hemocoel and transport in the hemolymph (blood), CLas/CLso are predicted to use an endocytosis-like process to enter the salivary glands from where transmission to the plant host occurs post-acquisition.

Contributions of citizen science to understanding patterns and trends in the distribution of ladybirds in the UK

Authors: Brown Peter M.J.[1], E. Roy Helen[2], [1]Anglia Ruskin University, United Kingdom, [2]Centre for Ecology & Hydrology, Wallingford, Oxfordshire, United Kingdom

Abstract: People have been contributing their wildlife observations from across the UK for centuries. Simple biological records (what, where and when a species was seen) can be made by anyone, anywhere. Technological developments such as smart phone apps are increasing the number of people participating in such citizen science initiatives. The information accruing from them is enabling us to track changes in wildlife over time and address many ecological questions. The UK Ladybird Survey is one of the volunteer recording schemes hosted by the Biological Records Centre (UK Centre for the Ecology & Hydrology) and encompasses the Harlequin Ladybird Survey which was initiated in 2005 in response to the arrival of the non-native species Harmonia axyridis within the UK. Formerly the Coccinellidae Recording Scheme, the UK Ladybird Survey has been active since the early 1970s. Much has changed over the last 50 years but the success of this citizen science initiative has contributed substantially to our understanding of the ecology of ladybirds and more broadly non-native species. Harmonia axyridis is a charismatic species that has been instrumental in engaging people in non-native species ecology and encouraging public participation in surveillance and monitoring. In 2019 we published the latest ladybird distribution trends using the UK Ladybird Survey dataset. Many species are showing declines in distribution but there have also been some expansions and indeed some new arrivals. Here we will provide an overview of the UK Ladybird Survey and celebrate the role of volunteers, through citizen science, in underpinning ecological studies with benefits for nature and people.

Resistance of wild potato species against Myzus persicae

Authors: Bruce Toby[1], Ali Jamin[1], [1]Keele University, United Kingdom

Abstract: Crop wild relatives have common ancestry with cultivated crops and provide increased genetic diversity. Wild relatives of potato have a vast history of use in breeding, even though a large number of species have not yet been tested for their future utilisation (Castañeda-Álvarez et al., 2015). Under natural selection they have evolved traits making them resistant to abiotic or biotic stresses (Maxted and Kell, 2009). They can be crossed with domesticated crops for crop genetic improvement (Maxted et al., 2016). The aim of the current study was to evaluate different genetic lines of wild potato Solanum stoloniferum for resistance to the aphid Myzus persicae. An aphid performance bioassay was done with the help of clip cages. We found that four accessions of wild potato had high levels of aphid resistance. Three out of the four were highly resistant with few aphids alive after 3 days and no surviving aphids after six days. The fourth line had low aphid survival. Nymph production was similarly affected with a marked in reduction in nymph production with the three most resistant lines and some residual nymph production in the fourth line. These lines could be used to breed aphid resistant potatoes.

Assessing a crop-rotation wide attract-and-kill approach for wireworms and adult click beetles in arable land

Authors: Brunner Michael[1] and Branco Leote Pedro Nuno[2], [1]Institute of Zoology, University of Innsbruck, Austria, [2]University of Innsbruck, Austria

Abstract: Due to their long belowground development, wireworms are durable by nature and hard to control, but cause tremendous damage worldwide. In Europe, larvae of the genus Agriotes spp. are most common and to date no sufficient control measure is available. Alternative control strategies are urgently needed and the use of entomopathogenic fungi (EPF) such as Metarhizium brunneum could be one component to develop a sustainable control strategy. Unfortunately it's efficacy in the field is low, but trap crops could help to boost the effectiveness of EPFs by providing improved conditions for M. brunneum to establish in the soil. We hypothesize that an optimized combination of (i) trap crops, (ii) entomopathogenic fungi and (iii) intensive soil cultivation can significantly reduce wireworm population and crop damage over a period of three years.

Influencing the oviposition of female click beetles could be another component to efficient wireworm control. To identify attractive plants and volatiles for female click beetles of the species Agriotes sputator, electroantennography (EAG) and olfactometer experiments will be performed. Identification of highly attractive plant species and volatiles is expected to provide the base for an advanced attract-and-kill strategy, concentrating eggs and emerging neonates in oviposition strips at field margins.

From red list to rogue: current research on the planthopper Pentastiridius leporinus, a vector of the fast spreading Syndrome “Basses Richesses” disease in sugar beet

Authors: Bruno Pamela[2], Rostás Michael[2], Detring Justus[2], Pfitzer René[1], Shakya Okas[2] and Varrelmann Mark[1], [1]Institute for Sugar Beet Research, Germany, [2]University of Göttingen, Germany

Abstract: The planthopper Pentastiridius leporinus (L.) (Hemiptera: Cixiidae) is the main vector of Candidatus Arsenophonus phytopathogenicus, a phloem-restricted γ-proteobacterium associated to the low-sugar content syndrome of sugar beet (Beta vulgaris L.) known as “basses richesses” (SBR). This disease was first identified after tremendous yield losses in eastern France in the nineties. In recent years, it has been rapidly expanding east and northward, thus becoming a major problem for sugar beet cultivation in Germany and Switzerland. The planthoppers spend most of their life as root-feeding nymphs, where they are protected from insecticide treatments. After sugar beet harvest, the nymphs are able to complete their life cycle in the subsequent winter wheat crops. Promising sustainable management strategies against SBR and its vector include crop rotation, breeding for highly-tolerant or resistant sugar beet varieties, and biological control of the insect vectors. To develop these, there is urgent need for a deeper understanding of the biology and chemical ecology of P. leporinus. Here we present an overview of our current research on the above-mentioned topics.

Status of entomological lidar

Authors: Brydegaard Mikkel[2], Brydegaard Mikkel[1], Li Meng[3], Månefjord Hampus[2], Müller Lauro[2], Xu Zhicheng[2] and Salvador Jacobo[2], [2]Lund University, [1]Dept. of Physics, Lund University, Lund, Skåne, Sweden, [3]Lund University, Sweden

Abstract: This will be a brief overview of our group’s latest accomplishments within the field of entomological lidar. Entolidars are capable of detection hundreds of thousands of insects per day, and several clues on target identity can be retrieved, for example, wing beat harmonics by kHz sampling, microstructural features by polarization or molecular and nanoscopic information by the implementation of lidar with multiple spectral bands. We currently explore the potentials and limitations regarding discriminating species and quantifying insect diversity by lidar. Our activities involve development of new spectroscopic lidar instruments which are 3D printed and sufficiently simple to test during in situ during field campaigns. We relate remotely sensed signals to detailed target analysis of ex vivo pinned specimen and develop new computational data pipelines for extracting meaningful information. Our new hyperspectral lidar techniques allow to distinguish insects both by their intrinsic nanostructures but also to monitor of fluorescence tagged insects during both night and daytime.

Unearthing the virome of Spodoptera species

Authors: Bryon Astrid[1], Mattia Annamaria[1], Gbenga Hussain Ahmed[1], Kon Matthijs[1], Kupczok Anne[1] and Ros Vera I.D.[1], [1]Wageningen University & Research, Netherlands

Abstract: The noctuid moth species, Spodoptera exigua and Spodoptera frugiperda, are two major polyphagous pests that are responsible for substantial yield losses worldwide. Besides the often ineffective conventional pesticides, there is a growing market for the application of specific biological control agents to combat these devastating pests. The production of such biological control agents requires a continuous moth mass rearing. Unfortunately, covert asymptomatic infections, both viral and non-viral, can have major impacts on the mass rearings. Covert viral infections can be triggered into symptomatic, overt infections by external triggers and cause major economic losses. Therefore, our research aimed to gain more insights in the virus diversity of two populations of the two pest species S. exigua and S. frugiperda. We unraveled the virome via Illumina sequencing DNA, RNA and small RNAs and showed that both known and new viruses are present in these Spodoptera populations. We confirmed their presence via PCR and reverse-transcription PCR. Although no symptoms were noted in the moth rearing, the interaction of the known and newly discovered viruses may influence the moth’s fitness posing a risk for mass rearing facilities or offering new opportunities for biological control by viruses.

Viruses of reared insects: the enemy within?

Authors: Bryon Astrid[2], Maciel-Vergara Gabriela[1] and van Oers Monique[2], [1]Laboratory of Virology, Wageningen University & Research, Netherlands; Department of Plant and Environmental Science, [2]Wageningen University & Research, Netherlands

Abstract: The outbreak of insect diseases severely threatens insect rearing. In particular, viral diseases can be devastating for the yield and quality of mass rearing systems. Here, I highlight disease-causing viruses in insects most commonly reared for food and feed, with a special focus on viruses threatening cricket rearing. In addition, I will discuss covert (latent/persistent) virus infections in insects, and how these can suddenly develop into overt (symptomatic) infections under stress conditions. In that context I will also elaborate on factors affecting the emergence of viral outbreaks in insect rearing, along with virus transmission routes. Lastly, I will give an overview of measures available to prevent and manage virus outbreaks.

Medical appointment for crickets – why do insect diseases matter in mass rearing systems?

Authors: Bryon Astrid[8], Maciel-Vergara Gabriela[6], Bruun Jensen Annette[7], M. Tanga Chrysantus[2], Beckers Erwin[5], van Lent Jan[5], van Loon Joop[3], Eilenberg Jørgen[1], Desutter-Grandcolas Laure[4] and van Oers Monique[5], [1]Department for Plant and Environmental Sciences, University of Copenhagen, Denmark, [2]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya, [3]Laboratory of Entomology Wageningen University, Netherlands, [4]National Museum of Natural History, France, [5]Wageningen University, Netherlands, [6]University of Copenhagen; Wageningen University, Netherlands, [7]University of Copenhagen, Denmark, [8]Wageningen University & Research, Netherlands

Abstract: Several species of crickets are reared as a source of protein with an ever-increasing number of start-up companies and projects engaging in cricket large scale rearing. In this presentation, I will talk about my work on cricket pathogens in wild and captive populations. I will also discuss my findings on the effect of abiotic factors on bacterial (Rickettsiella sp.)and viral diseases (Acheta domesticus densovirus) development in cricket rearing. Furthermore, I will concentrate on practical aspects of cricket rearing that render production systems resilient (or not) to diseases, including research done on egg sanitation. Finally, I will elaborate on the reasons why studying and understanding fundamental and applied aspects of cricket diseases is important to improve cricket rearing.

Evolution of symbiosis, colony organization and defense in termites

Authors: Buček Aleš[3], Šobotník Jan, Bourguignon Thomas[2] and Roisin Yves[1], [1]Evolutionary Biology and Ecology, CP 160/12, Université Libre de Bruxelles, Belgium, [2]Okinawa Institute of Science & Technology Graduate University, Japan, [3]Okinawa Institute of Science and Technology, Czech Republic

Abstract: Termites are the oldest social insect lineage, one of the few animal groups able to feed on lignocellulose and amongst the most abundant animal groups in tropical ecosystems. To understand the key evolutionary transitions during the ~ 140 Ma of extant termite evolution a robust molecular phylogenetic tree is required. To this end, we used datasets based on transcriptome sequences, ultraconserved element sequences, and mitochondrial genome sequences. I will summarize our current understanding of the termite phylogeny and how it informed the hypotheses on the evolution of the colony organization, the loss of symbiotic gut protozoa, and the evolution of the defensive soldier caste in termites. Our analyses challenge previous molecular phylogenies by recovering sister relationships between the comb-builders Sphaerotermitinae and Macrotermitinae, which changes our understanding of the chronology of the loss of protozoa and the origin of fungus-growing in termites. The termite phylogeny indicates that comb building is a derived trait within Termitidae and that externalization of some of the digestion to comb-like nest structures involving bacteria or fungi may not have driven the loss of protozoa from ancestral termitids, as previously hypothesized [1]. Our phylogeny of the second largest termite family - dry wood termites (Kalotermitidae) - uncovered their trans-oceanic dispersal capabilities and hinted at their ancestral potential to forage between separate wood pieces [2]. The major remaining challenge that I will discuss is the resolution of relationships within Termitidae family and particularly among one of its clades encompassing Cubitermitinae, Nasutitermitinae, Syntermitinae and polyphyletic Termitinae, that rapidly diversified ~ 35 Ma and which includes some of the most striking termite soldier defensive adaptations.

Predator-prey naïveté as a mechanism contributing to explain the invasion success of non-native ladybeetles in Europe and in North America

Authors: Bucher Roman[3], Gül Ünlü Ayse[3], Menzel Florian[2] and J. Obrycki John[1], [1]University of Kentucky, United States, [2]University of Mainz, Germany, [3]University of Marburg, Germany

Abstract: Invasive species pose a major threat to global biodiversity. Despite the growing scientific literature on detrimental effects of invasive species, we often lack a mechanistic understanding why some species become invasive while others remain benign. Possibly, invasive predators might remain undetected by native predators and thus suffer less intraguild interference (naïve predator hypothesis). In addition, invasive predators might benefit from a lack of predator avoidance by native prey (naïve prey hypothesis). The ability to recognize non-native predators is expected to depend on cue similarity with native predators. Consequently, non-native ladybeetles bearing a unique set of cues might have the double advantage of naïve ants and aphids and thus outcompete native ladybeetles.

To test this, we compared ant aggression towards native and non-native ladybeetles in Europe and in North America. Thereby, we manipulated cuticular hydrocarbons on ladybeetle elytra to elucidate the role of these chemical cues in predator recognition. In addition, we compared aphid consumption and avoidance behavior upon direct contact with native and non-native ladybeetles as well as with their chemical cues only. We analyzed chemical ladybeetle cues to establish their species-specificity, which is a prerequisite for predator-prey naïveté. Finally, we related cue similarity between native and non-native ladybeetles with the strength of behavioral responses of ants and aphids.

In line with our expectations, we found higher ant aggression towards native European ladybeetle species compared to the invasive Harmonia axyridis. Ant aggression was strongly influenced by the presence of chemical cues on ladybeetle elytra. Similarity in chemical cues between H. axyridis and the native European ladybeetle H. variegata led to similar ant aggression. In Europe, the aphid Acyrthosiphon pisum avoided cues of native ladybeetle species but not of the invasive H. axyridis. Contrastingly, the American strain of A. pisum avoided cues of all ladybeetle species. A. pisum predation in our experiments, however, was largely determined by ladybeetle body size rather than by species origin and did not differ across continents.

We suggest that high cue dissimilarity to voracious native ladybeetles and large ladybeetle body size contribute to the intensity of competition with native ladybeetles and ultimately to the invasion success of non-native ladybeetles. However, differences in aphid avoidance behavior between Europe and North America also suggest that rapid adaptation within few decades can normalize novel biotic interactions among insects. Nonetheless, small native ladybeetles (e.g. Adalia bipunctata in Europe) that co-occur in space and time with invasive ladybeetles are at particular risk.

Phylogeny and evolution of the New Zealand stick insects (Phasmatodea)

Authors: Buckley Thomas[2], Bradler Sven[1] and Mc Cartney Ann[2], [1]Johann-Friedrich-Blumenbach-Institute of Zoology and Anthropology, University of Göttingen, Göttingen, Germany, [2]Manaaaki Whenua - Landcare Research, New Zealand

Abstract: The New Zealand stick insect fauna includes approximately 20 species. These species are related to sub-tropical taxa from New Caledonia. We have been investigating their phylogenetic relationships, patterns of introgression and adaptation to the cool, temperate environments of New Zealand. Using transcriptomes and whole genome sequencing we describe the reticulate patterns of evolution among taxa caused by extensive hybridization. This has also resulted in the frequent development of parthenogenesis. We also show how colonization of cool environments has left an imprint on the genome sequences of these species.

Phylogenomics of Cynipoidea

Authors: Buffington Matthew[3], Blaimer Bonnie[1] and Brady Sean[2], [1]Museum für Naturkunde Berlin, Germany, [2]National Museum of Natural History, United States, [3]Systematic Entomology Laboratory USDA-ARS, United States

Abstract: A complete phylogeny of Hymenoptera has been sought after for over 100 years. While many trees and phylogenetic hypotheses have been published, their topologies have been limited by the number of characters available, the number of taxa coded or sequenced, or most typically, both of these issues. With the advent of next generation sequencing of ultraconserved elements (UCE's), the major hurdle of tackling both taxon sampling and data abundance/quality has been overcome. Herewith we present a comprehensive phylogeny of Hymenoptera based on around 1000 terminal species. Our taxon sampling aimed at representing lineages relative to their diversity in the analyses. Experts for each major clade selected representative taxa, many of which were derived from pinned specimens deposited in the USNM and no new fieldwork was needed to fill in taxonomic gaps. The resulting trees are based on variety of analyses ranging from 301 to 1687 UCE loci. We summarize the recovered topologies and compare/contrast these results with previous analyses.

The Expanding Range of the Asian Chestnut Gall Wasp Dryocosmus kuriphilus Yasumatsu (Hymenoptera: Cynipidae) in North America

Authors: Buffington Matthew[4], Mapes Carol[3], Tang Chang-Ti[1], Setliff Gregory[2], Gates Michael[5] and Courtney Richard[2], [1]George Washington University, Washington, DC, United States, [2]Kutztown University of Pennsylvania, Kutztown, PA, United States, [3]Kutztown University of Pennsylvania, Kutztown, PA, United States, [4]Systematic Entomology Laboratory USDA-ARS, United States, [5]USDA-ARS, Washington, DC, United States

Abstract: The Asian chestnut gall wasp, Dryocosmus kuriphilus Yasumatsu (Hymenoptera: Cynipidae) is an invasive species of global concern, and in North America it induces gall formation on chestnut species including Castanea mollissima Blume, C. crenata Siebold & Zucc., and C. sativa Mill., as well as the American chestnut, C. dentata (Marsh.) Borkh. The Asian chestnut gall wasp was first introduced into the United States in the 1970's, and since its initial introduction in Georgia, it has been reported to have spread to 13 other states. It has been documented as far to the northeast as Connecticut and Massachusetts, as far to the northwest as Michigan, and has recently been reported in Ontario, Canada. The introduction and spread of D. kuriphilus is of particular concern given the goal to restore American chestnuts into the North American landscape. This study explores the continuing spread of D. kuriphilus, providing new state records and evidence of the expansion of the range of this gall-forming invasive species in the United States to encompass all of the Mid-Atlantic States. The effectiveness of Torymus sinensis Kamijo (Hymenoptera: Torymidae) as a biological control agent will also be discussed.

Thermal diversity of ant communities at large and small scales

Authors: Bujan Jelena[2], Roeder Karl[3], D. Weiser Michael[1] and Kaspari Michael[4], [1]Department of Biology University of Oklahoma, United States, [2]Department of Ecology and Evolution University of Lausanne, Switzerland, [3]Department of Entomology University of Illinois Urbana-Champaign, United States, [4]Geographical Ecology Group University of Oklahoma, United States

Abstract: Ectotherm distributions and fitness will depend on their ability to adapt and acclimate to the ongoing increases in temperature. The thermal adaptation hypothesis predicts that more thermally variable environments favor organisms with wider thermal ranges and thermal limits which track climate. To test this, we used ants because they are globally distributed and, like other ectotherms, sensitive to temperature. We measured critical thermal minima and maxima (CTmin and CTmax) of 132 North American ant species across 15.7° of latitude from warm deserts to alpine tundra. Across 31 ant communities we found that ants were cold tolerant in cooler environments particularly at the community level where CTmin positively correlates with mean annual temperature (CTmin=0.20MAT+2.7; R2 = 0.30, p=0.001). In contrast, CTmax did not covary with environmental temperatures at the community or species level, but instead showed a strong phylogenetic signal suggesting that CTmax might be phylogenetically conserved.

The absence of CTmax tracking environmental temperatures and the high variation of this trait in each of our communities could be caused by the fact that CTmax is not a fixed trait but can be acclimatized to the changes in microclimates. Thus, air temperature averages might not be good predictors of the fine tuning of CTmax which could be achieved at the local scale.

To evaluate this, we focused on a single community experiencing significant differences in mean monthly temperatures across seasons and quantified CTmax of 27 ant species. On average species sampled during the winter had lower CTmax compared to the summer and spring. While some species showed no changes across the seasons, heat tolerance of others varied in a predictive fashion. Four out of five seasonal generalists—species actively foraging in all three focal months—had, on average, 6°C higher CTmax at the end of the summer. We show that heat tolerance can be plastic, and this should be considered when examining species level adaptations at large scales. Thermally plastic species might have a competitive advantage in communities under global warming with consequences for community composition and structure. For example, among the thermally plastic species was the invasive fire ant, Solenopsis invicta, suggesting that plasticity in thermal tolerance could be another trait enabling success of this invasive species. Thus, exploring the notion of thermal plasticity should be increasingly important for models that hope to predict the future of native and invasive species distributions.

Essentials of ecological knowledge that applied biological control urgently needs

Authors: Bukovinszky Tibor[1], Groot Tom[1], Calvo Francisco Javier[2], [1]Koppert Biological Systems, Netherlands, [2]R&D Koppert Biological Systems, Spain

Abstract: The call to increase the contribution of biological control in IPM is louder than ever before, but current research efforts are often not geared towards meeting this demand. We argue that more focus on currently largely ignored applied problems is needed in order to increase the efficiency of developing new biological control products. While finding natural enemies in nature is relatively easy, selecting the right ones to develop into products for augmentative biological control is much harder, and time consuming. There are several known selection criteria that are typically assessed in controlled laboratory and semi-field assays. Such assays typically quantify biological parameters essential in early phase of candidate screening, for example population growth rate, prey/ host acceptance, consumption rates. Besides these parameters, there is another group of criteria that a successful candidate biological control agent needs to pass. Such criteria examine versatile aspects of the candidate's suitability to be produced at an industrial scale as well as to be shipped to the growers arriving in good shape. Other criteria are related to the complexities of the often highly artificial agro-environmental conditions where the agents are released and need to perform. The evaluation at this relatively late point of product development, when already a significant time and financial commitments have been made, will ultimately "make or break" a product. Also, with the ongoing intensification of growing conditions, the importance of screening in this phase, will likely increase. We argue that such problems pertaining to the selection of candidates are not high enough on the agenda of biocontrol research. In this presentation we review the complexities based on published examples and our own extensive experience. We discuss how reducing the gap between the current scientific efforts and the realistic field situation at growers' site may increase the efficiency at which new biocontrol agents are developed.

Colour heritability in a variable aposematic insect

Authors: Burdfield-Steel Emily[1] and Kemp Darrell[2], [1]Institute of Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, [2]Macquarie University, Australia

Abstract: Despite the fact their colouration has been shown to work as an aposematic signal, and is thus expected to be under purifying selection, Hibiscus harlequin bugs (Tectocoris diophthalmus) show an impressive level of variation in their iridescent colouration both across and within populations. Previous work has shown that part of this variation may be due to plasticity in response to temperature. However, populations vary both in the extent of plasticity, and in the distribution of different colour patterns, suggesting a heritable component. No studies have yet examined heritability of colour in this species. Here we focus on a single population in the southern part of range, as these populations contain the greatest colour variation. We reared full-sib families of know pedigree in the laboratory and analysed the extent of iridescent colouration once they eclosed to adulthood. We then looked for evidence of heritability and antagonistic sexual selection acting on colour in this species. We found surprisingly low levels of heritability, particularly in males. There was however a sex by genotype interaction for iridescent cover, in the form of a negative intersexual genetic correlation: in families where sons had high iridescent cover the daughters had low, and vice-versa. Thus antagonistic sexual selection is unlikely to be maintaining diversity in colouration in this species.

A new association between insect and nudivirus producing virus-like particles

Authors: Burke Gaelen, University of Georgia, United States

Abstract: Some lineages of parasitoid wasps have evolved a remarkable strategy in their parasitism arsenal: they utilize domesticated endogenous viruses (DEVs) to breach host defenses. The most well-known examples are Polydnaviruses (PDVs), which are found in three diverse clades of parasitoid wasps, likely representing three unique origins. Despite their independent evolution, PDV genomes share some key characteristics. PDV genomes are integrated into the genomes of wasps, and their genome architecture has been rearranged compared to viral ancestors into two separate components: proviral segments containing virulence genes and replication genes. In addition to PDVs, DEVs have been documented in other parasitoid wasp species, and their recent genomic characterization has shown that these DEVs differ from the PDV paradigm. We have discovered another independently-derived DEV in Fopius arisanus that produces virus-like particles (VLPs) that do not contain nucleic acids. These data highlight existing diversity in viral symbiont genome architecture, which has important implications for symbiont function in hosts. In host insects, PDVs rely upon gene expression from existing DNAs for virulence. In contrast, the lack of DNAs in F. arisanus VLPs prevents delivery of virulence genes into host cells, likely necessitating other mechanisms for promoting parasitism in host insects.

Influence of increasing summer temperatures on an invasive forest pest

Authors: Burke Gaelen[1], Mech Angela[2], Rusty Rhea J.[4], J. K. Gandhi Kamal[1], Tobin Patrick[3] and Teskey Robert[1], [1]University of Georgia, United States, [2]University of Maine, United States, [3]University of Washington, Seattle, Washington, United States, [4]USDA Forest Service, United States

Abstract: Higher temperatures predicted under current climate change models are expected to have an overall positive effect on the success of invasive forest pests by increasing biological attributes such as survivability, geographic range, and fecundity. These changes in life history factors may result in negative cascading effects on forested ecosystems. However, heat may be a limiting factor for invasive insects that undergo summer diapause, such as the non-native hemlock woolly adelgid (Adelges tsugae) (Hemiptera: Adelgidae), which is causing widespread mortality of eastern hemlock (Tsuga canadensis) in eastern North America. The thermal ecology of A. tsugae was examined in the southernmost limit of hemlock's contiguous range by determining A. tsugae survivorship under increasing temperature regimens and heat waves. A positive correlation was found between increasing temperatures, duration of exposure, and A. tsugae mortality. These results showed evidence for a cumulative effect of temperature. Adelges tsugae mortality was minimal (< 20%) when exposed to 20° and 25°C, but markedly increased at temperatures above 30°C (up to 100%). High temperatures resulted in a significant increase in A. tsugae mortality over time and similar trends were exhibited in field populations. Field mortality of A. tsugae ranged from 8.5% to 62.8% in hemlock stands and was strongly correlated with temperature regimes. In addition, a controlled experiment was designed to determine whether any of the beneficial bacterial endosymbionts of A. tsugae are sensitive to heat stress and may be causing the decrease in host fitness. In response to lower A. tsugae densities, hemlock appears to be avoiding the anticipated rapid dieback and mortality caused by this pest.

Joint species distribution models of saproxylic beetle species: implications for forest management and climate change

Authors: Burner Ryan[1], Sverdrup-Thygeson Anne[1], Stephan Jörg[5], Drag Lukáš[2], Skarpaas Olav[3] and Birkemoe Tone[4], [1]Faculty of Environmental Science and Natural Management, Norwegian University of Life Sciences, 1433 Ås, Norway, [5]Swedish Species Information Centre, Swedish University of Agricultural Sciences, Uppsala, Sweden, [2]Field Station Fabrikschleichach, Biocenter, University of Würzburg, Germany, [3]Natural History Museum, University of Oslo, Norway, [4]Norwegian University of Life Sciences, Norway

Abstract: Saproxylic insects play a key role in a variety of forest ecosystem functions. Modern forestry practices result in low levels of dead wood compared to natural forest systems leading to loss of habitat for saproxylic communities. Saproxylic beetles are important for the decomposition of dead wood and are therefore crucial for nutrient cycling and maintaining healthy forest ecosystems. However, little is known about how their large-scale distributions will change under future forest scenarios with a changing climate and in a landscape with varying forestry practices and dead wood amounts.

Distributions of species and assembly of communities result from complex processes involving local and regional environmental conditions, species traits, and species interactions such as competition and facilitation. Additionally, these processes change through space and time, adding further complexity. Traditionally it has been difficult to model all these important factors simultaneously, and most research focuses on only a few of the many possible sources of variation in species distributions. Here we use a hierarchical species distribution model (HMSC) to understand the relationship between climate, habitat, forest management practices, species traits, phylogenetic relationships, and species interactions of saproxylic beetles across Norway. The model is a form of Joint Species Distribution Models (JSDMs) which, contrary to stacked species distribution models that combine models for each species, has the advantage of also drawing information from the co-occurrence patterns of species.

Using window trap records of 457 saproxylic beetle species from 468 sites sampled over three decades, we find that many saproxylic species are rare, and their abundance is best predicted by a combination of forest management and climatic covariates. Our current approach aims at including beetle species traits, like wing to mass ratio as proxy for dispersal capacity, and phylogenetic relatedness among the beetles in an HMSC to better predict species occurrences and disentangle the importance of each predictor. Because the model formulation is very tightly linked to the ecological theory of community assembly, we discuss how facilitation, competitive exclusion, and random processes may shape beetle communities. Importantly, mature and unmanaged forests provide key habitat for many rare and red listed species but are underrepresented in managed forest landscapes and should be preserved. HMSCs of saproxylic beetle communities provide a new and promising avenue of community research across a range of spatial scales to better understand these communities and make predictions how future forestry practices and climate change will impact these communities.

The fate of flies in fruit: implications of Drosophila suzukii infestations in fruit

Authors: Burrack Hannah[1], Isaacs Rufus[2], Diepenbrock Lauren[4], Kraft Laura[3] and van Timmeren Steve[2], [1]Department of Entomology and Plant Pathology, North Carolina State University, United States, [2]Michigan State University, United States, [3]North Carolina State University, United States, [4]University of Florida Citrus Research and Education Center, United States

Abstract: Drosophila suzukii (SWD, spotted-wing drosophila) is a globally invasive pest of soft skinned fruit which has undergone a dramatic range expansion during the last decade. Since 2008, SWD has been detected throughout North America, Europe, and South America in addition to its presumed native range in mainland Asia and Japan. Much of this recent movement has been potentially facilitated through trade. Larval SWD feed internally within host fruit, and at low infestation rates, eggs and small larvae may escape detection. There is presumed zero tolerance for SWD larval presence in fresh market or whole frozen fruit, and purchasers may reject whole shipments of fruit if any SWD are observed. Significant research efforts have focused on pre harvest management tactics to prevent infestation, including insecticide use, exclusion netting, and biological controls. However, in highly preferred hosts or fruit which ripen during peak fly activity may still experience infestation even with pre harvest management. This presentation will review post harvest monitoring and management strategies for SWD with a focus on the effect of cold storage.

Molecular evidence suggesting the re-examination of the taxonomy of the groundnut/soya bean leaf miner (Aproaerema sp.) (Lepidoptera: Gelechiidae)

Authors: Buthelezi Makhosi, Mangosuthu University of Technology, South Africa

Abstract: Mitochondrial DNA COI gene analyses of the groundnut/soya bean leaf miner (GSLM) conducted in South Africa linked the South African GSLM to the Australian Aproaerema simplexella (Walker) and the Indian Aproaerema modicella (Deventer). Thus, the genetic relatedness of the South African GSLM, the Australian A. simplexela and the Indian A. modicella was examined by performing MtDNA and nuclear DNA analyses (COI, COII, cytb, 28S and EF-1 ALPHA) on 44 specimens collected from South Africa, four from Mozambique, and three each from single locations in India and Australia. In the phylogenetic trees for COI, COII, cytb and EF-1 ALPHA, a similar pattern was observed in the way that the sequences assembled into different groups; i.e. some sequences of A. simplexella from Australia were grouped separately from the others, but some Australian sequences grouped with those of the GSLM from South Africa, India and Mozambique. In the phylogenetic tree for 28S, all sequences grouped together. Genetic pairwise distances ranged from 0.97 to 3.60% (COI), 0.19% to 2.32% (COII), 0.25 to 9.77% (cytb) and 0.48 to 6.99% (EF-1 ALPHA). Results of this study indicate that these populations are genetically related and presumably constitute a single species. Thus, further molecular and morphological studies need to be undertaken in order to resolve this apparent conundrum on the taxonomy of these populations.

The smelly sex lives of blow flies

Authors: Butterworth Nathan [4], Drijfhout Falko[2], Wallman James[4], Johnston Nikolas[1], Keller Paul[3] and Byrne Phillip[4], [1]Centre for Sustainable Ecosystem Solutions, School of Earth, Atmospheric and Life Sciences, University of Wollongong, NSW, Australia, [2]School of Chemical and Physical Sciences, Keele University, United Kingdom, [3]School of Chemistry and Molecular Bioscience, University of Wollongong, Australia, [4]School of Earth, Atmospheric and Life Sciences, University of Wollongong, Australia

Abstract: Blowflies (Diptera: Calliphoridae) are a biodiverse family that occupy a wide range of ecological niches. In carrion-breeding species, adults aggregate and breed around decaying animal matter, which is an ephemeral and speciose environment. Under these conditions, there is intense competition for mates, and a high risk of misguided mating investment. As such, it is likely that blowflies have evolved highly specific sexual signals to mediate mate recognition and sexual attraction. Most observations of blowfly sexual behaviour have focused on visual cues, and it appears that vision is an important aspect of blowfly communication. By contrast, very little attention has been given to chemical communication in blowflies, which is also likely to be important considering the prevalence of pheromones throughout other calyptrate fly groups. Cuticular hydrocarbons (CHCs), are long-chain hydrocarbons that are expressed on the cuticle of virtually all insects, and are common pheromones across many dipteran taxa. Within Calliphoridae, CHCs have been found to be highly species-specific. However, there is no evidence that they facilitate sexual communication. To assess whether CHCs may have a communicative function, we combined behavioural assays, gas-chromatography mass-spectrometry, and genetic data to analyse and compare CHCs between 10 Australian blowfly species. This presentation reports species- and sex-specific differences, and discusses the potential role for CHCs to mediate the sexual behaviour of flies.

Orthoptera Conservation in Italy: the Zeuneriana marmorata case. (Orthoptera, Ensifera)

Authors: Buzzetti Filippo Maria[2], Fanin Yannick, Leandri Fausto and Fontana Paolo[1], [1]Fondazione Edmund Mach, Italy, [2]Fondazione Museo Civico di Rovereto

Abstract: Listed as EN (Endangered) by IUCN in the Red List of European Orthoptera, Zeuneriana marmorata (Fieber, 1853) is under conservation project in Italy. Known current populations are in NE Adriatic coast of Italy, inland of Slovenia and one recently discovered in Italian inland.

These sub-populations are assumed to be remnant of a larger metapopulation that was most likely living in the wet habitats of the plains around the North Adriatic Sea and the Po river. Habitat loss and fragmentation due to human activity contributed dramatically to the disappearance of the species in most of its range. Regarding the Italian populations, study (bioacoustic) and conservation (translocation, area management) actions are applied to date and planned for the future.

Orthopteroid insects collections at the Museo Civico di Rovereto (Italy): the Galvagni collection and the Fontana collection

Authors: Buzzetti Filippo Maria[2], Fontana Paolo[1] and Stancher Gionata[2], [1]Fondazione Edmund Mach, Italy, [2]Fondazione Museo Civico di Rovereto

Abstract: The Museo Civico of Rovereto was founded in 1851 and hosts several art and science collections. Concerning Zoology, the entomology is noteworthy, consisting of the collection Halbherr (Coleoptera), the collection Tamanini (Hemiptera with several types especially among Gerromorpha), plus the recently acquired collections Galvagni (30,000 specimens: Orthoptera, Dermaptera, Blattodea, Mantodea, Phasmatodea) and Fontana (25,000 specimens: Orthoptera, Dermaptera, Blattodea, Mantodea, Phasmatodea).

Within a couple of years the entomological collections of the Civic Museum of Rovereto have been enriched with more than 50,000 identified specimens (2147 species of Orthoptera).

Thanks to the recently acquired entomological collections, the Rovereto Civic Museum becomes a reference point for Orthoptera studies, resulting attractive also for further donations such as the Fontana Orthopteroid collection recently acquired.

A biogeographic and systematic analysis of endemic damselflies in Vanuatu (Vanuatubasis: Ceonagrionidae: Odonata)

Authors: Bybee Seth[3], Ferguson Daniel[2] and Saxton Natalie[1], [1]Brigham Young University, United States, [2]Brigham Young University, United States, [3]Department of Biology, Brigham Young University, United States

Abstract: In this study we examined the phylogenetics relationships of the damselfly genus Vanuatubasis (Odonata: Zygoptera: Coenagrionidae), an endemic to the island archipelago of Vanuatu. We reconstructed a phylogeny of Vanuatubasis using all three previously described Vanuatubasis species, along with an additional 16 morphospecies representing putative undescribed taxa that were recently collected during extensive field work from 2017-2019. We sequenced the mitochondrial loci CO1 and 12S and the nuclear locus ITS for all taxa. Our molecular data are fairly limited in an effort to minimize missing data when including a larger taxon sampling of closely related taxa from previous studies. By so doing we were able to include 26 species of Nesobasis, the hypothesized closest relative to Vanuatubasis, and an endemic to Fiji. Phylogenetic reconstruction was conducted under both maximum likelihood and Bayesian inference methods and both were highly congruent and exhibited high support across most of our topologies. However, some low support and differences are seen within the Vanuatubasis grouping. Our analyses support Vanuatubasis as monophyletic and being placed within Nesobasis rendering it non-monophyletic. The phylogenetic analyses give more understanding of the relationships between the Vanuatubasis species across Vanuatu. Morphospecies from islands that were closer in distance were more closely related than those from farther islands. Though weather conditions and time of year may have been a factor, we did not observe any Vanuatubasis on islands with large active volcanoes. In the future, we plan to add additional molecular data and taxa to better understand the evolution of the group, particularly taxa from throughout the South Pacific.

Aphid-induced changes in the phloem exudate metabolome of wheat and positive effects on aphid offspring suggest niche construction by Sitobion avenae

Authors: Bühler Andreas[1], Schweiger Rabea[1], Wall Saskia[1], Wimmelbücker Maximilian[1], [1]University of Bielefeld, Germany

Abstract: Plant phloem sap imposes nutritional challenges on aphids. Previous studies revealed that aphids may change the phloem sap metabolome. However, it is unclear how these changes affect aphid performance. In this study, wheat (Triticum aestivum) leaves or ears were infested with grain aphids (Sitobion avenae) for 10 days or left uninfested. The performance of S. avenae offspring colonies on these differently treated plant parts as well as the preference behaviour of the aphids were assessed. Moreover, phloem exudates were collected and analysed for their amino acid composition and metabolic fingerprints of putative specialised metabolites. In the first days, nymphs showed higher survival on previously aphid-infested leaves than on control leaves, though colonies increased to similar sizes over 12 days. Positive effects of previous aphid infestation were more pronounced on ears, with colonies on previously aphid-infested plants growing substantially larger. In the choice bioassays, S. avenae showed a preference for previously aphid-infested ears, while on leaves no preference was observed. Taken together, our study indicates niche construction by S. avenae, which was transient on wheat leaves and more pronounced and longer lasting on ears. The findings may be partly explained by aphid-induced metabolic differences between the corresponding phloem exudates.

Effects of frequency and timing of methyl jasmonate treatment on pine weevil damage received by Norway spruce seedlings

Authors: Bylund Helena[1], Chen Yayuan[1], Puentes Adriana[1] and Björkman Christer[1], [1]Swedish University of Agricultural Sciences, Sweden

Abstract: It has been shown that induced defence in conifer seedlings can be triggered by treatment with methyl jasmonate (MeJA) on the above-ground parts of seedlings to reduce pine weevil (Hylobius abietis) damage. Thus, enhancing the plant's own defences can provide a novel and sustainable potential plant protection strategy. However, few studies have addressed the practical issues surrounding MeJA treatment such as treatment frequency and timing, optimal seedling age and if it is compatible with plant nursery practices. In this paper, we examined if levels of pine weevil damage differ depend on the frequency (once or twice) and timing (before or after nursery winter storage) of MeJA treatment, and if these effects differ depending on plant age. Norway spruce (Picea abies) seedlings from two different age cohorts (1 year and 1,5 year old plants) were each grouped into four MeJA (10mM) treatments as follows: One MeJA application before nursery winter storage, one MeJA application after winter storage but before spring planting, two MeJA applications: before storage and before planting, and no MeJA applications at either time point). A lab and field experiment was set-up to examine differences in pine weevil damage among treatments. Seedlings were exposed to pine weevils in a non-choice lab experiment, and in the field we followed survival and levels of damage both the year of planting and the following year. We found that the timing and frequency of MeJA treatment significantly affects the amount of damage inflicted by pine weevils, and these effects were mostly consistent among age cohorts. Previous application, before winter storage, provided the most effective protection compared to the other treatments. This reduction in damage was comparable to that provided by a currently used method of in nurseries, Conniflex. Thus, our results indicate that MeJA treatment can be conducted in line with nursery practices (before winter storage) for plant age cohorts usually used for re-planting, and provide adequate protection the following year.

Spinning in Embioptera (Part 1): a behavioural perspective

Authors: Büsse Sebastian[2], Edgerly Janice[1], [1]Department of Biology, Santa Clara University, United States, [2]Department of Functional Morphology and Biomechanics, Institute of Zoology, Kiel University, Germany

Abstract: Webspinners (Embioptera) are unique in their ability to spin silk by stepping with their front feet against the substrate to release dozens of fibers as they fashion a domicile. Their silk fibers are among the finest known but via complex spinning behaviours, the webspinner produces thick sheets and tubes. Despite the apparent fragility of such structures, the occupants are protected from predators and rainfall. We have quantified spinning behaviours of two dozen species from across the range of the order and found stereotypy in their spin-steps. An individual displays 26 possible spin-steps as she constructs a silk framework around her body and then thickens the emerging structure with reinforcement steps. Even though individuals express the same actions, the emphases and stepping combinations display a phylogenetic signal to some degree. However, individuals in some species show high intraspecific similarity while individuals of other species are spontaneous and unpredictable. Embiopteran body shapes are highly constrained throughout the entire range because of uniformity of lifestyle—living in tightly spun silken tubes. Despite this morphological homogeneity, analysis of variation in spin styles revealed that species with higher intraspecific similarity tend to live in regions with greater seasonality, higher temperatures and less rainfall. One interpretation is that individuals living in more predictable climes, such as tropical rainforests, are more spontaneous, while those from Mediterranean climes display more predictable species-specific spin-step routines. We will discuss methods for discovering phylogenetic signal and environmental correlates as they relate to the diversification of spinning behaviour.

Spinning in Embioptera (Part 2): a biomechanical perspective

Authors: Büsse Sebastian[2], Edgerly Janice[1], [1]Department of Biology, Santa Clara University, United States, [2]Department of Functional Morphology and Biomechanics, Institute of Zoology, Kiel University, Germany

Abstract: Using the legs for multiple functions in addition to walking, potentially imposes constraints and compromises. Within this context, webspinners (Embioptera) show a unique morphological adaptation: they use their front feet to produce silk for building a shelter. The morphology of the so-called spinning-tarsus is well studied; however, the actual process of silk ejection, is addressed only vaguely. The spinning apparatus, located within the prothoracic basitarsus, is composed of: i) multinucleated silk glands enclosing a reservoir used for silk storage; ii) the ejection duct with canal cage; iii) hollow, cuticular hair-like tubes (silk-ejectors) located on the ventral surface of the spinning tarsus.

We here present morphological and experimental evidence for a "passive" pressure-induced spinning mechanism induced by external mechanical stimuli. Material distribution of the tarsal cuticle and anatomy of the spinning apparatus provide both deformability of the basitarsus and mechanical resistance for proper pressure generation; resulting in ejection of the silk, when the silk-ejectors contact the surface. When the first contact between single threads and substrate is established, it is sufficient pulling off the tarsus to continue silk spinning. Furthermore, we experimentally induced silk production in anaesthetised individuals by applying a mechanical stimulus to the spinning-tarsus. As silk spinning is induced by likely any mechanical contact of the ventral surface of the spinning-tarsus, the proposed mechanism results in a complex behaviour for both application of the silk as well as for contact avoidance of the spinning apparatus with the substrate during locomotion.

Korean species of the genus Caloptilia Hübner, 1825 (Lepidoptera: Gracillariidae)

Authors: Byun Bong-Kyu[1], Kim Da-Som[2], [1]Hannam University, South Korea, [2]National Science Museum of Korea

Abstract: In this study, a total of 27 species of the genus Caloptilia Hübner, 1825 belonging to the family Gracillariidae are recognized from Korea. Among them, seven species, Caloptilia acericola Kumata, 1966, C. celtidis Kumata, 1982, C. dentata Liu & Yuan, 1990, C. kadsurae Kumata, 1966, C. monticola Kumata, 1966, C. recitata (Meyrick, 1918) and C. soyella (van Deventer, 1904), are reported for the first time from Korea. All the known species are enumerated with their available information. Adults and genitalia of all species are redescribed and illustrated.

Review of the subfamily Phyllocnistinae (Lepidoptera: Gracillariidae) in Korea

Authors: Byun Bong-Kyu[1], Kim Da-Som[2], Lee Ji-Young[1], [1]Hannam University, South Korea, [2]National Science Museum of Korea

Abstract: This study was conducted to review of the subfamily Phyllocnistinae, belonging to the family Gracillariidae, in Korea. Only one species, Phyllocnistis citrella, has been known from Korea to date. In this study, a total of 7 species of the subfamily are recognized from Korea. Among them, three new species Phyllocnistis sp. nov. 1, Phyllocnistis sp. nov. 2 and Phyllocnistis sp. nov. 3 are described as new to science. Also, three species, Phyllocnistis chlorantica, P indistincta and P. saligna are reported for the first time from Korea. All the known species are enumerated with their available information including images of adults and genitalia of all species are redescribed and illustrated.

Reverse chemical ecology applied to odorant receptors in the crop pest insect Spodoptera littoralis

Authors: Caballero Vidal Gabriela[3], Jacquin-Joly Emmanuelle[2], Montagné Nicolas[1], Bouysset Cédric[4], Golebiowski Jérôme[4] and Fiorucci Sébastien[4], [1]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [2]INRA, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [3]INRAE, Sorbonne Université, Institute of Ecology & Environmental Sciences of Paris, Versailles and Paris, France, [4]Institute of Chemistry of Nice, UMR CNRS, Université Côte d'Azur, Nice, France

Abstract: Insects detect, via their odorant receptors (OR), a variety of volatile compounds found in the environment and use them to carry out vital activities such as identifying food sources and sexual partners. The identification of attractive or repellent semiochemicals that interfere with crop pest behaviors is a major issue for their biocontrol. Yet, their application for the control of pest Lepidoptera mainly targets adults, whereas the caterpillars represent the feeding stage.

In this context, this work consisted in searching semiochemicals active on the behavior of caterpillars in a model crop pest, the moth Spodoptera littoralis, using a reverse chemical ecology targeting the larval ORs. First, a transcriptomic study allowed us to identify the repertoire of chemosensory genes expressed in the larva. Then, the function of some ORs was determined via their heterologous expression in Drosophila, in order to identify which olfactory cues are detected by larvae. Last, we combined in silico ligand-targeted modeling, functional analyzes of ORs expressed in Drosophila and behavioral assays to identify new ligands for the targeted ORs that are active on the larval behavior. This work validates the use of ORs as targets to accelerate the discovery of new semiochemicals active on behaviors, which, in the long term could be used for the bioncontrol of herbivorous caterpillars. The data obtained also provide fundamental knowledge in the field of neurobiology and the ethology of larvae.

Bacteriocyte differentiation and cell death in the aphid/Buchnera symbiotic system

Authors: Calevro Federica[2], Parisot Nicolas[3] and Callaerts Patrick[1], [1]KU Leuven, Belgium, [2]UMR 203 INRA/INSA Lyon - BF2i, France, [3]UMR0203, Biologie Fonctionnelle, Insectes et Interactions (BF2i); Institut National des Sciences Appliquées de Lyon (INSA Lyon); Institut National de Recherche

Abstract: Symbiosis is a key source of ecological and evolutionary diversification of eukaryotic organisms throughout the animal and plant kingdoms. In insects that are obligatorily dependent on intracellular bacterial symbionts, novel host cells, the bacteriocytes, have evolved for harboring beneficial microbial partners. These cells constitute a fascinating riddle in developmental and evolutionary cell biology, as the molecular mechanisms governing their homeostasis in response to host physiology remain largely unsolved. Using the pea aphid/Buchnera aphidicola symbiotic system, we demonstrated that bacteriocytes not only house symbiotic bacteria, but they are a core tissue in aphid physiology: (i) they are sensors of nutritional stress and respond to amino acid depletion by entirely reprogramming their transcription and modifying their sizes and numbers, (ii) they are highly dynamic cells, adjusting their growth and death, and their symbiont load to the variation of the aphid demand throughout its developmental cycle. These studies led to the discovery of a non-apoptotic and non-autophagic form of cell death, novel for insects, involved in the elimination of senescent bacteriocytes. Combining molecular and cellular approaches we characterized aphid bacteriocyte cell death as a multi-step process that starts with the hypervacuolation of the endoplasmic reticulum, and is followed by a cascade of cellular stress responses including the formation of autophagosomes in intervacuolar spaces, activation of oxygen reactive species, and Buchnera endosymbiont degradation by the lysosomal system. To address the molecular mechanisms governing bacteriocyte cell death, we annotated and studied the expression patterns of apoptosis pathway genes in the pea aphid. We found that, while the executive pathway of apoptosis is incomplete, with homologs for only four out of the eight proteins present in Drosophila melanogaster, apoptosis inhibitors underwent a large gene expansion, with over 30 Inhibitor-of-Apoptosis Proteins (IAPs) (contrary to 4 to 7 in other insects). Tissue-specific qRT-PCR and RNAseq analyses have shown that only two apoptotic effectors are induced in senescent bacteriocytes, while several apoptosis inhibitors are concomitantly over-expressed. We have confirmed the anti-apoptotic role of these bacteriocyte cell death-associated IAPs in heterologous expression experiments using a tractable in vivo model, the D. melanogaster developing eye. The induction of a restricted set of strong anti-apoptotic IAPs provides a possible mechanism whereby apoptosis is prevented in senescent bacteriocytes, enabling the emergence of a novel cell death process. Considering that aphid IAPs are differentially expressed in different life stages and tissues, this suggests an as yet not understood functional diversification.

Agriculturally Relevant Venom Peptides Derived from Arthropods. A Systematic Review Of Known Venom Peptides With A View To Their Development As Novel Bioinsecticides

Authors: Calvert Robert, Newcastle University, United Kingdom

Abstract: The European Green Deal aims to, by 2030, improve insect pest management (IPM) strategies whilst halving the current usage of chemical and non-environmentally friendly pesticides used in agriculture. A recent study has highlighted that the European Green Deal could result in a crop yield reduction of 10-20 percent if only current IPM strategies are utilised. Looking towards insect antagonists, such as spiders and parasitoid wasps, we discover a treasure trove of insecticidal venom peptides, many with novel modes of action. Though promising, only κ/ω-ACTX-Hv1a derived from the spider Hadronyche versuta has been developed by Vestaron Corp as a bioinsecticide in the USA. The development of new biological insecticides derived from arthropod venom peptides could help mitigate this loss, whilst minimising off-target effects on ecosystems. This systematic review used the PRISMA guidelines to collate published insecticidal venom peptides derived from arthropods into a potential database and makes recommendations for their future development.

Early establishment of the omnivorous predator Nesidiocoris tenuis increased uptake of biological control in tomato. Is it an alternative for others?

Authors: Calvo Francisco Javier[1], Soriano José David[1] and Moreno Jesús[1], [1]R&D Koppert Biological Systems, Spain

Abstract: The tobacco whitefly, Bemisia tabaci and the tomato borer Tuta absoluta are major pests in tomato crops. Laboratory trials showed that Nesidiocoris tenuis could be an effective biological control agent of T. absoluta. Nevertheless, to be effective against T. absoluta under greenhouse conditions, it was necessary to develop an alternative release method. The adult predators were released on seedlings before transplanting to inoculate the plants with predator eggs. Nymphs started to emerge immediately after transplanting, once the plants were inside the greenhouse. With this method, the predator was already present in the greenhouse before the occurrence and in sufficient numbers to provide effective whitely and T. absoluta control. Here we present the results from the experiments conducted to develop this early release method and to evaluate the possibilities of other natural enemies for augmentative biological control when combined with this release estrategy. Additionally, we show the implications of the implementation of this new tactic in the uptake of augmentative biological control in southern European tomato crops and how this could serve as an example for other areas.

SCAN-Clim: a tool to support climate suitability analysis of plant pests based on climate classification.

Authors: Campese Caterina[1] and Maiorano Andrea[1], [1]European Food Safety Authority

Abstract: Climate suitability analysis is a crucial step in evaluating the likelihood of establishment of an invasive pest in an area. SCAN-Clim is a tool designed to perform climate suitability analysis based on climate classifications, thus evidencing the occurrence of climates that favour pest development and persistence in a specific area. The current version is the first prototype of the tool, developed in R and publicly available (https://zenodo.org/record/5780031#.YhZh6OjMKUI). The tool is currently used to support EFSA climate suitability analysis for pest categorisation and for quantitative pest risk assessment, under EU mandate. Tested on over 34 EFSA opinions, SCAN-Clim significantly improved the production of climate suitability maps, guaranteeing a standardised map format and providing clear documentation on the tool inputs and outputs. Further improvements will include the development of an interactive web app that will be freely accessible for registered users through the EFSA R4EU Portal (expected to be delivered in 2022).

Climate suitability analysis in the context of EFSA Pest Risk Assessment. Amyelois transitella, the navel-orange worm, as a case study.

Authors: Campese Caterina[1], Maiorano Andrea[1] and Van der Werf Wopke[2], [1]European Food Safety Authority, [2]Wageningen University & Research

Abstract: EFSA conducts plant pest risk assessments (PRA) under EU mandate. The assessment of the potential area of establishment is based on the presence of suitable hosts in combination with suitable climate. We conduct systematic literature search to collect data on pest distribution and eco-physiology, to develop pest-specific climate suitability models. We detail the full process, applied to the polyphagous pest Amyelois transitella, currently present in North and South America, but absent from the EU territory. Following two EC mandates, EFSA completed a pest categorisation and it is currently conducting a PRA. For this PRA, we collected 771 scientific documents, screened at title-abstract level. Out of these 191 studies were further screened as full-text. Ninety-seven studies were selected for data extraction. Out of these, 69 contained information on pest distribution and 51 on eco-physiology. We extracted 160 geographical-presence-records, out of which 91 related to specific locations with geographical coordinates. Climate suitability analysis was conducted based on the Köppen–Geiger climate classification and modelling with Climex. Preliminary results showed that, if the insect enters in the EU territory, it is more likely to establish in Southern and Mediterranean areas of the EU, where it could cause an impact on susceptible EU crops.

Effects of thermal extremes on male bumble bee reproduction

Authors: Campion Claire[2], Rajamohan Arun[1] and Dillon Michael[2], [1]UDSA ARS, [2]University of Wyoming, United States

Abstract: Bumble bee populations are increasingly under threat from habitat fragmentation, pesticides, pathogens, and climate change. Climate is likely a prime driver of declines in abundance and distribution, as bumble bees are limited by their thermal tolerance. However, the tolerance of whole organisms often exceeds that of their gametes; for example, insects can be sterilized by temperatures below their upper thermal tolerances. In Bombus, males are independent from the colony and can withstand extreme temperatures, but whether these temperatures compromise spermatozoa is unclear. Using commercially-reared Bombus impatiens males, we measured how exposure to sublethal temperatures near male critical thermal minimum and maximum impact spermatozoa viability. We measured temperature effects on spermatozoa in intact males and outside the body to determine if males are potentially protecting spermatozoa. A live dead assay and cell counter were used to estimate sperm count and viability. Males exposed to 45^{0}C for 85 minutes had significantly lower spermatozoa viability (control= 80%, heat= 58%). However, males exposed to 4^{0}C for 85 min had no significant decrease in spermatozoa viability (control=82%, cold= 76%). We discuss how exposure time may influence temperature effects on viability and the role of males in protecting sperm from damage due to temperature exposure.

Influence of conservation agriculture on carabid community's diet revealed by high throughput sequencing

Authors: Canard Elsa[1], Sacco-Martret de Préville Ambre[2], Ortiz-Martinez Sebastian[1], Plantegenest Manuel[3], [1]INRAE, UMR IGEPP, [2]INRAE, UMR IGEPP, France, [3]L'Institut Agro, UMR IGEPP

Abstract: Conservation agriculture is developing rapidly as part of the promotion of environmentally friendly agriculture. However, the consequences of conservation agriculture on trophic interactions and biological control remain poorly known. We used DNA-based gut content analyses to reveal the diet of the entire carabid community of winter wheat fields cultivated under different soil management systems (conservation and conventional) in Brittany, France.

In five pairs of fields, 985 carabid individuals belonging to 35 species were trapped alive in April, May, and June, the period of highest carabid abundance in the region and habitat under study. To avoid overrepresentation of the consumer DNA, we used regurgitates for large carabids. For small carabids, the whole body was processed.

DNA was amplified using fwhF2 and fwhR2n primer pairs (Vamos et al., 2017), targeting a 254bp fragment of the mitochondrial COI region. Amplicons were sequenced employing MiSeq Illumina run v2 and sequences were treated using a modified Dada2 pipeline using a custom-made reference database for taxonomic assignation.

739 single ASVs were detected mostly corresponding to invertebrate pests, such as slugs and aphids, but also to other predators, such as spiders and to organisms involved in the decomposition of organic matter, such as earthworms and springtails.

Profiling smallholder vegetable crops production landscape ecologies for sustainable management of viral diseases and associated vectors

Authors: Canas Luis[2], Sseruwagi Peter[1], [1]Mikocheni Agricultural Research Institute (MARI), Dar-es salaam, Tanzania, [2]Ohio State University, United States

Abstract: Studies to assess viral diseases and insect vector abundance were carried out in three major vegetable crops production landscape ecologies: at low (Coast), medium (Morogoro) and high (Iringa) altitudes from 2016 to 2018 in Tanzania. Vegetable crops are grown with and in the immediate surroundings of multiple crop and non-crop plant species that serve as good sources of inoculum for plant viruses and the associated insect vectors that affect vegetable crops in smallholder farming systems. There was a high incidence (60-94%) of plants infected with viral diseases in the smallholder vegetable fields. Similarly, there was a high abundance of insect vectors such as aphids, whiteflies, leaf hoppers and thrips. The study showed that 87.5% of the farmers were aware of viral diseases as one of the major production constraints to vegetable crops production. There was a fair knowledge of the insect pests, including aphids, caterpillars, leaf minors and whiteflies. However, the respondents were less aware of the biology (cause, mode of transmission and spread), ecology (cropping practices and host range) and integrated management of the viral diseases and associated insect vectors. Thus, majority of the farmers resorted to use of pesticides as their first and 'only' line of defense. Unfortunately, this has not only failed to decrease viral disease incidences, but it has also led to ineffective pest control, partly due to lack of knowledge of disease and pest species identity and diversity, biology and production ecology and sustainable management strategies. The study findings were used to create awareness among vegetable producers, agricultural extension officers, agro-dealers, scientists and government plant health regulatory agencies on the importance of understanding the ecology and biology of crop-infecting diseases and associated insect vectors. The study results will be discussed in the context of understanding virus-vector interactions in smallholder cropping ecologies, to advise IPM strategies that encourage the use of cultural practices to manage the viral diseases and insect vectors, with reduced pesticides usage.

Potential for insecticide resistance on Kenyan populations of Tuta absoluta

Authors: Canas Luis[2], Nyamu Denis[2], Mbaka Jesca[1] and Andrew Michel[2], [1]Kenya agricultural & livestock research institute, Kenya, [2]Ohio State University, United States

Abstract: Tomato (Solanum lycopersicum) is one of the most important vegetable crops cultivated for the domestic market in East Africa. In East Africa particularly in Kenya, most tomato growers are small scale farmers, practice open field cultivation and are faced with invasive pest species. Tuta absoluta (Meyrick, 1917) (Lepidoptera: Gelechiidae), commonly referred to as the South American tomato moth, is a major invasive pest species in Kenya threatening tomato production. Traditionally this pest has been controlled using conventional insecticides in many parts of the world where it has been introduced. Several classes of insecticides have been used in the management of this pest including organophosphates, pyrethroids, diamides and spinosyns. This over-reliance and overuse of pesticides has led to insecticide resistance development of T. absoluta in many parts of the world.

Diamides include the most recent class of insecticides that has been widely used to manage T. absoluta in Kenya. Its popularity stem from its narrow spectrum, its low mammalian toxicity and less non-target effects. Recently, control failures have been reported by Kenyan farmers. This calls for investigations of a possible resistance of T. absoluta to diamides. Its detection will inform stakeholders of the need to incorporate insecticides with different modes of action as well as incorporate other management techniques and will aid in strengthening current pest management techniques. Integrated pest management packages for tomatoes have been developed through collaborative efforts of various institutions notably KARLO (Kenya) and Ohio State University. These packages include proper use of chemicals through the development of appropriate rotations for pest management.

Counting bees like birds: Roadside bumble bee monitoring in Canada

Authors: Cannings Sydney[2], S. Sheffield Cory[3], Leung Maria[1], [1]Consultant, Canada, [2]Environment and Climate Change Canada, Canadian Wildlife Service, Canada, [3]Royal Saskatchewan Museum, Canada

Abstract: A number of bumble bee species are known to have declined dramatically, but sparse monitoring data has made it difficult to assess the magnitude of these declines across the broad ranges of some of these species in North America. Extensive, simple and effective monitoring programs are needed across the continent to establish range-wide trends. In this study we sampled bumble bees with hand-netting along roadsides in northwestern Canada, using established breeding bird survey routes as a basis of our effort. Within each 36-km transect, bees were sampled for ten minutes at each of ten sites. Early results show that species that have declined in southern Canada and the United States (e.g. Bombus bohemicus, B. occidentalis, and B. suckleyi) are still present in the northwest, and probably at historical densities.

Predators under spotlights! Behavioral responses of Orius insidiosus to supplemental light spectra and intensity: first step towards selection of light favoring predator in a tri-trophic system

Authors: Canovas Morgane[5], Abram Paul[1], Dorais Martine[4], Galarneau Pierre[2] and Galstian Tigran[3], [5]Université Laval, Canada, [1]Agriculture and Agri-Food Canada, Canada, [2]National Institute of Optics, Québec, Canada, [3]Physics, Physical Engineering & Optics department, Laval University, Québec, Canada, [4]Phytology department, Laval Unitersity, Québec, Canada

Abstract: Supplemental lighting (SL) is now considered as an efficient tool to disrupt pest activity, including in greenhouses. Despite its current use in controlled environments, SL potential to favor biocontrol agents have been overlooked, especially regarding predators. Our approach is to use Light Emitting Diodes (LEDs) to control SL environments (spectra × intensity × photoperiod combinations) and screen different SL combinations to identify optimal conditions for arthropod predators. As light both have direct and indirect (plant or prey mediated) effects on predators in “plant-herbivore-predator” tri-trophic systems, SL-related responses of the whole system must be considered. We selected an economically relevant study system, linked to an actual horticultural concern. The greenhouse cucumber (Cucumis sativus) is a model plant since the beginning of SL sources’ development. Its photobiology is now well known, and SL conditions have been accordingly optimized in commercial greenhouses. Like various crops, cucumbers are susceptible to thrips activity, impacting both plant performance and fruit quality. The thrips Frankliniella occidentalis (Pergande) is considered as a major international pest, causing substantial losses in greenhouses worldwide. As F. occidentalis pesticide resistance globally strengthens, biocontrol should increasingly appear as an appealing alternative. The predatory bug Orius insidiosus (Say) is an efficient generalist biocontrol agent, widely use against thrips. However, its photobiology remains mostly unknown and diapause issues are frequent under greenhouse conditions, disrupting biocontrol. To select optimal SL conditions for O. insidiosus and ensure biocontrol enhancement in commercial greenhouses, predator’s responses to light environment will be investigated at various spatiotemporal scales. The presented experiment corresponds to the first step and focus on O. insidiosus predation performance at small scale. Both prey and predator were exposed to monochromatic spectra treatments under a range of light intensities, based on previous works with other bug species and wavelengths used to promote crop productivity. Locomotion (walking time, distance, speed, etc.) and alimentation (time before first capture, time spent eating, attack/defense, etc.) were analyzed from video tracking data. Results were used to identify the most favorable light spectra × intensity combinations for O. insidiosus, to consider them in subsequent experiments. To our knowledge, those observations are the first concerning O. insidiosus behavior under SL at small scale, as well as being the initial act towards optimizing SL conditions for this widespread biocontrol agent.

Promoters and effectors for the development of a Killer-Rescue system in Aedes aegypti (Diptera, Culicidae)

Authors: Carabajal Paladino Leonela Z[4], Sy Victoria[4], Keen Elizabeth[4], Alphey Luke[4], Leftwich Philip[1], Cuber Piotr[4], YL Tng Priscilla[3], Wilson Ray[4], Potts Robert[2] and Dhokiya Vishaal[4], [1]The Pirbright Institute, School of Biological Sciences, University of East Anglia, Norwich Research Park, United Kingdom, [2]The Pirbright Institute, The Roslin Institute, University of Edinburgh, United Kingdom, [3]The Pirbright Institute, The Royal Veterinary College, London, United Kingdom, [4]The Pirbright Institute, United Kingdom

Abstract: Mosquito-borne diseases are a severe public health burden, causing morbidity and mortality worldwide. The mosquito Aedes aegypti is found in tropical and sub-tropical regions throughout the world and is a vector for multiple arboviruses including chikungunya, Zika, and dengue; no safe and effective vaccines currently exist for these diseases. The primary preventative method for reducing new infections from these diseases is mosquito population control, primarily eliminating larval habits by physical or chemical measures. Chemical insecticides are themselves challenged by emerging resistance, and are also relatively non-selective.

Recent advances in genetics-based vector control methods such as gene drives could modify populations of disease vectors such as Ae. aegypti to make them less able to transmit pathogens. This has caused both excitement about the prospect of disease eradication and concerns around safeguards. Drive mechanisms that balance these competing interests for invasiveness and control are therefore highly desirable.

Here we characterise our work towards building the components of one such system as a Killer-Rescue drive. This simple toxin-antidote system requires effective lethal genes and efficient rescues, and is attractive due to its inability to spread to neighbouring populations and self-limitation over time. We have developed and tested a variety of lethal genes; through the bipartite Tet-OFF system. This has allowed us to systematically characterise different combinations of lethal proteins, gene expression and insertional effects, while simultaneously developing novel tools for the mosquito research community.

We characterised the expression pattern of two different transgene insertions of a midgut specific promoter (Carboxypeptidase A - AeCPA) driving the transactivator tTA, by crossing the mosquito lines with a TRE line expressing a fluorophore, and then tested them against a range of inducible lethal effectors.

The two AeCPA lines demonstrated high expression of tTA from the late larval stage onwards in the midgut of both males and females, but with different levels of ectopic expression, highlighting the importance of the transgene insertion site for expression.

Regarding the analysis of the different lethal genes crossed with the promoter lines, we observed death, reduction in female fecundity or no effect depending on the combination of promoter and lethal lines tested. The Tet-OFF system has proven useful in the evaluation of the different components required for the potential development of a Killer-Rescue system in Ae. aegypti, allowing the identification of a number of promising promoter-effector combinations.

Focus on Antarctic Springtails: the true “pachyderms” of the Continent

Authors: Carapelli Antonio[4], Leo Chiara[2], Cucini Claudio[3], Frati Francesco[2], Nardi Francesco[2], Convey Peter[1] and Paolo Fanciulli Pietro[2], [1]British Antarctic Survey, NERC, United Kingdom, [2]Department of Life Sciences, University of Siena, Italy, [3]Dept. of Life Sciences, University of Siena, Italy, [4]Dept. of Life Sciences, University of Siena, Italy

Abstract: From an evolutionary standpoint, springtails (Collembola) are considered an archaic terrestrial group, part of the earliest diversification of hexapods, and differing from derived insects in the peculiar structure of (internal) mouth parts and by the primitive lack of wings. With ca. 9000 described species, springtails can be found in almost every terrestrial environment of the planet, including the Antarctic, where a basic ecosystem supports the development of communities of a limited number of taxa that are active only during the summer season.

Together with mites, springtails are the most diverse group of Antarctic land invertebrates and amongst the largest strictly terrestrial animals of the Continent. In Antarctica, springtails have a long evolutionary history and must have survived multiple glacial cycles in refugia. Consistent with the scale of isolation of Antarctic terrestrial habitats and the limited active dispersal capabilities of springtails, most population genetic studies so far performed on Antarctic species have showed moderate to high levels of intraspecific genetic divergence. However, the extreme environmental conditions of Antarctica may have preserved successful morphological traits even if clear genetic divergence has taken place, fostering morphological stasis. It is consequently likely that a large number of cryptic taxa may be present. Therefore, we have recently investigated the morphology and genetic differentiation of springtail species through a multidisciplinary comparative analysis, testing the efficacy of an integrative taxonomic approach to assess whether or not cryptic speciation is at play in Maritime and Continental Antarctica.

In addition, metabarcoding analyses of the gut microbial communities of some springtail species, and sequencing of the transcriptome of specimens stressed at temperatures higher than measured in their natural environment, as well as mitogenome comparison among taxa subject to different evolutionary pressures, were also performed. The aim of these studies was to evaluate the resilience of specimens exposed to climate change, and to characterize the microbiomes associated with species from the two Antarctic bioregions.

The results of combined morphological and genetic studies clearly suggest that Cryptopygus terranovus and Friesea antarctica both comprise complexes of at least three cryptic species. Some mitochondrial genes involved in the oxidative phosphorylation process are under positive selection. RNA-seq results from C. terranovus detect differences in the gene expression related to protein unfolding, protein degradation and synthesis of fatty acids between springtails arbitrarily stressed at +6°C, with respect to control conditions. Data obtained from the microbiome analyses highlight (as previously detected in non-polar species) the occurrence of interesting OTUs, including from genera such as Streptomyces and Bacillus.

Invasion biology of the American Boatman Trichocorixa verticalis verticalis in Western Europe: The role of ecophysiology and biological interactions

Authors: Carbonell José Antonio[4], Millán Andrés[2], J. Green Andy[3], Coccia Cristina[1], Velasco Josefa[2], I. Sánchez Marta[3] and Céspedes Vanessa[3], [1]Center of Applied Ecology and Sustainability (CAPES), Pontificia Universidad Católica de Chile, Santiago, Chile, Spain, [2]Department of Ecology and Hydrology, Regional Campus of International Importance “Campus Mare Nostrum” University of Murcia, Espinardo Campus, Murcia, Spain, [3]Wetland Ecology Department, Estación Biológica de Doñana (EBD-CSIC), Seville, Spain, [4]Wetland Ecology Department, University of Seville, Spain

Abstract: The corixid (lesser water boatman) Trichocorixa verticalis verticalis (Fieber, 1851) originates from North America is the only aquatic Hemipteran alien to Europe, where it is concentrated on the Atlantic coastal plain in the south west of the Iberian Peninsula. Recent studies of its ecophysiology, ecology and interactions with native corixids are reviewed. The main questions addressed are: (1) What is its potential non-native range within Europe and beyond? (2) How does its physiological performance compare to that of native species? (3) What physiological/biological factors determine why it is so dominant in saline wetlands yet so much rarer in low salinity wetlands? (4) How does its trophic ecology relate to that of native species? (5) What effects is it having on other aquatic communities? We show that this species has the potential to disperse across a high proportion of the coastal European lowlands across a wide range of latitudes, and the projections are not significantly modified by climate change. The invasion success of Trichocorixa verticalis in permanent, saline wetlands seems to be mediated by high plasticity in response to changes in temperature and salinity, together with high plasticity in diet. However, the most important factors seem to be its higher fecundity compared to native corixids, and ability to reproduce throughout the year. Moreover, although its eggs are not resistant to drought, epizoochory of eggs by waterbirds such as flamingos may contribute to the expansion of this alien species around the Mediterranean region. As in the native range, Tricocorixa verticalis is an important predator in its introduced range, and is likely to reduce the abundance of native Anostraca such as brine shrimps, thus increasing phytoplankton abundance through trophic cascades. According to microcosm experiments, Trichocorixa verticalis is able to live and reproduce in freshwater in the presence of native corixids, so its rarity in fresher wetlands may be explained by its greater susceptibility to parasitic mites, together with a higher predation rate by Odonata larvae compared to native corixids. The presence of Trichocorixa verticalis has been shown to modify the distribution and co-occurrence patterns of native corixids, niche differentiation being the main mechanism to avoid competition among the invasive and native species, enabling coexistence and resource partitioning.

Finding odor-linked resources in a turbulent and complex odor landscape

Authors: Cardé Ring, Department of Entomology University of California Riverside, CA, United States

Abstract: Many insects locate resources such as a mate, host or food by tracking the odor plumes these resources generate to their source. As the plume is carried downwind, it becomes more spatially dispersed and dilute, but filaments above behavioral threshold can persist for long distances. Plume tracking can extend to 100s of meters. Flying insects track along a plume by flying upwind, sensing the wind's direction by the optomotor reaction, not by detecting a concentration gradient or by mechanoreception of wind flow.

In the case of moths, there should be strong selective pressure for males quickly locating calling (pheromone-emitting) females. Females as well may compete for mates. In many moth lineages, a female can be triggered into imitating calling after detecting pheromone from nearby females. Such contagious calling should concentrate males in their vicinity and also attractant more males. Females can also be induced to call by host-plant volatiles (HPVs).

We now know that most moth pheromones are blends of 2-4 compounds, often released in precise ratios, thereby creating a species-specific communication channel. A second factor seemingly concentrating males and females near their host plants is the detection of HPVs. This seems to be reflected in many cases wherein addition of HPV to the pheromone blend increases capture of males. What remains to be discovered is how influential HPVs are in concentrating males in host plant patches to position themselves in the likely vicinity of calling females.

Similarly, female anthropophilic mosquitoes also may use odors from human hosts as cues for house entering, which can occur well before biting.

These and other recent studies suggest that volatile "habitat" chemical cues, released over larger areas in larger quantities, may concentrate responders in areas where more specific, resource-linked odors are more apt to be found.

Lessons learned from fruit fly eradication efforts in California

Authors: Carey James, University of California, Davis, United States

Abstract: Drawing from analyses of and multiple publications on the 70-year/10,000 fly database containing detection details for individual flies involving 17 different fruit fly species in California, I will offer answers to the following questions: What are the probabilities of first and subsequent fruit fly outbreaks in a randomly-chosen 10 x 10 km grid cells in the state? What is the spatial distribution of outbreak risk? What is the meaning of zero capture? O a single fly? Which species of fruit fly is the most invasive? Does the interval between new outbreaks change after each outbreak? Once eradication is declared what is the interval before fruit fly recurrence? How concerned should grower be in located just outside of a regulated area? Why is eradication so difficult? I will end with a synopsis of lessons learned including policy implications for future intervention programs on tephritids.

Development of Leishmania parasites in Culicoides

Authors: Carpenter Simon[4], Volf Petr[1], Sadlova Jovana[1], Siriyasatien Padet[3], Bates Paul[2] and Becvar Tomas[1], [1]Dept. Parasitology, Faculty of Science, Charles University, Prague, Czech Republic, [2]Division of Biomedical and Life Sciences, Faculty of Health and Medicine, Lancaster University, Lancaster, United Kingdom, [3]Vector Biology and Vector Borne Disease Research Unit, Department of Parasitology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, [4]Institute for Animal Health (IAH), Pirbright Laboratory, United Kingdom

Abstract: Leishmaniases are vector-borne diseases whose etiological agents are protozoan parasites of the genus Leishmania (Kinetoplastida: Trypanosomatidae). The genus consists of four subgenera, three of them, Leishmania, Viannia and Sauroleishmania, are transmitted by phlebotomine sand flies (Diptera: Phlebotominae) which represent their only proven vectors. Some authors reported wild-caught biting midges PCR-positive for Leishmania but we experimentally demonstrated that Culicoides nubeculosus and Culicoides sonorensis are refractory to development of the principal Old-World parasites, namely L. major, L. infantum and L. donovani.

On the other hand, the vectors of the most ancient phylogenetic group of leishmania, parasites of the subgenus Mundinia, are not known. The recently established subgenus Mundinia consists of 5 species known before as L. enriettii complex – L. enriettii, L. macropodum, L. orientalis, L. martiniquensis and the unnamed species from Ghana. First two species are parasites of guinea pigs and red kangaroos, respectively, but rest three are causing human diseases characterized by symptoms varying from self-healing skin lesions to visceral form. In Australia, biting midges of the subgenus Forcipomyia (Lasiohelea) were found with heavy late stage infection of L. macropodum and recent studies demonstrated development of Leishmania orientalis in Culicoides sonorensis.

Here we studied experimental infections of eight leishmanial strains belonging to five Mundinia species. Infection rates and parasite localization in C. sonorensis was compared to several sand fly species, namely Phlebotomus argentipes, Phlebotomus duboscqi and Lutzomyia migonei. Our experiments demonstrated high susceptibility of C. sonorensis to L. orientalis and suggest that Mundinia parasites could be transmitted by midges rather than sand flies. Therefore, we propose that biting midges should be assessed in the field when searching for the vectors of L. enriettii, L. martiniquensis and other related parasites of subgenus Mundinia.

Ticks Find Hosts Using Infrared Homing

Authors: Carr Ann[2] and Salgado Vincent[1], [1]BASF, United States, [2]Vanderbilt University, United States

Abstract: Ticks are second only to mosquitoes as vectors of disease to humans and animals. Commercial insect repellents provide an effective means of personal protection against potentially infectious tick bites by disrupting host-seeking, but their mechanism of action and indeed the sensory cues used in host-seeking are not well understood. While there is anecdotal evidence that ticks and other ectoparasites are attracted to heat, it has never been demonstrated that they sense radiant heat. Using a novel thermotaxis assay to investigate the detection range, temperature dependence and repellent sensitivity of heat perception in ticks and to identify the sensory organ responsible for this sense, we showed that Amblyomma americanum and Dermacentor variabilis ticks home in on objects at human body temperature by sensing radiant heat with the Haller's organ posterior capsule, a covered spherical pit organ that was previously thought to be olfactory. An aperture in the capsule cover confers directionality and highly reflective interior surfaces of the capsule concentrate radiation, to provide enough sensitivity to locate a human from several meters away. Low concentrations of the insect repellents DEET, picaridin, 2-undecanone, citronellal and nootkatone eliminated thermotaxis without affecting olfaction-stimulated tick host-seeking behavior. We anticipate that this discovery will significantly aid insect repellent research and provide novel targets for the development of innovative integrated pest management programs and personal protection strategies for ectoparasites and vector-borne disease.

The Evolution and Diversity of Parental Care in Insects

Authors: Carroll Scott[1], Washington, Jr. Ralph[2], [1]University of California, Davis Inst. for Contemporary Evolution, United States, [2]University of California, United States

Abstract: Insects exhibit a stunning variety of ecologies and life histories, which has contributed to and been influenced by the evolution of a tremendous diversity of parental care strategies. Yet, outside of eusociality, the evolution of insect parental care has been the subject of limited systematic study. Elaborated non-eusocial insect parental care is well represented in certain groups of beetles, flies, cockroaches, and heteropterans. At the same time, it is unclear how often parental care has evolved, what forms it takes, and the extent to which it is phylogenetically enabled or constrained. We review the diversity of insects in which parental care has arisen, plumbing lesser known instances to build a stronger data set. Incorporating recent phylogenetic advances, we compare among taxa to test hypotheses about the eco-evolutionary conditions under which selection favors added investment in individual offspring. By combining these approaches, we aim to form a deeper understanding of how, when, and where parental care evolves within the Insecta, and how their capacities and constraints have shaped both insect niche evolution and resulted in types of parental care unobserved in other animals. We expect our findings from insects to help inform and broaden the prevailing vertebrate-biased theory about the eco-evolutionary dynamics of parental care.

'Neoclassical' Biological Control: prescriptive eco-evolution of native biological control agents

Authors: Carroll Scott[3], Loye Jenella[2] and J. LeRoux Johannes[1], [1]Department of Biological Sciences, Macquarie University, New South Wales, Australia, [2]Department of Entomology and Nematology University of California, Davis, United States, [3]University of California, Davis Inst. for Contemporary Evolution, United States

Abstract: In Classical Biological Control, 'invasive' species are reunited with their natural enemies, re-establishing lost ecological connections as if turning back the eco-evolutionary clock to match the native range. Most environmental weeds, however, receive little or no management, leaving trophic relationships to perhaps ultimately arise from within the resident community. 'Neo-classical' Biological Control is a prospective approach that leverages the latent adaptive potential of native herbivores to exploit established non-native species. By spinning the eco-evolutionary clock forward, it aims to control populations by accelerating their ecological integration into resident communities.

We believe that two fundamental drivers of Neoclassical opportunities are predicted to be phylogenetic niche conservatism and ecological opportunity. Prescribed evolution in wild insect herbivores is feasible because naturalized plants frequently have native family members and even congeners in their new ranges, much more so than expected by chance. Related plants in turn commonly share related herbivores within and among continents. When introduced, those plants can be evolutionary traps for partially pre-adapted resident herbivores, hindering their survival and reproduction or exposing them to novel risks. Neo-classical interventions seek to resolve critical deficits in pre-adaptation that limit the spread of resident herbivores onto targeted non-natives. And secondly, when those plants are abundant and underexploited, differences in ecological opportunity suggest that even struggling 'maladapted' herbivore lineages, if able to persist upon them, will sometimes show disproportionately increased fitness compared to 'adapted' lineages feeding on highly contested native hosts.

Those eco-evolutionary dynamics and related genetic and ecological factors can reinforce the field efficacy of prescribed interventions such as mass rearing under selection to improve phenotypic match to local opportunities. Such work may be conducted in the same semi-field facilities that are used to screen Classical control agents for nontarget risks. Translating resulting fitness gains into natural wild is the challenge. We will touch on multiple scenarios where Neoclassical Biological Control practices could be trialed to extend the reach of current control efforts in an Epoch of increasingly novel ecosystems

Identification and characterisation of a Masculinizer homolog in the diamondback moth Plutella xylostella

Authors: Carter Ruth[1], Lovett Erica[1], Alphey Luke[1], Harvey-Samuel Tim[1] and Norman Victoria[1], [1]The Pirbright Institute, United Kingdom

Abstract: Recently, a novel sex-determination system was identified in the silkworm (Bombyx mori) in which a piRNA encoded on the female-specific W chromosome silences a Z-linked gene (Masculinizer) which would otherwise initiate male sex-determination and dosage compensation. Masculinizer provides various opportunities for developing improved genetic pest management tools. A pest lepidopteran in which a genetic pest management system has been developed, but which would benefit greatly from such improved designs, is the diamondback moth, Plutella xylostella. However, Masculinizer has not yet been identified in this species. Here, focusing on the previously described 'masculinizing' domain of B. mori Masculinizer, we identify P. xylostella Masculinizer (PxyMasc). We show that PxyMasc is Z-linked, regulates sex-specific alternative splicing of doublesex and is necessary for male survival. Similar results in B. mori suggest this survival effect is possibly through failure to initiate male dosage compensation. The highly conserved function and location of this gene between these two distantly related lepidopterans suggests a deep role for Masculinizer in the sex-determination systems of the Lepidoptera.

Study of an insecticide, the sulfoxaflor, on learning and memory honeybee's

Authors: Cartereau Alison[1], Thany Steeve[1] and Taillebois Emiliane[1], [1]LBLGC, University of Orléans, France

Abstract: Honey bees are major pollinators of crops and wild plants, and are therefore essential to the agricultural economy and wild plant diversity. Unfortunately, despite their important role in human activities, there is clear evidence of the decline of honey bee colonies worldwide. Several studies have shown that pesticide exposure is involved in this decline. Among insecticides, neonicotinoids are the most widely used to control a wide range of insect pests. These insecticides target neuronal nicotinic acetylcholine receptors (nAChRs) which play an important role in cognitive function. Recently, sulfoxaflor (SFX) has been used to replace neonicotinoid insecticides. In the present study, we have evaluated the effect of sublethal concentration of SFX on honey bees Apis mellifera learning and memory processes. Using the proboscis extension response paradigm, we found that, depending on the conditions, SFX can impair learning and memory recovery. Relative quantitative PCR experiments demonstrated different nAChRs expression levels in the bee brain after SFX exposure. These results demonstrated that a sublethal dose of SFX could affect bee learning performance and modulate the expression of specific nAChR subunits in the brain.

Pheromones transport: role of aerosols and multiscale antennae on odor capture

Authors: Casas Jerome[1], Engels Thomas, Jami Ludovic, Durêche Jean-François, Zemb Thomas, Krijnen Gijs[3], Jaffar-Bandjee Mourad[1] and Steinmann Thomas[3], [1]University of Tours, France, [2]University of Tours/CNRS, France, [3]University of Twente, Netherlands

Abstract: Understanding the role of aerosols in pheromone transport is of fundamental interest as aerosol phase can alter the transport properties, accessibility and chemical reactivity of the pheromones in the air. To lay the foundations of our approach in which pheromones partition between a gas phase and an aerosol phase, we will first present the key concepts from thermodynamic theory that are needed to discuss the complex physico-chemical processes at stakes and their consequences. The multiscale modeling of the phase exchanges of pheromone when transported in the air will subsequently be presented. Then, a running experiment with Bombyx moths reacting to air flows differently loaded with aerosols will be described, highlighting their double-edge sword impact. Finally, we will consider the flow around pectinate antennae, for which a mechanistic understanding of odor capture is still lacking. We focus on the functional, two-scales sub-structure of an antenna of Samia cynthia (Lepidoptera, Saturniidae): a brush of sensory filliform sensilla attached to one rami, the supporting tubular structure. We had to plit the structure of the antenna because 3D printing cannot currently fabricate multiscale structures spanning the antennal four orders of magnitude. A semi-analytical model to compute mass transfer, originally developed for heat transfer in pipes, is then adapted. Particle Image velocimetry (PIV) is used with scaled-up physical models for estimating the leakiness of the structure, i.e. the proportion of flow passing through the structure rather than around. The combination of these experimental and modeling approaches delivers the capture efficiency over a biologically relevant range of air speed. We found that two distinct processes are setting pheromone capture efficiency. At low Re numbers, leakiness at the higher organizational scale, i.e. the entire substructure, determines the efficiency of odor capture. At higher Re numbers, advection at the lower organizational scale of a single sensillum is determining efficiency. We then study how to embed the sub-structure within an entire antenna and observe that the multiscale architecture of the pectinate antenna is highly adapted for odor capture over a large range of flow speeds. We end up comparing the efficiency of pectinate antenna with more classical, cylindrical forms and consider why the multiscale antennae have evolved so many times, as well as the possible relationship between antennal forms and pheromone diffusive coefficients.

“Sensory neuron membrane proteins (SNMPs)” indicate distinct roles in olfactory signal detection in insects

Authors: Cassau Sina, Martin-Luther-University Halle Wittenberg

Abstract: The sense of smell enables insects the recognition of vital olfactory signals that are essential for their survival. The detection of various odorants is dependent on a complex interplay of proteins expressed by the insects' olfactory sensory neurons (OSNs) and the adjacent support cells which are housed together in the main chemosensory units on the antenna, named sensilla. Among the well-studied odorant binding proteins (OBPs) and various families of olfactory receptors, another class of proteins appear to play an important role in the detection of distinct odorants, termed the sensory neuron membrane proteins (SNMPs). SNMPs are classified as CD36 proteins due to their sequence identity to this family of two-transmembrane receptors of various lipophilic compounds. Here we assess the distribution pattern of two SNMP homologs in the antenna of the hemimetabolic desert locust Schistocerca gregaria via immunohistochemical investigation. To further elucidate the role of SNMPs in insect olfaction, we performed functional investigations with HEK293 cells expressing each SNMP homolog utilizing fluorescent lipid analogs. The data suggests that SNMPs play an important role in detecting and possibly even eliminating specific lipophilic compounds, which may aggregate in the sensillum lymph after the initial detection of odorants.

Connecting the pieces: Evolution of genitalia in Cimicoidea and the phylogenetic revision of the group (Heteroptera: Cimicomorpha)

Authors: Cassis Gerasimos[1], Tatarnic Nikolai[3] and Bonduriansky Russell[2], [1]University of New South Wales, [3]Western Australian Museum, Australia, [2]University of New South Wales (UNSW), Sydney, Australia

Abstract: Cimicoidea is a superfamily of predaceous and ectoparasitic insects that include the infamous human bedbugs. Most species of Cimicoidea practice traumatic insemination, where the male pierces the abdomen of the female and ejaculate directly into the haemoceol. Traumatic insemination is regarded as textbook case of sexually antagonistic coevolution, with elaboration of both male and female genital morphology across the Cimicoidea. Knowledge of genital morphology across the Cimicoidea is still in its infancy, with many of the key works dating to the 1960s and 1970s. To address this shortfall, we have employed microCT methods to virtually dissect male and female genitalia separately and, where possible, in copula. These data have been compiled to (1) assess genital complexity and variation for exemplars of the bedbug, batbug and minute pirate bug families, and (2) optimise character evolution in a phylogenetic context and determine if they exhibit a phylogenetic signal. The consensus tree produced revealed highly unresolved relationships with most families. This limited support between the distribution of traumatic inseminating characters on the phylogeny and currently available phylogenies showing relationships in the Cimicoidea, is likely due to the lack of a well-resolved phylogeny of the Cimicoidea. Higher taxonomic relationships within the Cimicoidea is still in a state of controversy, and several alternative hypotheses for relationships exists. We furthermore, aimed to reconstruct the evolutionary relationship in the Cimcoidea by next-generation sequencing (NGS) to target ultraconserved elements (UCEs) across all Cimicoidea.

Insights into DEET's mode of action in ticks

Authors: Cassone Bryan[1] and Koloski Cody[1], [1]Brandon University, Canada

Abstract: DEET is far and away the most common active ingredient in commercial repellents, providing effective protection against blood-sucking insects and ticks. However, its mode of action appears complex and is not yet fully understood. Since ticks possess a unique sensory structure, the Haller's organ, the specific genes and pathways associated with DEET repellence may differ from insects. Using the American dog tick, Dermacentor variabilis, as our model system, we carried out a series of transcriptional studies to explore the genetic basis of DEET repellence and the relative roles of the Haller's organ and other tissues (synganglion, palps, salivary glands) in DEET recognition. Further, we used a variety of behavioural assays to explore natural insensitivity and the effects of concentration on the repellency. Overall, our studies furthers our understanding of DEET repellence in hard ticks.

Insights into the repellency effect of DEET on human-biting ticks (Dermacentor variabilis)

Authors: Cassone Bryan[1], Duncan Carlyn[1] and Gohl Patrick[1], [1]Brandon University, Canada

Abstract: Developed for use by the United States military nearly eight decades ago, N,N-Diethyl-m-toluamide (DEET) is considered the gold standard in repellents. Despite its widespread commercial availability, the precise mechanisms underlying the mode of action of its active ingredient remain unclear. Most of the research has focused on mosquitoes and fruit flies, and indicate the repellent affects insect taste, smell, and also acts on contact. However, little is known about the underlying basis of DEET repellency in human-biting ticks, including the American dog tick (Dermacentor variabilis). In these studies, we present evidence that DEET acts as both an olfactory confusant and mild acaricide. We further disentangle the relative roles of the Haller's organ in the repellency effect. Finally, we explore natural insensitivity to DEET and the effects of concentration on the repellency of D. variabilis in Manitoba, Canada.

How do trees protect trees from herbivores in urban environments?

Authors: Castagneyrol Bastien[1] and Benot Marie-Lise[2], [1]Inra, France, [2]University of Bordeaux, France

Abstract: Trees are key components of human well-being in urban areas, in particular through urban cooling and improved citizen physical and mental health. Yet, several pest insects are prone to cause major damage and to threaten the health of urban trees. Over the past decades, ecologists had a mounting interest for tree-pest interactions in urban ecosystems and several studies showed that tree-pest interactions are strongly affected by the urban environments. Yet, discrepancies among existing studies are such that it is still unclear what are the main factors driving pest insect damage on urban trees. For instance, the urban environment may enhance herbivory through the heat island effect, favouring the activity of ectothermous herbivorous insects. Alternatively, because of the fragmentation of habitats, the urban environment may alter the diversity and distribution of insectivorous birds, thereby affecting the strength of the top-down control they exert on herbivore populations. Yet, trees, and in particular tree density, are key determinants of both urban temperatures and bird habitats. In this study, we ask how urban temperatures and tree density jointly affect (i) insect herbivory on urban trees and (ii) the top-down control of herbivory by herbivores' enemies. We selected a total of 49 trees from three species along two orthogonal ecological gradients in Bordeaux city (South-Western France): one temperature gradient defined as summer temperatures in a circular buffer of 200m radius centered on sampled trees and one gradient of tree density defined as the percentage of canopy cover in a circular buffer of 20m radius around sampled trees. In each tree, we measured insect herbivory as the percentage of leaf area impacted by insect herbivores. We additionally installed artificial clay caterpillars in the same trees to study predator activity. By linking insect herbivory with predation pressure along well defined ecological gradients, our study will help understand the ecological drivers responsible for tree health in urban environments.

Cephalonomia tarsalis, a promising parasitoid for the control of the sawtoothed grain beetle

Authors: Castañé Cristina[3], del Arco Lidia[2], Agusti Nuria[1] and Riudavets Jordi[3], [3]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain, [2]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain, [1]IRTA, Spain

Abstract: The sawtoothed grain beetle, Oryzaephilus surinamensis (L.) (Coleoptera: Silvanidae) is an important pest in stored rice, particularly because it has developed resistance to some pyrethroids, more precisely to deltamethrin. Cephalonomia tarsalis (Ashmead) (Hymenoptera: Bethylidae) is a specialized parasitoid that attacks larval stages of this beetle and can be an alternative control agent.

We have studied the dispersion of this parasitoid, and we have shown that females were able to disperse, to locate sawtoothed grain beetles and parasitize them when placed at the bottom of a 1.5m paddy rice column (20cm diameter). This result suggests that this parasitoid would be able to find and parasitize these hosts in piles of stored rice, where most of the pest populations are concealed in the 1m upper layer. We have also shown that under optimum environmental conditions (28ºC, 70% relative humidity) this parasitoid can prevent sawtoothed grain beetle population growth, because the final size was more than 90% lower than the population of the control treatment without parasitoids. This suggests that, with periodical releases of the parasitoid, beetle populations could be maintained under control.

Control of the maize weevil, Sitophilus zeamais, with the larval parasitoid Anisopteromalus calandrae in rice big bags

Authors: Castañé Cristina[4], Campos José Miguel[2], Martínez Maria Teresa[2], del Arco Lidia[3], Agusti Nuria[1] and Riudavets Jordi[4], [1]IRTA, Spain, [2]Sustainable Plant Protection, IRTA, Amposta (Tarragona), Spain, [3]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain, [4]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain

Abstract: The maize weevil, Sitophilus zeamais, is a key pest of stored rice that is currently controlled mainly with pesticides. This procedure has well-known associated drawbacks, as the presence of toxic residues in the grain and a decline of efficacy due to repeated applications of the few available active ingredients. Under optimum conditions in laboratory tests, the larval parasitoid Anisopteromalus calandrae (Hymenoptera: Pteromalidae) is effective in preventing the weevil population to reach pest density. However, few data are available on its performance when released in commercial situations.

We have demonstrated that females were able to locate hosts and parasitize them when placed in a 1.5m paddy rice column (20cm diameter). Females were not only able to reach the bottom of the column, but also to reduce up to 90% the weevil population. Moreover, when females were released in commercial bags (500kg paddy rice, 1x1x1m in size), they also reached the bottom of the bag and reduced the weevil population up to 50-60%, depending on the season. The presence in the bags of a secondary pest, the lesser grain borer Rhyzopertha dominica which is also a host for this parasitoid, did not interfere with the control of the maize weevil.

Genetic diet specialization in phytozoophagous and zoophytophagous mirids

Authors: Castañé Cristina[3], Dumont François[1], Solà Mireia[2], Lucas Eric[4] and Provost Caroline[1], [1]Centre de recherche agroalimentaire de Mirabel (CRAM), Canada, [2]Laboratoire de Lutte Biologique, Biological sciences department, Université du Québec à Montréal (UQAM), Canada, [3]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain, [4]Université du Québec à Montréal, Canada

Abstract: The Miridae have a true omnivorous diet that includes varying proportions of animal and plant resources. Species belonging to this family can, therefore, be classified on a spectrum varying from phytozoophagy to zoophytophagy according to the relative proportion of plant and animal resources in their diet. The differences in diet composition can be as important within the species, than between species. Genetic variability in omnivorous populations generates diet specialization (individuals of the same population may consume a different proportion of available resources). Here, we compare genetic diet specialization among three North American species of Miridae, namely the tarnished plang bug Lygus lineolaris, the mullein bug Campylomma verbasci and Dicyphus hesperus. These species form a spectrum from phytozoophagous to zoophytophagous. The consequences of genetic diet specialization in these economically important species in agricultural environments is discussed.

Biocontrol of Aculops lycopersici (Massee) (Acari, Eriophyidae) on tomato with releases of Transeius montdorensis

Authors: Castañé Cristina[4], Vila Enric[1], Belén Arévalo Ana[1], Riudavets Jordi[5], González Mónica[2] and Alomar Oscar[3], [1]Agrobío S.L., Spain, [2]Estación Experimental Cajamar, Spain, [3]IRTA, [4]Sustainable Plant Protection, IRTA, Cabrils (Barcelona), Spain

Abstract: Aculops lycopersici is an increasing pest in protected tomato crops without a biocontrol solution. Despite that several promising predatory mites have been described in laboratory, results in field conditions have not been successful enough to implement augmentative programs. The introduction of astigmatid mites has been recently implemented as a method to improve the establishment of the predatory mites in different crops. In this study, preventive strategies have been tested with releases of Transeius montdorensis complemented with this feeding system. A trial on potted tomato plants placed in a climatic chamber showed that the pest did not develop after release on the plants where the predator had been established. Success was obtained in all three evaluated treatments, with different timing and ratios of releases. Two of these strategies were tested in a greenhouse in walk-in cages. After artificial infestation, successful control was also obtained as long as the climate conditions allowed to keep high predator populations. A program of releases was then evaluated in an experimental greenhouse. Natural infestation of the tomato plants with the pest occurred in all the control plots without predators, where severe damage occurred. The plots with predators were only colonized by the pest when high populations had already developed in the control plots, and no damages were recorded. Additional trials have been performed in Spain and Holland both in experimental and commercial greenhouses, where lower dosages have been tested. Different machineries have been examined to release the mite populations that allow to reduce the labor costs. A commercial biocontrol program is discussed for different crop conditions.

Phylogenomics of the braconid subfamily Doryctinae: towards a complete genus sampling of an extraordinarily diverse, cosmopolitan taxon

Authors: Castañeda-Osorio Rubén[2], Alejandro Zaldívar-Riverón[2], Belokobylskij Sergey A.[1], Quicke Donald L. J.[5], Jasso-Martínez Jovana M.[2], Kula Robert K.[6], Penteado-Dias Angelica M.[7], Zaldívar-Riverón Alejandro[3] and Samacá-Sáenz Ernesto[4], [1]Institute of Zoology, Russian Academy of Sciences, St. Petersburg, Russia, [2]Instituto de Biología, Universidad Nacional Autónoma de México, Mexico City, Mexico, [3]National Collection of Insects, Institute of Biology, Universidad Nacional Autónoma de México, Mexico, [4]National Insect Collection, Institute of Biology, National Autonomous University of Mexico (UNAM), Copilco, Coyoacán, Mexico, [5]Science, Chulalongkorn University, Bangkok, Thailand, [6]Smithsonian Institution, NMNH, Washigton D. C., USA, [7]Universidade Federal de São Carlos, SP, Brazil

Abstract: The Doryctinae is a highly diverse, morphologically heterogeneous braconid wasp subfamily with currently over 200 recognised genera and more than 1,700 described species. This cosmopolitan group is mainly represented by ectoparasitoids of xylophagous beetle larvae, though it also contains some phytophagous species. Previous phylogenetic studies on the subfamily, based on rather few gene markers and a limited taxon sampling, showed that its generic relationships are largely congruent with the geographical distribution, and not with its current tribal classification. They also failed to recover doryctine monophyly but with weak support. Here we present preliminary results of an ongoing study that seeks to reconstruct the phylogenomic relationships among all the currently within the subfamily based on both mitochondrial and ultraconserved elements, and that also is characterizing the mitochondrial genome of representative members of the main doryctine clades (Neotropical, Afrotropical-Holarctic-Oriental, Australian and Holcobraconini clades). Our phylogeny estimates will serve to propose a stable higher taxonomic classification for the subfamily, and will serve to conduct further studies about its origin, diversification and evolution of hosts preferences.

Evolution of raptorial legs in assassin bugs (Hemiptera: Heteroptera: Reduvioidea)

Authors: Castillo Stephanie[2], Knyshov Alexander[1] and Weirauch Christiane[2], [1]United States, [2]University of California, Riverside, United States

Abstract: Assassin bugs (Reduvioidea) are amongst the most morphologically and ecologically diverse lineages of predators, with approximately 7000 described species. Predacious reduvioids are either generalists or specialists of various arthropods and possess an astounding variety of leg modifications to handle prey. However, the evolutionary history of these modifications remains limited by the lack of a comprehensively robust phylogenetic hypothesis and detailed assessments of leg modifications across Reduvioidea. Here we reevaluate raptorial modifications with a phylogenetic dataset comprised of various data types and significantly improved taxon sampling. Reconstructing the evolutionary history of raptorial characters will serve as a framework for understanding the complex morphological diversity in this group of predators.

Temporal comparison of pheromone gland chemical content and volatile emissions between Bactrocera tryoni and Bactrocera neohumeralis

Authors: Castro-Vargas Cynthia[2], Pandey Gunjan[1], Oakeshott John[1], Taylor Phillip[3] and Lee Ronald[2], [1]CSIRO, Australia, [2]Macquarie University CSIRO, Australia, [3]Macquarie University, Australia

Abstract: Bactrocera tryoni and Bactrocera neohumeralis are closely related sibling pest species that occur sympatrically in eastern Australia. They are often distinguished morphologically by the colour of the humeral calli, which is yellow in B. tryoni and brown in B. neohumeralis. Also, they differ in their time of mating: B. tryoni mates during a small window at dusk whereas B. neohumeralis mates during the middle of the day. This difference in mating time is an important factor that contributes to the maintenance of reproductive isolation between them. During courtship, sexually mature males from both species release a volatile blend from a specialized gland located in the rectum. The content of the rectal gland secretions is complex and interspecific comparisons so far have been limited the six aliphatic amides, which constitute the major components of the blend. Recent data, however, has revealed the presence of additional compounds in rectal gland extracts in B. tryoni and it is unclear if B. neohumeralis also contains additional compounds.

The current study compares the chemical profiles of pheromone rectal gland content and volatile emissions in B. tryoni and B. neohumeralis during courtship using solid-phase microextraction followed by gas chromatography-mass spectrometry. While the six amides remain the major components in the gland in both species, we identified two compounds, ethyl isobutyrate and 2-ethyl-1-hexanol, that differ significantly in their relative proportions, and diethyl succinate, which is only present in B. tryoni. Upon identity confirmation with authentic standards and functional validation, the variations in the non-amide components of the rectal gland may represent an additional reproductive isolation mechanism in addition to the mating time difference. In addition, it could aid to the development of strategies for the regulation and control of these two pests.

Management of the Redbanded Stink Bug (Piezodorus guildinii) the Mid-Southern United States Soybean

Authors: Catchot Angus[2], Crow Whitney[2], Cook Don[2], Bao Dung[2] and Gore Jeff[1], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States

Abstract: The redbanded stink bug, Piezodorus guildinii (Westwood), has recently become a significant pest of soybeans in Mississippi and other southeastern United States. The first description of the redbanded stink bug originated from the Caribbean island of St. Vincent. The redbanded stink bug was first reported in the United States in the early 1970s but the time of its arrival in North America is still unclear (Panizzi.2005). As of 2016, the redbanded stink bug has been recorded in several southern states including Alabama, Florida, Louisiana, Mississippi, New Mexico, South Carolina, and Texas (Temple et al. 2013). Redbanded stink bugs are of particular concern because they appear to be much more damaging to seed than traditional species commonly found in the Mid-South. This study indicated that during severe outbreaks even the most aggressive foliar insecticide treatments at various thresholds were not enough to avoid seed quality and yield loss.

Novaluron Impacts Lygus Ovarian Development and Maturation

Authors: Catchot Beverly[2], Musser Fred[2] and Gore Jeff[1], [1]Mississippi State University, Department of Biochemistry, Molecular Biology, Entomology, and Plant Pathology, United States, [2]Mississippi State University, United States

Abstract: The tarnished plant bug (TPB), Lygus lineolaris (Palisot de Beauvois) (Miridae: Hemiptera) is the most economically important pest in cotton in the mid-south region. It is highly polyphagous, and the most widely distributed species of Lygus in North America. Novaluron is an insect growth regulator and chitin synthesis inhibitor, which has primarily been used for its ovicidal and larvacidal activities. Here, we examined the impacts of novaluron on TPB ovarian (telotrophic ovariole) development and maturation, including fecundity and egg hatching. Results indicate that novaluron has a detrimental effect on ovarian development and maturation as revealed from histological studies resulting in degenerated follicular epithelial cells coupled with distorted oocytes exhibiting large vacuoles in vitellogenic sites. Field exposure results showed a significant reduction in percent hatch rate and nymphs/female/day compared to TPB from non-treated fields. Laboratory studies on joint exposure of males and females or single sex exposure indicated no significant differences in fecundity compared to controls. However, significant differences in egg hatch rate were observed with least eggs hatching following joint exposure or exposure of only females. On the contrary, in the male exposure treatment, significantly more eggs hatched than in the female only or the joint exposure treatments. Thus, the effects of novaluron may be female specific. This in turn can reduce overall nymph populations in the field through sublethal effects on adult female TPB. Also, impacts vary depending on adult age at the time of exposure, but effects persist throughout the life of the adult. Taken together, our results support the application of novaluron on young TPB adult populations to disrupt ovarian development and maturation and hence its fecundity and hatchability.

Metabarcoding high elevation leaf litter arthropods in southern Appalachia - diversity and endemism

Authors: Caterino Michael, Clemson University, United States

Abstract: The highest peaks of the southern Appalachian Mountains (USA) harbor a unique and relictual spruce-fir forests that hosts many endemic species. While a handful of arthropod lineages have been examined and found to have diversified in the region, the vast majority have received only cursory study. These communities are threatened by invasive species and habitat loss through climate change. However, the dearth of information on their diversity and uniqueness provides a weak foundation for conservation management. We have undertaken thorough arthropod community inventories using a voucher-based COI plus 16S multiplexed metabarcoding approach. Results to date indicate good success rates and generally high levels of divergence among putatively conspecific populations across peaks. This suggests that levels of endemism and cryptic species richness are much higher than currently supposed.

Functional characterization of codling moth chemoreceptors

Authors: Cattaneo Albaero Maria[1], Bobkov Yuriy V.[2], Benton Richard[3] and Walker III William B.[4], [1]Swedish University of Agricultural Sciences, Plant Protection - Chemical Ecology, [2]University of Florida, Whitney Laboratory for Marine Bioscience, [3]University of Lausanne, Center for Integrative Genomics, Switzerland, [4]USDA-ARS, Temperate Tree Fruit and Vegetable Research Unit

Abstract: The codling moth Cydia pomonella is a worldwide pest of apple, pear and walnut orchards, whose sensing of chemicals plays a dominant role in its ecology, from mate-location to host selection, oviposition and larval feeding. To decipher chemical sensing of this pest insect, we have performed transcriptome analyses to identify moth chemosensory genes, including those encoding Odorant receptors and Ionotropic receptors. Using heterologous expression, in both olfactory sensory neurons of transgenic Drosophila melanogaster and in human embryonic kidney cells, together with gas chromatography, electrophysiological recordings and fluorescent imaging, we have characterized the physiological and pharmacological properties of several of these receptors, confirming that they form functional cation channels. Our findings represent an important advance in the study of chemical sensing of the codling moth towards the development of sustainable control strategies manipulating its chemosensory communication.

Functional characterization of Drosophila suzukii OR69a transcript variants unveiled response to kairomones and to a candidate pheromone

Authors: Cattaneo Alberto Maria[1] and Walker William[2], [1]Swedish University of Agricultural Sciences, Switzerland, [2]USDA-ARS, United States

Abstract: Drosophila suzukii is among the main pests of berries, to which control, application of insecticides, is challenging and it urges alternative strategies. Methods based on targeting chemical sensing and interfering with the behavior of this pest insect are promising, and is facilitated by the functional characterization of chemosensory receptors with the aim to identify novel behaviorally active ligands. Previously, we functionally characterized subunits of the OR69a locus of Drosophila melanogaster as being capable to bind both pheromones and kairomones, representing possible candidates within the genus Drosophila for broad behavioral interference control strategies based on targeting chemosensory communication. By means of heterologous expression in empty ab3A olfactory neurons of D. melanogaster together with Single Sensillum Recording (SSR), we screened three OR69a-subunits we have identified in D. suzukii with a panel of 48 ligands. In these subunits, we characterized olfactory responses to several compounds, including two possible kairomones and a possible fly-emitted volatile compound. Similarities and differences were observed in the olfactory tuning of these receptors, relative to their D. melanogaster homologues, reflecting potential evolutionary adaptations relevant to the ecology of the species.

Public perceptions of the benefits of biological control

Authors: Catton Haley, Agriculture and Agri-Food Canada, Canada

Abstract: Public perceptions of biological control are critical to the continuation of the discipline, but are dynamic, complex, and sometimes surprising. Public perceptions result from an integration of many factors beyond the general training of entomologists such as psychology, perceptions and acceptance of risk, media influences, and history. Depending on the biological control agent, region, target species, and culture of stakeholders involved, multiple publics with different values, motivations, and perceptions of risk may exist. In recent decades, scientific advances in modern biological control have been remarkable, but social aspects have lagged far behind. This talk will discuss what different publics may exist, what is known about public perceptions, and why the benefits of biological control are undervalued. Case studies and recommendations for improving public perceptions of biological control will be discussed. The biological control community must increasingly and proactively respect social aspects such as a public's values, motivations, perceptions and acceptance of risk to avoid and solve conflicts. This objective can be achieved by collaborating with social scientists, publicizing successes, improving communication, and identifying risk- and value-based disagreements for possible resolution. Only then can public perceptions of modern biological control rise to match the value of this discipline to ecology and society.

Contributions of a non-native cover crop to native parasitoids in controlling the pest wheat stem sawfly

Authors: Cavallini Laissa[1], Peterson Robert K. D. and Weaver David K, [1]Montana State University

Abstract: Wheat stem sawfly, Cephus cinctus, is a major pest of wheat, causing losses that exceed $350 million annually in North America. Two native parasitoids, Bracon cephi and B. lissogaster, suppress C. cinctus populations in wheat fields. The success of natural enemies is linked to access to supplemental food in the field, which increases their life span and benefits their reproductive parameters. To assess the benefits of supplemental nutrition to these parasitoids, we conducted greenhouse experiments with cowpea, Vigna unguiculata, as an extrafloral nectar source for parasitoids. Cages containing individual females were placed on living plants enclosing either cowpea inflorescence stalk extrafloral nectar (IS-EFN) or the leaf stipel extrafloral nectar (LS-EFN), with water as the negative control and buckwheat nectar as the positive control. Females were observed daily to assess longevity, while egg load and volume were assessed 2, 5, and 10 days after placement. Results show that IS-EFN increases longevity in both parasitoids. B. lissogaster kept constant egg load and volume, while B. cephi increased reproductive parameters with IS-EFN. Our results show cowpea IS-EFN improves our parasitoids longevity and reproductive parameters. Therefore, cowpea should be considered as a food supplement crop in conservation biocontrol programs to reduce C. cinctus populations.

Nutritional dimensions of locust research and management

Authors: Cease Arianne, Global Institute of Sustainability, Arizona State University, United States

Abstract: As transboundary migratory pests, locusts, present complex agricultural challenges that are best addressed with an interdisciplinary systems approach. During outbreak years, species like the desert locust (Schistocerca gregaria) can cause 80–100% crop losses in effected areas and cost hundreds of millions of US dollars to control. At high densities locusts switch from a solitarious to a gregarious/swarming form. Many abiotic and biotic factors affect locust population dynamics; however, macronutrient balance (e.g. protein and carbohydrates) has emerged as a potential modulator of locust phase polyphenism and outbreaks. Despite a general paradigm that terrestrial herbivores should be protein limited, we present evidence from both the field and lab, across multiple continents, that locusts prefer carbohydrate-biased diets and perform better on diets rich in carbohydrates. These results have potentially broad implications for land-management practices and their interactions with locust plagues. The Global Locust Initiative is working across boundaries and sectors to explore this space.

LIFE FOR SPECIES: Contribution by the LIFE FOR SPECIES project to the protection of threatened entomofauna in Latvia (LIFE19 GIE/LV/000857)

Authors: Cekstere Gunta[2], Telnov Dmitry[3] and Dzenis Jekabs[1], [1]Nature Conservation Agency, [2]University of Latvia, [3]University of Latvia, Institute of Biology, Latvia

Abstract: The current regulations, which determine the list of the specially protected species and micro-reserve species in Latvia, were issued several years ago. During this time, scientific information on the species occurrence and threatening factors has been gathered, as well as changes have taken place in Latvian economy. Thus the project LIFE FOR SPECIES main activities and results to protect Europe's threatened insect species in Latvia relate to: assessment of threatened insect species (for instance, beetles, dragon-flies, butterflies, etc.) based on IUCN criteria (i); development of species data sheets and Red Data Book (ii); compiling of a new list of protected species and micro-reserve species (iii); development of criteria for including threatened species in the national regulations on legally protected/micro-reserve species and a flexible system for updating the list (iv); drawing a draft legislative amendment for improving the national legislation (v); improvements of the quality and quantity of data in the National Biodiversity Data System OZOLS (vi); increase of capacity of governmental institutions, experts, stakeholder involvement and awareness of the general public (vii).

The project LIFE FOR SPECIES (LIFE19 GIE/LV/000857) is implementing by UL, NCA, LOB and DU (2020-2024) with financial support of EU LIFE program and the State Regional Development Agency.

Game of viruses: JEV is coming

Authors: Cernicchiaro Natalia, Valent Biosciences LLC, United States

Abstract: As demonstrated by the introduction of other flaviviruses (WNV, Zika) in the American continent, United States represents a region favorable for potential entry and spread of other vector-borne viruses that can potentially pose a similar risk of introduction. The objective of our study was to quantify the probability of Japanese Encephalitis Virus (JEV) introduction in the United States using qualitative and quantitative risk assessment frameworks. Of all pathways of entry considered, the probability of introduction of JEV through infected adult mosquitoes via aircraft was deemed very high. We predicted a median 95% probability that at least one infected mosquito is introduced via aircraft from JEV-affected countries, most likely from Eastern China to the US Mediterranean California and East coast, every year. Although the probability of transmission of JEV ranged from low to high, the probability of establishment was deemed negligible under current conditions. Though JEV has not established in the US, the conditions are rapidly changing, and as such newer pathways may dictate the future emergence and spread of JEV in the US. Based on our models, prevention and control plans should be placed towards vector control as well as surveillance efforts on the west and east coasts.

Inventing the Future: Understanding and developing the tools that agencies need for combating vector borne diseases

Authors: Cernicchiaro Natalia, Valent Biosciences LLC, United States

Abstract: Vector borne diseases like Dengue and Malaria have a major impact on human lives. Vaccinations are few and for more than a century the best-known defense is vector control. There used to be a time when blanketing huge areas with arsenic was effective in managing vector borne diseases but in modern times the need for environmentally rational approaches have increased. Research has shown that vector specific control is a better approach for rational use of pesticides. For example, although spot treatments using residual biological larvicide is the common approach, broadcasting liquid Bti larvicide droplets as part of an integrated vector management approach has a greater impact on the container breeding Aedes aegypti and on the diseases such as Chikungunya and Dengue that are transmitted by Ae. aegypti. This underscores the importance of working closely with public agencies in order to understand what is needed as a tool. A blanket approach that works on other insect pests is not a guarantee that it will work on all mosquitoes of disease importance. The talk will focus on new approaches that have been developed due to successful collaboration in research and development between public and private agencies in the United States.

Role of endogenized lef-4 and lef-8 nudiviral genes in Virus-Like-Particle production in the parasitoid wasp Venturia canescens

Authors: Cerqueira de Araujo Alexandra[2], Huguet Elisabeth[1], Leobold Matthieu[2], Bézier Annie[2], Musset Karine[2], Uzbekov Rustem[3], Drezen Jean-Michel[2] and Josse Thibaut[2], [1]IRBI-CNRS-University of Tours, France, [2]UMR 7261, CNRS - Université de Tours, France, [3]Université de Tours, Département des Microscopies

Abstract: Nudiviruses are large double-stranded DNA viruses related to baculoviruses that are endogenized in genomes of certain parasitic wasps. These wasp-virus associations allow the production of viral or virus-like particles that ensure wasp parasitism success within lepidopteran hosts. Venturia canescens is an ichneumonid wasp belonging to the Campopleginae subfamily that has endogenized alphanudivirus genes to produce “Virus-Like Particules” which package proteic virulence factors. The aim of this study was to determine whether alphanudivirus gene functions have been conserved following endogenization. The expression dynamics of alphanudivirus genes was monitored by a RNA-seq approach and the functional role of lef-4 and lef-8 genes predicted to encode viral RNA polymerase components was investigated by RNA interference. As described for baculovirus infections and for endogenized nudivirus genes in Braconid wasp species producing bracoviruses, a transcriptional cascade involving early and late expressed alphanudivirus genes could be observed. Lef-4 and lef-8 expression was also required for the expression of alphanudivirus late genes allowing correct particle formation. Together with previous literature, the results show that endogenization of nudiviruses in parasitoid wasps has repeatedly led to the conservation of the viral RNA polymerase function, allowing the production of viruses or viral-like particles that enable wasp parasitic success.

Chrysomelidae (leaf beetles) is the most diverse beetle family (Coleoptera) documented in Peru, a Neotropical biodiversity hotspot

Authors: Chaboo Caroline, University of Nebraska-Lincoln, United States

Abstract: Peru is known for its exceptionally high species richness, endemism, and habitat complexity, yet little is known about its beetle fauna. This presentation reviews results from a 10-year study of annual surveys using structured, semi-structured and unstructured trapping of beetles in Peru. The beetles were sorted, curated, digitized and sorted to families, then sent to beetle experts for further study and identifications. We documented 100 families, with ten new family records for Peru—Biphyllidae, Bothrideridae, Eucinetidae, Omethidae, Monotomidae, Rhipiceridae, Scirtidae, Scraptiidae, Silvanidae, and Throscidae, along with many new generic and species records. Many new genera and species have been described so far. Remarkably, Chrysomelidae (leaf beetles) is found to be the most diverse family, with 1 786 species and 278 genera, of the 100 families we document in Peru. Within Chrysomelidae, Cassidinae s. l. (leaf-mining and tortoise beetles) is documented as the most diverse subfamilies. These two findings about Chrysomelidae in Peru are counter to global diversity patterns. In the ancient and remarkably complex terrain of Peru, many factors have influenced speciation to make Peru one of the most biodiverse countries on Earth. Peru's extraordinary high plant-species richness undoubtedly also plays a role in the hyperdiversity of herbivorous insects like Chrysomelidae.

Ten International Symposia on the Chrysomelidae - a retrospective and an outlook

Authors: Chaboo Caroline[2], Schmitt Michael[1], [1]Universitaet Greifswald Allgemeine & Systematische Zoologie, Greifswald, Germany, [2]University of Nebraska-Lincoln, United States,

Abstract: The series of ten symposia dedicated to all aspects of the biology of leaf and seed beetles began in 1984 within the frame of the 17th International Congress of Entomology in Germany. David G. Furth organised the first five, nearly always jointly with local co-organisers. From 2004, Michael Schmitt organised the next five, also in co-operation with colleagues from the respective host country. From the beginning, these symposia were highly welcomed by the community of leaf beetle workers worldwide. The proceedings volumes were published originally with different publishers. Since 2008, we have compiled special volumes of ZooKeys as the series "Research on Chrysomelidae" (RoC). The symposia are not only valuable platforms of discussion and co-operation but also made the group of leaf beetle enthusiasts an intensively communicating society. From symposium no. 11 on, Caroline S. Chaboo will take responsibility for the organisation of these symposia, calling on colleagues everywhere to support, promote, and expand leaf beetle research.

Discovery of novel engineered Cry proteins to control fall armyworm

Authors: Chae Hyunsook[1], Wen Zhimou, Bramlett Matthew and Chen Jeng S, [1]Syngenta Seeds, United States

Abstract: Fall armyworm (FAW) is one of the most devastating insect pests in crop fields of the Americas and is rapidly expanding its range worldwide. Although GM traits can be an effective way to control FAW, it is very rare to find native genes that provide the necessary level of FAW control in crop fields. Protein engineering enabled us to discover novel chimeric Cry proteins devised from inactive parent sequences. Some of these chimeras show excellent efficacy against FAW from Brazil and North America. One of these shared here is IC3002. IC3002 also effectively controls Vip3A-resistant FAW and Cry1F-resistant FAW indicating the protein acts through a novel mode of action compared to these existing traits. In addition, IC3002 is efficacious against key soybean pests, Soybean looper and Velvetbean caterpillar. When IC3002 was introduced into corn and soybean, transgenic events showed strong efficacy against target pests, but no adverse plant phenotypes. This suggests that in planta expression of the gene does not compromise plant growth or reproduction but can protect plants from FAW related damage. IC3002 will be a differentiating FAW control trait that will give growers another tool to help them reduce yield loss due to the pests.

Horizontal and vertical transmission of an entomopathogenic fungus, Metarhizium anisopliae, among Bactrocera dorsalis fruit flies

Authors: Chailleux Anaïs[2], Brévault Thierry and Dosso Fatime[1], [1]- CIRAD, UPR HortSys, Centre commun ISRA-IRD, Dakar, Senegal - Biopass, Cirad-IRD-ISRA-UCAD, Dakar, [2]Senegal

Abstract: Entomovectoring is a novel pest management technique that relies on the use of insects to deliver highly targeted and continuous pest or disease control. The control of the Oriental fruit fly, Bactrocera dorsalis (Hendel) (Diptera, Tephritidae), using males of the same species as vectors of spores of the entomopathogenic fungus, Metarhizium anisopliae (Sorokin) (Hypocreales, Clavicipitaceae), is a promising avenue. However, triggering epizootics in a fly population requires high rate of transmission of the pathogen among individuals. In the present study, horizontal transmission of spores from contaminated vs. non-contaminated wild or mass-reared sterile B. dorsalis males to wild females was assessed under laboratory conditions with a focus on mating success of each male category and mortality of wild females. Additionally, a field cage experiment was conducted to assess the effect of contamination or sterility on population dynamics. Vertical transmission of fungal spores was evaluated under laboratory conditions to assess the effect of contamination on egg laying and hatching rate. Contamination and sterility by themselves did not significantly affect the mating success of males, whereas cumulated sterility and contamination of males reduced their mating success. During mating, males were able to transmit infectious doses to females leading to 34 % female mortality. Female fecundity and egg hatching were also affected by fungal contamination. These results are key to model the dynamics of a fungal epizootics within a population of B. dorsalis fruit flies so as to optimize the field implementation of the technique.

Improving pest management of field-grown tomato in Senegal: the combination of net and biological control

Authors: Chailleux Anaïs[2], CORREA Philippe[1], Deletre Emilie, Haran Julien, Diarra Bousso Ba Mame, Diakhate Massamba, Kane Modou, Ndjiliw Saliou, Simon Serge, Sylla Serigne and Brévault Thierry, [1]-CIRAD, UPR HortSys, Centre Commun ISRA-IRD, Senegal -Biopass, Cirad-IRD-ISRA-UCAD, Dakar, Senegal -UCAD-FST, ED SEV, Dakar, Senegal, [2]Senegal

Abstract: The need to produce healthier food with low impact of cropping systems on the environment implies a combination of ecologically intensive methods to effectively control pests. We investigated how net-houses can be used in combination with a generalist predator to protect tomato crops from the tomato leafminer, Tuta absoluta (Lepidoptera, Gelechiidae), and other minor pests in smallholder farmers in Senegal. Net-houses have been developed to protect tomato crops from large size arthropod pests, such as the tomato fruitworm, Helicoverpa armigera (Lepidoptera, Noctuidae). However, this technique delays crop colonization by large size pests but also natural enemies, and often favors the outbreak of some others. Field surveys were carried out to search for natural enemies and insectarium plants for the setup of augmentative biological control in tomato crops in Senegal. The indigenous predatory mirid bug, Nesidiocoris tenuis (Heteroptera: Miridae), and its insectarium plants were identified and evaluated under laboratory conditions. Then, we tested the combination of the net, the false sesame as an insectarium plant, and the predatory bug using pre-plant release in an experimental station. Pests, including the tomato leafminer, were successfully controlled and tomato yield significantly increased. These results support the upscaling of this method for the benefit of African smallholder farmers.

Impact of insecticides application in paddy fields: tendency and consequences of the parasitoid in the rice hispa (Dicladispa armigera)

Authors: Chaiwong Jintana[1], Paoteerasarn Pakorn[1] and Thanikkul Ploypirin[1], [1]Division of Rice Research and Development, Rice Department, Thailand

Abstract: Rice hispa, Dicladispa armigera (Olivier) is one of the major pests in rice that which occasionally found in rice fields. Previous studies reported the outbreak of rice hispa has cropped up in 1932, 1984, and 1998 in central Thailand including in Chachoengsao, Nakhon Pathom, Suphan Buri, and Chainat provinces but no report of further outbreaks. In 2018, outbreaks were found again in Chachoengsao, Suphan Buri, and Chainat province surprisingly. The information according to the farmers in Si Prachan District, Suphan Buri provinces referred to the continuous outbreaks by rice hispa on every crop from 2015 to till date. In this study, we conducted with the purpose to study the effect of insecticides on parasitoids of rice hispa and the data will be helpful to deal with any outbreak situations in the future. Our study was carried out in two crop seasons between September 2018 to March 2019. We randomly collected some samples of rice hispa eggs, nymphs, and pupa along with the higher number of parasites. Our findings revealed that they are mostly ingested by Trichogramma spp., parasitoid on eggs, larva parasitoid Bracon spp., and Trichomalopsis spp., parasitoid on the pupa. Interestingly, the mortality rate of rice hispa in insecticide method that is proposed to apply more than 2 times in a season had only 9.4 %. Conversely, the mortality rate of rice hispa has increased to 90.2% in the non-insecticide method and majorly ingested by Bracon spp. and Trichomalopsis spp., which are parasitoids of larva and pupa rice hispa.

Spatio-temporal evolution of egg parasitoids of the processionary moth, Thaumetopoea pityocampa (Denis & Schiffermüller 1775) (Lep, Thaumetopoeidae) in cedar and pine forests at Algeria

Authors: Chakali Gahdab, Agronomic National High School, Algeria

Abstract: The processionary moth, Thaumetopoea pityocampa is the main defoliator pest in both cedar and pine forests at northern Algeria. Worldwide this pest populations are naturally controlled by parasitoids therefore it's very important to identify and quantify the main species. Study of 604 egg batches collected from the biosphere reserve at cedars of Chrea, Djurdjura and Theniet El-Had as well as from the pine forests of the sub-humid and semi-arid areas highlighted three species of egg parasitoids: Ooencyrtus pityocampae (Mercet) (Hymenoptera, Encyrtidae), considered as polyphagous, Baryscapus servadeii (Domenichini) (Hymenoptera, Eulophidae), a specialist of the genus Thaumetopoea emerging in synchronization with their hosts oviposition patterns. These two parasitoids were found in all the prospected sites of the two bioclimatic stages. However, the third species Trichogramma embryophagum (Hartig) (Hymenoptera, Trichogrammatidae) was presented only in pure cedar forests of altitudinal areas. The extension of theses oophagous antagonists is related to the evolution of the gradation of the two processionary clades (pityocampa clade and Eastern North African clade). The analysis of the egg batches showed an average of 246 + 47 eggs per batch from cedar forests, and 142 + 40 eggs per batch from pine forests, with an average parasitism rate ranging from 6 to 16%. The parasitoids Baryscapus servadeii and Ooencyrtus pityocampea were found at varying rates of parasitism, up to 48% per egg mass in the cedar plantation, and up to 28% in pine settlements. The parasitoid Trichogramma embryophagum was collected only in cedar plantations, at a rate not exceeding 3% despite its frequency of presence in the eggs located at the both ends of the ovipositions in elongated form 4 to 6 centimeters. A strategic evolution of the parasitoids species listed and their distribution through the cedar groves and the pine forests is noted. The ecological conditions of the prospected ecotypes participate in the spatial distribution of parasitoids in their distribution areas. This result showed that these parasitoids preferred the cedar forests, which may offer the best condition for their development. The performance of these parasitoids is highly related to the altitudinal variable that has impacted the intra-interspecific competition between the egg parasitoid species. Results are discussed focusing on the evolution of the egg parasitoids populations aiming its practical use in future biological control strategies.

Challenges and Sustainability of Commercial Beekeeping and Pollination in the United States

Authors: Chakrabarti Priyadarshini[1], Sagili Ramesh[2], Breece Carolyn[2], Topitzhofer Ellen[2] and M. Lucas Hannah[2], [1]Honey Bee Lab Oregon State University, Agriculture and Life Sciences Building, Corvallis, OR, United States, [2]Oregon State University, United States

Abstract: Pests, poor nutrition and pesticides are considered primary stressors among multiple factors implicated in honey bee colony losses. Migratory beekeeper colonies encounter a variety of challenges including high density of colonies, timely monitoring and management of pests/diseases, and nutritional stress resulting from crop pollination. In the wake of significant honey bee colony losses, best management practices are becoming increasingly important. This presentation will discuss the challenges facing commercial beekeepers in the USA, and relevant research efforts to understand and address these challenges with a goal of developing appropriate best management practices for sustainable apiculture and pollination.

Understanding the nutritional landscape available to bees

Authors: Chakrabarti Priyadarshini[1], Sagili Ramesh[2], S. Maier Claudia[2], M. Lucas Hannah[2] and T. Morre Jeffrey[2], [1]Honey Bee Lab Oregon State University, Agriculture and Life Sciences Building, Corvallis, OR, United States, [2]Oregon State University, United States

Abstract: Significant annual honey bee colony losses have been reported in the USA and across the world over the past years. Malnutrition is one among several causative factors for such declines. Optimal nutrition serves as the first line of defense against multiple stressors such as parasites/pathogens and pesticides. Given the importance of nutrition, it is imperative to understand bee nutrition holistically, identifying dietary sources that may fulfill bee nutritional needs. Pollen is the primary source of protein for bees and is critical for brood rearing and colony growth. Currently, there is significant gap in knowledge regarding the chemical and nutritional composition of pollen. Targeted sterol analysis and untargeted metabolomics were conducted on five commercially available crop pollens, three bee-collected crop pollens, three vegetable oils (often added to artificial protein supplements by beekeepers), and one commonly used artificial protein supplement. This study reports key phytosterols and metabolites present across a spectrum of bee diets, including some of the major bee-pollinated crop pollens in the western United States. Significant differences were observed in sterol concentrations among the dietary sources tested. Among all quantified sterols, the highest concentrations were observed for 24-methylenecholesterol and further, pollen samples exhibited the highest 24-methylenecholesterol among all diet sources that were tested. Also, 236 metabolites were identified across all dietary sources examined. Information gleaned from this study is crucial in understanding the nutritional landscape available to all bee pollinators and may further assist in future efforts to develop comprehensive database of nutrients and metabolites present in all bee diets.

Recent advances in understanding the impact of agriculture on pollinators

Authors: Chakrabarti Priyadarshini[2], Smith Barbara[1], [1]Centre for Agroecology, Water and Resilience, Coventry University, United Kingdom, [2]Honey Bee Lab Oregon State University, Agriculture and Life Sciences Building, Corvallis, OR, United States

Abstract: Research has shown that agricultural practices act as a major stress on pollinator populations, driving their declines. However, the main focus of empirical work has been on how the impact of both local and landscape level agricultural intensification impacts pollinators within farms. Here we summarize recent advances in our understanding of how agricultural intensification impacts insect pollinators and pollination in adjacent ecosystems. We will consider pollinator abundance, species diversity, health and function and identify key priorities for research.

Location, location, location: Why eyespot location matters to butterflies!

Authors: Chan Ian[1], Monteiro Antonia[1], Naing Lin[1], Lee Yueying[1] and Ching Ngan Zhe[1], [1]Department of Biological Sciences, National University of Singapore, Singapore

Abstract: Eyespots are circular “eye-like” markings on animals and can be found on the wings of numerous butterfly species. A previous comparative study of 450 nymphalid species revealed that there are markedly fewer eyespots on forewings than on hindwings, e.g. Bicyclus anynana butterflies have two forewing eyespots and seven hindwing eyespots, but the reasons for this asymmetry remain poorly understood. Through experiments involving mantis predators preying upon wildtype and Spotty variants (with two additional eyespots on the ventral forewing) of Bicyclus anynana butterflies, we demonstrate that butterflies with more forewing eyespots are attacked more often on the eyespots of both wings. We further show that these butterflies exhibit a greater amount of damage to the forewing sectors which contain eyespots, and that they are significantly disadvantaged in terms of survival and fecundity. These results suggest that having too many forewing eyespots is detrimental for butterflies. We propose that flight performance is more severely hindered when forewings, as opposed to hindwings, are damaged and butterflies would therefore benefit from placing their attack-deflecting eyespots primarily on the more expendable hindwings. These results help explain the asymmetric eyespot distribution patterns previously observed across nymphalids.

The contribution of phenolics to the antioxidant potentials of propolis from Tetragonula laeviceps and T. pegdeni with its correlation to dominant plant sources in different regions in Thailand

Authors: Chanchao Chanpen[1], Meemongkolkiat Thitipan[1], Khongkarat Phanthiwa[1], Rod-im Preecha[2] and Duangphakdee Orawan[2], [1]Chulalongkorn University, [2]Ratchaburi Campus, King Mongkut's University of Technology Thonburi

Abstract: Propolis from two dominant stingless bee species in Thailand, Tetragonula laeviceps and T. pegdeni were collected from four locations in Ratchaburi and one location in Chiangmai provinces. In each location, the dominant plants are different. Samples were extracted in methanol (MeOH) and sequentially partitioned with hexane, dichloromethane (DCM) and MeOH. All partitioned extracts were examined by three antioxidant methods [1,1-diphenyl-2-picrylhydrazyl (DPPH), 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) and ferric reducing ability (FRAP) assays]. For DPPH assay, MeOH partitioned extract of T. laeviceps from Bankha district (MPE7) was the most active. While DCM partitioned extract of T. pegdeni from Suan phueng district (DPE2) was the most active by ABTS and FRAP assay. The DPE2 also showed the highest phenolic and flavonoid contents. The identification and quantification of twelve phenolic compounds with the highest concentration of vitexin in MPE7 and MPE5 are reported by high performance liquid chromatography (HPLC). Interestingly, kaempferol was only detected in DPE2. The different antioxidant potentials among sites are expected due to specific flora of each location. Furthermore, significant difference in this bioactivity was found between both species in the same location suggesting the different preference of flora. These results verified the potential of extracts to effectively scavenge radicals.

Carbon Nanomaterials in Drosophila suzukii (Diptera:Drosophilidae) control

Authors: Chaniotakis Nikos[2], Belenioti Maria[2] and Chaniotakis Manos[1], [1]Sole proprietorship: BioMarkerImaging, [2]University of Crete, Department of Chemistry, Laboratory of Analytical Chemistry

Abstract: Crop losses due to insect infection are one of the greatest issues to address in agriculture and food production. In order to control these kinds of pests, such as D. suzukii, farmers usually resort to the use of insecticides. Unfortunately, their efficacy is limited, while the environmental impact is devastating. Nanotechnology can provide new means for a variety of industrial activities, providing novel tools in many human activities. Nanomaterials can provide solutions for pest management in agriculture without harming the environment. There are only a few studies in which D. melanogaster is used as model species to study the toxicity of nanomaterials. Based on these preliminary results, it is proposed here that NPs could be used successfully in pest management formulation. We used different carbon nanomaterials to study their effects on larval and adult Drosophila suzukii. It is shown that dietary uptake of certain carbon nanomaterials has no detectable effect on egg to adult survivorship. However, when the adult species were exposed to the same nanomaterials through the skin via spraying, led to a total locomotor function impairment and mortality.

Development of a Scrub Typhus Diagnostic Platform Incorporating Cell-Surface Display Technology

Authors: Chao Yu-Chan [2] and Liao Chih-Chi[1], [2]Department of Entomology, National Chung Hsing University, Taiwan, [1]Department of Entomology, Academia Sinica, Taiwan

Abstract: Scrub typhus (ST), also known as tsutsugamushi disease and caused by rickettsia Orientia tsutsugamushi, is an underestimated fatal epidemic in the Asia-Pacific region, resulting in a million human infections each year. ST is easily misdiagnosed as a clinical diagnosis is based on non-specific skin eschar and flu-like symptoms. Thus, the lack of accurate, convenient, and low-cost detection methods for ST poses a global health threat. To address this problem, we adopted baculovirus surface-display technology to express three variants of TSA56, the major membrane antigen of O. tsutsugamushi, as well as the passenger domain of ScaC (ScaC-PD), on insect Sf21 cell surfaces rather than biosafety level 3 bacteria in an enzyme-linked immunosorbent assay (ELISA). Recombinant TSA56 and ScaC-PD were all properly expressed and displayed on Sf21 cells. This cell-based ELISA presented high accuracy (96.3%), sensitivity (98.6%), and specificity (84.6%) when tested against the ST-positive rat sera. Results using human sera were also highly consistent with the results of immunofluorescence analyses. By adopting this approach, we circumvented complex purification and refolding processes and reduced the need for expensive equipment and extensively trained operators. Thus, our system has the potential to become a widely used serological platform for diagnosing ST.

Display of acetylcholinesterase on cell surface for enzymatic analyses and pesticide detection

Authors: Chao Yu-Chan[1], Liao Chuan-Yu[2] and Liao Lin-Li[2], [1]Department of Entomology, National Chung Hsing University, Taiwan, [2]Institute of Molecular Biology, Academia Sinica, Taipei, ROC, Taiwan

Abstract: Insecticides detection in agricultural products is usually tedious and expensive. Thus, a convenient method is needed to screen for their toxicity in the fruits and vegetables. In this study, two highly toxic major pesticide groups, organophosphates (OP) and carbamates (CB), frequently used in agriculture, including the field application for killing fall armyworm, are studied. Since acetylcholinesterase (AChE) is the target of OP and CB compounds to kill insects, the detection of pesticide residues could rely on the inhibition of AChE activity by these pesticides. AChE hydrolyzes an alternative substrate, acetylthiocholine (ATCh), into thiocholine and acetic acid. Thus, AChE activity is frequently measured by the colorimetric Ellman's method, whereby thiocholine reacts with 5,5'-dithio-bis-2-nitrobenzoic acid (DTNB, Ellman's reagent) to yield yellow 5-thio-2-nitrobenzoate (TNB), which can be observed by the naked eye or be measured at 412 nm. This colorimetric method is especially important for the rapid detection of OP and CB pesticides in agricultural products, as the presence of such pesticides will inhibit the enzyme activity and eliminate the yellow coloring. In this study, we have developed a novel cell surface display technology by insect baculovirus expression system to efficiently express acetylcholinesterase on insect cell membrane in 96-well plates for the detection of OP and CB pesticide residue with high efficiency. This measure should help for the safe application of pesticides to control insect pests including fall armyworm.

Bioflows through migration hotspots are dominated by hoverflies (Diptera: Syrphidae): uncovering key genetic/physiological adaptations and orientation strategies

Authors: Chapman Jason[1], Wotton Karl[5], Hawkes Will[5], Massy Richard[5], Gao Boya[3], Hu Gao[4] and Doyle Toby[2], [1]Centre for Ecology and Conservation, and Environment and Sustainability Institute, University of Exeter, China, United Kingdom, [2]Centre for Ecology and Conservation, University of Exeter, Penryn, Cornwall, United Kingdom, [3]Centre for Ecology and Conservation, University of Exeter, Penryn, Cornwall, United Kingdom, China, [4]Nanjing Agricultural University, China, [5]University of Exeter, United Kingdom

Abstract: Insect migrants number in the trillions and carry out vital ecological roles. Understanding their migration routes, seasonal patterns of abundance and associated orientation behaviours remains a formidable task, but is necessary if we are to understand the contribution these organisms make when moving between distant ecosystems. Our studies utilise migration hotspots: geographic sites that occupy major flyways and provide topological funnelling to concentrate huge numbers of active migrants. Our research takes a comparative approach, identifying differences in migratory assemblages and numbers across multiple sites spanning Western to Eastern Europe. Using traditional techniques of trapping, counts and transects, together with high-resolution imaging, we provide evidence for huge seasonal bioflows that are dominated by Diptera, numbers of which may reach >10 million / day through a single funnel point. To uncover the orientation strategies of the most abundant of these Diptera, the hoverflies, we have developed a flight simulator based on magnetic tethering and computer vision algorithms to automatically record responses to various cues. We find evidence for strong orientation behaviour due south, but only when the sun is visible, additionally, this behaviour is maintained under time-shift conditions. Finally, using a range of genomic techniques, we have identified differentially expressed transcripts between migrant and non-migrant forms of the marmalade hoverfly, together with a fully sequenced genome these have allowed us to begin to uncover the pathways involved in long-distance migration.

Individual tracking reveals consistent headings in migrating hawkmoths

Authors: Chapman Jason[1], Menz Myles[2], Thoma Marco[3] and Wikelski Martin[2], [1]Centre for Ecology and Conservation, and Environment and Sustainability Institute, University of Exeter, China, United Kingdom, [2]Max Planck Institute of Animal Behavior, Germany, [3]University of Bern, Switzerland

Abstract: In comparison to vertebrates, the migratory pathways of insects and behaviour en route are relatively poorly understood. While individual tracking can allow for insects to be monitored during migration, this technique is rarely applied, primarily due to most insect species being too small to carry radio-transmitters. Here we present the first study to individually track nocturnal migrating insects, to identify migratory routes and understand factors affecting flight behaviour. Using a Cessna 172 aeroplane, we tracked individual hawkmoths (Acherontia atropos, Sphingidae), fitted with 0.25 g radio-transmitters. During tracking, all moths maintained consistent headings, which persisted across days in some individuals. However, there was variation in headings among individuals and between animals from different origins. Analysis of high-resolution wind data determined that moths maintained seasonally-adaptive headings regardless of wind direction, indicating that they compensated for wind drift en route.

Migratory routes of the invasive fall armyworm in eastern Asia

Authors: Chapman Jason[1], Hu Gao[2], Zhai Bao-Ping[3], Gao Bo-Ya[2], Ma Jian[2], Wu Ming-Fei[2] and Li Xi-Jie[2], [1]Centre for Ecology and Conservation, and Environment and Sustainability Institute, University of Exeter, China, United Kingdom, [2]Nanjing Agricultural University, China

Abstract: The fall armyworm (FAW), an invasive pest from the Americas, is rapidly spreading through the Old World, and has recently invaded the Indochinese Peninsula, China and Korea. In the Americas, FAW migrates from winter-breeding areas in the south into summer-breeding areas throughout North America where it is a major pest of corn. Asian populations are also likely to evolve migrations into the corn-producing regions of eastern China, where they will pose a serious threat to food security. To evaluate the invasion risk in East Asia, the potential routes and mechanisms by which FAW moved from Africa into India, Indochina and then into China was modelled by a trajectory simulation approach, combined with flight behaviour and meteorological data. Our results reveal that (i) FAW could potentially have reached India and Indochina by natural migration from Africa with the help of Somali Jet, which is characterized by persistent, high-speed winds over the Arabian Sea, southern Asia, and the Bay of Bengal; (ii) that FAW will annually expand from its new year-round breeding regions in the Indochinese Peninsula and southern China into the two main corn-producing regions of eastern China (North China and Northeast China) by July, via separate eastern and western migration pathways involving the northward movement of four generations; and (iii) there is a high risk that FAW will invade Japan and Korea in the summer monsoon season in June and July. Information on migration pathways and timings can be used to inform integrated pest management strategies for this emerging pest.

Radar observations of the seasonal migration of the oriental armyworm moth, Mythimna separata, and other insects

Authors: Chapman Jason[1], Hu Gao[4], Wu Qiulin[3], Wu Kongming[2], Jiang Yuying[5] and Haowen Zhang[2], [1]Centre for Ecology and Conservation, and Environment and Sustainability Institute, University of Exeter, China, United Kingdom, [2]Chinese Academy of Agricultural Science, China, [3]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [4]Nanjing Agricultural University, China, [5]National Agro-Technical Extension and Service Center, Beijing, China

Abstract: The migrations of the oriental armyworm moth, Mythimna separata (Walker), and other insects over the Bohai Sea were observed by entomological scanning radar at a site on Changdao Island in the center of the sea. Aerial samples of the insect migrants were collected using a searchlight trap, thus long-distance and across sea movement of M.separata populations in the surrounding regions could be detected and well studied using data from the entomological scanning radar, a standardized light trap network, field surveys, atmospheric trajectory simulations and a next-generation meso-scale numerical weather prediction system. Our main results were summarized as follows. Seasonal migrations of M.separata moths over Beihuang from May to October in 2003 to 2017 governed by wind streams exhibited three main migratory stages: 9 May to 28 June, 28 June to 17 August, and 17 August to 6 October, which were consistent with the results of ovarian dissection. Northward migration of M.separata moths usually started in early May and persisted until mid-August, then the migration pattern shifted and southward migration (i.e., return migration) occurred during late August to October. It is also suggested that the migration of M.separata performed a closed loop between the central and eastern China and the northeastern China, and the Changdao Island was distinctive on its vital pathway. Furthermore, displacement speed and direction of insect targets were measured to obtain individuals' flight heading and speed. Abiotic meteorological cues adjusting the long-distance migratory movement were also identified incorporating with the combination approaches of the numerical weather simulation and the entomological scanning radar. Furthermore, the seasonally aerial migration fluxes of M.separata population and other insects flying over the island were estimated to explore their adaptive strategies to atmospheric features in migration arena.

Epitope specific conditional discrimination of FREPs expression in An. stephensi

Authors: Chauhan Charu[1] and Dixit Rajnikant[1], [1]National Institute of Malaria Research, India

Abstract: Hemocytes are the blood cells of mosquitoes' circulatory system, which imparts a selective immune response against various micro-organsims/pathogens. Among diverse members of PRR family, FREPs have been recognized as key modulator of cellular immune responses, however, their physiological relavance has not been investigated in detail. A comprehensive In-silico analysis of 24 putative FREPs from Anopheles stephensi, predicts a common evolutionary relationship across blood feeding mosquitoes and Drosophila. Finding of at least seven putative transcripts in our hemocyte RNAseq data in response to Plasmodium vivax prompted us to access their potential immune-physiological responses. AsFREPs showed a highly selective response of individual FREPs against blood meal, exogenous bacterial challenge and Plasmodum vivax infection. Our study revealed relatively high affinity of FREP13 and another FREP towards gram negative bacteria and P.vivax infection respectively. Functional knock down assay reveals that FREP13 is not only involved in regulation of TEP1 mediated immune response but also modulate microbiota during blood feeding which may indirectly work against plasmodium infection.

Molecular mechanism for metabolic adaptation to muscle hypoxia during flight in migratory locusts

Authors: Chen Bing, College of Life Sciences, Hebei University, China

Abstract: Animals indigenous to very high altitudes have evolved a distinctive suite of physiological traits to cope with the environmental hypoxia. We have used Tibetan migratory locusts as an ideal model to study the physiological and molecular mechanisms of insects for hypoxia adaptation. We previously demonstrated that modulation of mitochondrial respiration in flight muscle contributes to adaptation of Tibetan locusts to hypoxia (Zhang et al. 2012 Proc. R. Soc. B.). Transcriptome analysis revealed the different molecular pathways enriched in aerobic metabolisms between Tibetan and lowland locusts under hypoxia (Zhao et al. 2013 BMC Genome). We further performed whole-Genome genetic analysis and functional studies and found that the Tibetan locusts regulate the hypoxia-induced metabolic adaptation through mediating the activity of insulin signaling pathway (Ding et al. 2018 Nat. Commun.). Here, in this report, we show that one hypoxia-inducible factor (HIF) is mutated in the Tibetan locusts. The mutation endows them with long flight capacity under hypoxia. Our findings provide novel insight into the evolution of metabolic adaptation to muscle hypoxia during flight in insects.

Systematic and taxonomic study of the egg parasitoid family Scelionidae in China

Authors: Chen Huayan, Sun Yat-Sen Univeristy, China

Abstract: Species of the family Scelionidae are important egg parasitoids of 9 orders of insects and spiders. Many species have been successfully used as biological agents against insect pests in agriculture and forestry. Due to its large number of species, host diversity and specificity, Scelionidae may serve as an ideal group for testing the adaptive evolution of host use and the mechanism of host finding. However, the Chinese fauna of Scelionidae taxonomically remains a large void in our knowledge. In addition, the interrelationships within the family are largely unclear, which in turn have impeded research on how these wasps have adapted to different hosts. My project aims to thoroughly revise the Chinese fauna of Scelionidae, including their taxonomy, distribution, host range, biology, and phylogenetic hypotheses and adaptive evolution patterns of host use across multiple hierarchical levels in the family. We are hoping to provide scientific basics for further biological study of these wasps and their implications in pest biological control as well as baseline data for biodiversity conservation in China.

Biocontrol characteristics of the fruit fly pupal parasitoid Trichopria drosophilae (Hymenoptera: Diapriidae) emerging from different hosts.

Authors: Chen Jiani[1], Pang Lan[2], Zhou Sicong[1], Huang Jianhua[1], Chen Xuexin[1], [1]Institute of Insect Sciences at Zhejiang University in Hangzhou, China, [2]Institute of Insect Sciences, Zhejiang University, China

Abstract: Trichopria drosophilae (Hymenoptera: Diapriidae) is an important pupal endoparasitoid of Drosophila melanogaster Meigen (Diptera: Drosophilidae) and some other fruit fly species, such as D. suzukii, a very important invasive and economic pest. Studies of T. drosophilae suggest that this could be a good biological control agent for fruit fly pests. In this research, we compared the parasitic characteristics of T. drosophilae reared in D. melanogaster (TD m) with those reared in D. hydei (TD h). TD h had a larger size than TD m . The number of maximum mature eggs of a female TD h was 133.6 ± 6.9, compared with the significantly lower value of 104.8 ± 11.4 for TD m . Mated TD h female wasp continuously produced female offspring up to 6 days after mating, compared with only 3 days for TD m . In addition, the offspring female ratio of TD h, i.e., 82.32%, was significantly higher than that of TD m, i.e., 61.37%. Under starvation treatment, TD h survived longer than TD m. TD h also survived longer than TD m at high temperatures, such as 37 °C, although they both survived well at low temperatures, such as 18 °C and 4 °C. Old-age TD h females maintained a high parasitism rate and offspring female ratio, while they were declined in old-age TD m . Overall, TD h had an advantage in terms of body size, fecundity, stress resistance ability and the parasitism rate compared with TD m . Therefore, T. drosophilae from D. hydei could improve biocontrol efficacy with enormous economic benefits in the field, especially in the control of many frugivorous Drosophilidae species worldwide.

Larval secretions of two Drosophila endoparasitoids with distinct infection strategies.

Authors: Chen Jiani[3], Pang Lan[4], Zhou Sicong[2], Huang Jianhua[2], Chen Xuexin[1], [3]Institute of Insect Sciences at Zhejiang University in Hangzhou, China, [4]Institute of Insect Sciences, Zhejiang University, China, [2]Institute of Insect Sciences at Zhejiang University in Hangzhou, China, [1]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, Hangzhou, China

Abstract: Parasitic wasps are exceedingly diverse and the most successful group of biological control agents. Successful parasitization and development of wasps depend not only on diverse parasitic strategies but also on their diverse parasitic factors, including venom, polydnavirus (PDVs), and teratocytes. However, for the wasps with venom only, there may exist some novel parasitic factors, like larval secretions, to regulate host development and immunity, as well as manipulate host nutrition. Leptopilina boulardi and Leptopilina heterotoma, two species of Drosophila larval-pupal endoparasitoids, which have two distinct infection strategies: L. boulardi evades host immune response, and L. heterotoma breaks host immune response. Therefore, these two wasp larvae might secret different immune related proteins. Here, we dissected the larvae of two parasitic wasps from the hosts, cultured them in vitro and collected their larval secretions. We used mass spectrometry to sequence peptides of the secretory proteins and then mapped the peptide spectral data against the larval transcriptomes to identify putative genes for each group. In total, we obtained 948 and 168 larval secretory proteins from L. boulardi and L. heterotoma, respectively. The protein numbers of L. boulardi were much higher than L. heterotoma, which indicated that the L. boulardi needed more proteins to evade host immune response. The present study greatly contributes to the understanding of the biological diversity of larval secreted proteins which have been seldom reported, and is helpful to study the regulation of secretions into host to facilitate the development of wasp larvae.

The developmental transcriptome of Trichopria drosophilae (Hymenoptera: Diapriidae) and insights into cuticular protein genes

Authors: Chen Jiani[3], Pang Lan[4], Zhou Sicong[2], Huang Jianhua[2], Chen Xuexin[1], [1]Institute of Insect Sciences at Zhejiang University in Hangzhou, China, [2]Institute of Insect Sciences, Zhejiang University, China

Abstract: The pupal endoparasitoid wasp Trichopria drosophilae (Hymenoptera: Diapriidae) plays an important role in biological control of many frugivorous fruit fly species including Drosophila suzukii, a well-known invasive pest. Here, we report the transcriptomes of T. drosophilae among different developmental stages. A total of 601,148,438 high-quality reads were obtained and de novo assembled into 187,704 unigenes with an average length of 1096 bp. Among them, 21,735 unigenes were annotated into 52 Gene Ontology terms and 36,898 were assigned to 25 Cluster of Orthologous Groups categories, whereas 30,585 unigenes were mapped to 270 Kyoto Encyclopedia of Genes and Genomes different pathways. Numbers of differentially expressed genes were found through comparisons between different developmental stages. We further identified 137 cuticular protein genes (CPs) from T. drosophilae transcriptome, including 59 from CPR family, 2 from Tweedle family, 1 from CPF family, 46 from CPAP family, and 29 from other CP families. We analyzed expression patterns of the CPs at different developmental stages of T. drosophilae, and found some stage-specific CPs. Quantitative real-time PCR results confirmed RNA sequencing findings based on the relative expression levels of eight randomly selected CPs. This study provides a valuable transcriptomic resource for a comprehensive understanding of the development and physiology of T. drosophilae, and will help to improve their parasitism efficiency for biological control purposes.

The impact of cover crops on the predatory mite Anystis baccarum (Acari, Anystidae) and the leafhopper pest Empoasca onukii (Hemiptera, Cicadellidae) in a tea plantation

Authors: Chen Li-Lin[1], Pozsgai Gabor[4], Zhu Huaiping[3], You Min-Sheng[1], Yuan Pei[3] and Chen Ping[2], [1]a State Key Laboratory of Ecological Pest Control for Fujian and Taiwan Crops, College of Plant Protection, China b Institute of Applied Ecology, China, [2]Biology Centre AS CR, v.v.i, Institute of Entomology, Ceske Budejovice, Czech Rollege of Plant Protection, Fuzhou, China b Institute of Applied Ecology, [3]LAMPS, Department of Mathematics and Statistics, York University, Toronto, Canada, [4]Institute of Applied Ecology Fujian Agriculture and Forestry University, China

Abstract: BACKGROUND: Empoasca onukii, the tea green leafhopper, is a key pest of tea, whose control often requires the extensive use of insecticides. As a predator of the tea green leafhopper, the mite, Anystis baccarum, is a potential biological control agent worldwide, though little is known about how intercropping cover crops can impact its suppressing effect on E. onukii. Therefore, we conducted a field experiment to investigate how the relationship of the abundance of the predatory mite and its leafhopper prey is influenced by different two cover crops and a manually weeded inter-row treatment as a contrast to naturally growing vegetation in a tea plantation in China.

RESULTS: The abundance of A. baccarum was signi?cantly higher in tea canopies of intercropped treatments than in canopies over natural ground cover. Litter samples showed higher abundances of A. baccarum when tea was intercropped with Paspalum notatum than with natural ground cover, in the first year of treatment. The abundance of E. onukii in tea canopies was higher over the bare ground treatment in the first year but the opposite was observed in the second year.

CONCLUSIONS: Results suggest that the abundance of A. baccarum in a tea plantation is influenced by intercropping and it can affect its leafhopper prey, albeit, with varying levels of suppression. For informing biological control and suppression of pests, long term experiments are needed to investigate the interactions of both pest and predator with cover crop treatments.

WAKE mediates Drosophila male-male courtship activity through insulin-like signaling pathway

Authors: Chen Shiu-Ling[1], Liu Bo-Ting[1], Shih Bo-Ting[1], Chiang Cheng-Yu[1], Tzeng Huey-Fen[1], Ho Shuk-Man[2], Liao Sin-Bo[1], Fu Tsai-Feng[1], Deng Yao-Bang[2] and Chou Yi-Qi[1], [1]Department of Applied Chemistry National Chi-Nan University, Taiwan, [2]Department of Applied Chemistry, International Chi Nan Unversity, Hong Kong

Abstract: WAKE is highly important to neurological functions in Drosophila, implicated in circadian and sleep maintenance and it is an essential regulator in asymmetric cell division (ACD) of neuroprecursor cells in developmental stage. In this study, we evidenced WAKE deficits in insulin producing cells (IPCs) that prompts inter-male courtship underlie insulin/insulin-like growth factor signaling (IIS) pathway. This is an interesting discover but how IIS induced male to male courtship needs further study.

Large-scale annotation and evolution analysis of microRNAs in insects

Authors: Chen Xuexin[2], Xingzhou Ma[2], Li Fei[2] and He Kang[1], [1]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, Hangzhou, China

Abstract: MicroRNAs are small no-coding RNAs with crucial biological functions. Accumulation of miRNAs is believed to contribute significantly to the increase in morphology complexity of animal evolution. Insects have been through at least two round of morphological innovations during the evolution. However, the question how miRNAs evolved in insects and how miRNA evolution related to these important evolution events such as the appearance of wing and metamorphosis in insect remains elusive. To address these issues, we annotated miRNAs from 152 arthropod genomes (including 132 insects represent major evolutionary clades of Insecta) using homologous searching and de novo method. We obtained 15680 miRNA genes and 489 miRNA families. By adding the presence and absence of miRNA families to a phylogenetic tree constructed by protein-coding genes, we use Dollo parsimony model to reconstruct the gain and loss of miRNA in insect evolution. Our result showed that the common ancestor of insects shared 64 conserved miRNA families. After derived from Apterygota ancestor, winged-insect gained 5 miRNAs at the stem of Pterygota and 3 at the stem of Neoptera. After that, miRNA evolution became quiescent with no miRNA gained at the clades of Polyneoptera and Paraneoptera, and only one gain and loss at Endopterygota. In Endopterygota, we show two independent rounds of miRNA innovations occurred at the stem of Hymenoptera and Lepidoptera. Meanwhile, we show an extensive loss of conserved miRNAs in paraneoptera (especially Coccidae) and twisted-wing insect (Strepsiptera), which concur with the morphological simplification in these clades. Our result suggests the gain and loss of miRNAs is consistent with the morphological evolution of insects, and provide new insight into the miRNA evolution in insects.

Species and phylogenetic diversity within the tribe Alysiini (Hymenoptera, Braconidae, Alysiinae) from China

Authors: Chen Xuexin[1], Zhu Jiachen[2], Tang Pu[2] and Van Achterberg Cornelis[2], [1]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, Hangzhou, China, [2]Institute of Insect Sciences, Zhejiang University, China

Abstract: Hymenoptera are one of the four hyperdiverse orders of holometabolan insects, in which more than 90% species are Apocrita. However, the research on species richness and phylogenetic diversity in the Parasitoid hymenoptera are largely unknown. The tribe Alysiini belonging to the order Hymenopetra, are known as koinobiont endoparasitoids of larval cyclorrhaphous Diptera, which play an important role in the biological control. Here, we systematically assessed the taxon biodiversity in the parasitoids, Alysiini using both morphological and molecular data across the China for the first time. We found distinct 26 genera, additional seven subgenera and 98 new species in the tribe Alysiini (with one new genera and one new subgenera) from total 2400 specimens. Moreover, we present the first phylogenetic hypothesis for these tribe and species richness by the whole mitochondrial genome and barcoding sequencing respectively, combined with morphological matrix. We found that the species in Alysiini are phylogenetically diverse and closely related parasitoids use main host taxon. Various Bayesian inferences using different data partitions and phylogenetic methods recovered similar phylogenetic trees with strong statistical support for almost all nodes. Our results demonstrated the general pattern that most genera of Alysiini are much diverse in the humid, shady habitat like Yunnan, Hainan province (especially new species are often found in these area) or mountainous regions like Zhejiang and Sichuan province. Such patterns are strongly coincided with the distribution of host use and habitat. We supported that the species richness is related with host habitat, together with morphological traits and genetic heterogeneity, highlighting the important influence of host-association, evolutionary constraints and environmental phenology on the diversification in the tribe Alysiini.

The flightin gene is necessary for the emission of vibrational signals in the rice brown planthopper (Nilaparvata lugens St?l)

Authors: Chen Xuan, State Key Laboratory of Rice Biology and Ministry of Agriculture Key Laboratory, China

Abstract: In duet-based courtship, species- and sex-specific vibrational signals enable animals to identify the species and sex of the singer and also provide the necessary information to locate a partner. Substrate-borne communication has been described in a wide variety of insects. Here, we focused on the gene necessary for the emission of male vibrational signals and whether male songs fulfil such functional roles in mating systems in the brown planthopper (BPH, Nilaparvata lugens). We generated mute BPH adult males by RNA interference of the flightin gene, which encodes a myosin-binding protein expressed exclusively in the dorsal longitudinal muscle (DLM) in the basal two abdominal segments for driving vibration of the male-specific tymbal structure in short-winged (brachypterous) BPH adults. Transmission electron microscopy observation showed that flightin knockdown disrupted the normal sarcomere structure of abdominal DLM. No courtship song could be detected in the brachypterous males after RNAi of flightin. Behavior and competition trials showed that the lack of male courtship songs prolonged copulation latency and even caused female rejection. Unexpectedly, the mute males exhibited greater competitiveness when competing against normal males.

Male homosexual mating behaviors in Bactrocera dorsalis

Authors: Chen Yaoyao[1], Cui Gaofeng[1], Zhong Guohua[1], Sun Ranran[1], Yi Xin[1], [1]Key Laboratory of Crop Integrated Pest Management in South China, Ministry of Agriculture. Key Laboratory of Natural Pesticide and Chemical Biology, Ministry of Education, South China Agricultural University, Guangzhou, China

Abstract: The variety and ubiquity of same-sex courtship, pair bonding and copulation have been observed in a wide range of species, and it is always a puzzle to interpret the reason to such behavior. Many hypotheses have been proposed to explain the persistence of same-sex sexual behavior, some hypotheses have hold, but others haven't explained this particular phenomenon. In our study, the sex pheromone identification hypothesis was verified by us in Bactrocera dorsalis. As the case in Drosophila, cis-vaccenyl acetate (cVA) and 7-tricosene (7-T) have roles in mediating male-male mating behavior in B.dorsalis, as cVA increase the frequency of male-male mating behaviors at low concentrations, and 7-T could significantly reduce male-male mating frequency. Then we used genetic approaches to investigate the consequence of odorant receptor manipulation on male-male mating behaviors. And the results showed six odorant receptors (BdorOr2d, BdorOr2e, BdorOr7, BdorOr13b, BdorOr2a, BdorOr10) play roles in mediating male-male mating behavior in B.dorsalis. Further, studies confirmed that BdorOr2d, BdorOr2e, BdorOr7, BdorOr13b could participate in regulating male-male mating behavior as cVA recognition receptors, and BdorOr2a, BdorOr10 are important recognition receptors for 7-T. As the results indicated that one of the reasons for male-male mating behaviors could be that the sex pheromone cannot be correctly identified. This study described the existence of same-sex sexual mating behavior in B.dorsalis for the first time, and the results in this study could providelines of evidence and information to utilize sex pheromone and their odorant receptors to manipulate male-male mating behavior of B.dorsalis to accomplish green, sustainable and specific pest control.

Insecticide exposure alters epigenetic modifications in the Colorado potato beetle, Leptinotarsa decemlineata

Authors: Chen Yolanda[4], Schoville Sean[2], Bueno Erika[3], Brevik Kristian[3] and McKay Stephanie[1], [1]Dept. of Animal and Veterinary Sciences University of Vermont, United States, [2]Dept. of Entomology University of Wisconsin, United States, [3]Dept. of Plant and Soil Science University of Vermont, United States, [4]University of Vermont, United States

Abstract: Although it is widely assumed that insects eventually evolve resistance to commonly used insecticides, the evolutionary processes underlying insecticide resistance remain poorly understood. Insecticide resistance seems to arise in response to the frequency and intensity of insecticide exposure, suggesting insecticide exposure itself may increase the rate of mutation or cause heritable physiological changes in pest organisms. Environmental stress has been shown to influence epigenetic modifications such as DNA methylation, which can be heritable across generations. We studied if changes in DNA methylation may be associated with the evolution of insecticide resistance. Using a whole genome bisulfite resequencing study, we tested how insecticide exposure influenced patterns of DNA methylation in the Colorado potato beetle, a widely adaptable beetle. We exposed third instar larvae to treatments that varied in toxicity (water, LC50 dose of imidacloprid, LC10 dose of imidacloprid, and a LC¬10 dose of a modified imidacloprid compound). After dosing them, we reared beetles to adult we tested how the treatments influenced % DNA methylation and patterns of differential methylation in the parent and F2 generation. All beetles exposed to imidacloprid showed significantly lower levels of % of CpG methylation, which was significant in the F¬2 generation but not the parent generation. We found differential levels of methylation across over 100k sites, but 221 differentially methylated sites exceeded the more conservative cut-off. Although the majority of the 221 differentially methylated sites fell in genomic regions that were not annotated, a few annotated genes were differentially methylated.

Biological and chemical control of coconut rhinoceros beetle (Oryctes rhinoceros), a recent invasive pest on Oahu, Hawaii.

Authors: Cheng Zhiqiang[2], Li Jing[1], Russo Mason[2], Kellar Matthew[2], [1]Hebei Agricultural University; University of Hawaii at Manoa, China, [2]University of Hawaii at Manoa, United States

Abstract: Coconut rhinoceros beetle (CRB, Oryctes rhinoceros) is a large scarab beetle native to Southeast Asia and a serious pest of palm species, most notably coconut and oil palms. CRB adults damage palms, particularly younger ones, by boring into the center of the crown, where they injure the young, growing tissues and feed on the sap. Adult CRBs were found at the Honolulu International Airport and the adjacent Joint Base Pearl Harbor-Hickam (JBPHH) on Oahu in December 2013. Further examination revealed CRB larvae in mulch at JBPHH, representing the first time a breeding population of CRB had been confirmed in Hawaii. CRB has been identified by USDA Animal and Plant Health Inspection Service (APHIS) as one of the most damaging invasive insect pests of coconut and other palm species whose introduction could result in significant economic losses to commercial coconut and palm nurseries, and Hawaii's residents and tourists who appreciate palm trees for their aesthetic and cultural values. Since then, USDA APHIS, in collaboration with Hawaii Department of Agriculture (HDOA), University of Hawaii at Manoa, Hawaii Invasive Species Council, and other entities, launched the CRB eradication program, the largest invasive species eradication program in Hawaii's history. This presentation reports our latest research updates on biological and chemical control of CRB. Due to the strict regulations on importing biological control agents into Hawaii set by HDOA, our approach for biological control research is to collect locally occurring entomopathogenic fungi and nematodes, and then screen them for effective strains in both lab assays and field trials. We collected over 60 entomopathogenic fungal strains and over 20 entomopathogenic nematode strains from various landscape sites on Oahu. Based on our multiple lab assays, we identified 6 Metarhizium strains that caused > 70% mortality of CRB larvae. A small-scale field trial with 3 most effective Metarhizium strains resulted in > 40% mortality of CRB larvae in field condition. Larger scale field trials will be conducted as soon as permission from HDOA is obtained. For chemical control, we focus on low-risk systemic insecticides. Based on our multiple lab assays, we identified that acephate and imidacloprid were very effective, causing 40% paralysis of CRB adults within 4 hours, 50% mortality of CRB adults within one day, and 100% mortality of CRB adults within three days. Based on these lab assay results, we conducted a field trial with 125 coconut palms for 2 years. Field trial results did not yield significant difference among treatments, but resulted in an area-wide reduction of CRB population indicated by the decreased number of CRB adults caught by traps. Most up-to-date research results will be presented at 2022 ICE.

Functional morphology of Trichadenotecnum male and female genitalia analyzed using µCT (Insecta: Psocodea: Psocomorpha)

Authors: Cheng Zixin[2] and Yoshizawa Kazunori[1], Hokkaido University, China, Japan, [1]Hokkaido University, Japan, [2]Systematic Entomology, Graduate School of Agriculture

Abstract: Although the great genital diversity of the barklouse genus Trichadenotecnum has been described in previous studies, the specific function of the genital structures during the copulation process has received less investigative attention. We reconstructed the 3D models of each structure and muscle of the male and female genitalia of T. incognitum in copula and those of uncopulated male and female of T. pseudomedium. By comparing the changes in male and female genital structures and related muscles in copulated and uncopulated states, the function of each genital structure can be described. During the Trichadenotecnum copulation process, we found that the female subgenital plate was hooked into the male body by the distal process on the male paraproct and was fixed by the male epiproct, hypandrium and phallosome. In addition, the presence of sexually antagonistic coevolution was suggested by tightly contacting structures, i.e., thorny male hypandrium and female gonopore plate. These results not only give us a new understanding of the copulating process of Trichadenotecnum but also explain the reasons why each genital structure is extremely diversified in the genus.

Survival and Behavior of Melanotus communis (Coleoptera: Elateridae) in Florida Sugarcane Soils

Authors: Cherry Ronald[1], McCray Mabry[1], Karounos Michael[1] and Ji Shangning[1], [1]University of Florida, United States

Abstract: Wireworms (Coleoptera: Elateridae) are major economic pests of Florida sugarcane (Saccharum spp. hybrid). The corn wireworm, Melanotus communis (Gyllenhal), is the most important wireworm pest of Florida sugarcane occurring in both sandy and muck soils. The objective of this study was to determine survivability, preference, and dispersal of wireworms in sandy and muck soils. There was no significant difference in starved wireworm survival between the soils after 2 mo. However, the starved wireworms gained more weight in muck soil than sand. Wireworms dispersed at similar rates towards oat baits in both soil types. Interestingly, in free choice tests, wireworms showed a high preference to reside in muck versus sandy soil which corresponds to the greater wireworm weight change found in muck versus sandy soil. The high preference for muck and greater weight gain in muck found in this study partially explains why M. communis is more abundant in muck soils than sandy soils in Florida sugarcane.

Assessing the contribution of the bacterial symbiont Rickettsia to the salivary functions of the sweet potato whitefly Bemisia tabaci

Authors: Chesnais Quentin[3], Kenney Jaimie[4], Mauck Kerry[2], Hunter Martha[1] and Sun Penglin[2], [1]Department of Entomology, University of Arizona, United States, [2]Department of Entomology, University of California, Riverside, United States, [3]Université de Strasbourg, INRAE, SVQV UMR-A1131, Colmar, France, [4]University of California, Riverside, United States

Abstract: Now ranked among the top 100 most damaging invasive pests worldwide, the sweet potato whitefly, Bemisia tabaci MEAM1 is a generalist insect capable of feeding on and transmitting viruses to numerous high-value crops. Development of effective and sustainable whitefly control methods requires a fundamental understanding of the molecular mechanisms underlying host plant exploitation and feeding behaviors necessary for virus transmission, which we currently lack for B. tabaci MEAM1 and other globally important whitefly species. Sufficient nutrient ingestion, and transmission of many plant viruses depend on aphids, whiteflies, and related hemipterans engaging in prolonged uptake of plant sap from the phloem. Studies on aphids demonstrate that this process is made possible by delivery of effector proteins into the plant during bouts of salivation that precede sap ingestion. Salivary effector proteins suppress plant defenses and phloem occlusion to enable prolonged sap uptake by the vector, during which virus acquisition can occur. However, effector discovery and functional validation has only been carried out for a handful of hemipteran organisms. As new insect effectors are being discovered, we are also learning that bacterial symbionts can have profound effects on saliva content and activity. For example, proteins from an obligate symbiont of aphids can enter saliva and subsequently modify plant defenses and aphid performance. Considering that most hemipterans, including whiteflies, are host to a suite of obligate and facultative vertically-transmitted bacterial symbionts, it is essential to consider symbiont contributions to the salivary proteome. We present a work that uses a combined transcriptomic and proteomic approach to characterize the contributions of the whitefly host and a key facultative symbiont that enhances whitefly fitness, to saliva composition and function of two B. tabaci MEAM1 populations that share >98% similarity in nuclear genomes, but differ in the presence of Rickettsia.

Age-stage, two-sex life table: important basis for achieving successful biological control programs

Authors: Chi Hsin, National Chung Hsing University, Taiwan

Abstract: The age-stage, two-sex life table incorporates the age-stage structure of a population and the male individuals - two critical parameters that are missing in female-based life tables. It is an important tool for population ecology studies and pest management programs. Because both the predation rate and the vulnerability of prey vary with the stage, and male predators and the male pests are components of the predator-prey system, it is obvious that using the age-stage, two-sex life table is vital to understanding the intricacies involved in planning successful biological control programs.

Comparative demography and mass rearing of Aedes aegypti fed on live mice versus pig blood using a novel perforated feeder

Authors: Chi Hsin[3], Dai Shu-Mei[2], Hsu Pei-Chen[1] and Atlihan Remzi[4], [1]Applied Zoology Division, Taiwan Agriculture Research Institute council of Agriculture, Executive Yuan, Taiwan, [2]Department of Entomology, National Chung Hsing University, Taiwan, [3]National Chung Hsing University, Taiwan, [4]Van Yuzuncu Yil University Agriculture Faculty Department of Plant Protection, Turkey

Abstract: A novel thermal-constant blood-feeder covered with a perforated film and using pig blood was developed for rearing Aedes aegypti (L.) (Diptera: Culicidae). The perforated film was used as a substitute for the membrane or parafilm that is normally used in conventional blood-feeders to prevent the mosquitoes from directly contacting the blood. The efficiency of this perforated blood feeder was assessed by using live mice and comparing the engorgement rate of female mosquitoes and their demographic parameters. In a no-choice test, no significant differences were observed in the engorgement rates and fecundity between females fed on perforated feeders containing pig blood and those fed on live mice. In a three-minute-long free-choice test, the accumulated engorgement rate was significantly higher in mosquitoes feeding on the perforated feeders than in those feeding on live mice. The demographic characteristics indicated that mosquitoes fed on the perforated feeder containing pig blood had a higher immature survival rate and prolonged adult male and female longevity. Although a lower intrinsic rate of increase and lower finite rate of increase were observed when female adults fed on the perforated feeder, computer projection of the population growth was comparable using both blood sources. Mass-rearing analysis showed that the perforated blood feeder was much more cost-effective than using live mice. These results demonstrate that the perforated blood feeder containing pig blood is more effective and cost efficient than using live mice for maintaining and mass rearing of mosquitoes in the laboratory.

Differential life-history responses in Neolema abbreviata, a biological control agent for Tradescantia fluminensis under water and nitrogen gradients

Authors: Chidawanyika Frank[2], Mbande Abongile[1] and Tedder Michelle[3], [1]Agricultural Research Council, South Africa, [3]University of KwaZulu Natal, South Africa, [2]Department of Zoology and Entomology, University of the Free State, Bloemfontein, South Africa

Abstract: Due to their sessile nature, plants inexorably endure both transient and chronic environmental stressors with subsequent impact on their interactions with other trophic groups. Water and nitrogen variability are key abiotic factors mediating the interaction between plants and insect herbivores. For insects used in classical biological control of plants, such factors may determine extent of herbivory, population dynamics and ultimately field establishment and persistence. We conducted a full factorial experiment to determine the impact of water and fertiliser variability on the performance of Neolema abbreviata (Lacordaire) (Coleoptera: Chrysomelidae) and its host plant Tradescantia fluminensis Vell (Commelinaceae). Water and fertiliser variability strongly influenced T. fluminensis biomass accumulation and foliar nitrogen content. These changes in host plant quality resulted in preferential oviposition selection by the beetles with optimally irrigated plants that received moderate fertilizer being most favoured. Larval performance, in terms of weight gain and time to pupation, was highest in this treatment providing support for the preference–performance hypothesis. There were similarities in feeding performance and subsequent performance among plant treatments between larvae and adults suggesting uniform nutritional quality requirements between the life-stages. Overall, our study reveals differential effects of paired abiotic stressors and performance among herbivorous insects with both juvenile and adult feeding life-stages. The study, therefore, calls for multi-trait and factor evaluation to understand the impact of plant quality on insect life history traits. Our findings

Olfactometer bioassays help defining ecological host range of a candidate biocontrol agent of Halyomorpha halys

Authors: Chierici Elena[2], Rondoni Gabriele[2], Giovannini Lucrezia[1], Sabbatini-Peverieri Giuseppino[1], Roversi Pio Federico [1] and Conti Eric[3], [1]CREA-Research Centre for Plant Protection and Certification, Florence, Italy, [2]DSA3, University of Perugia, Italy, [3]University of Perugia, Italy

Abstract: In agriculture, management of invasive arthropod species involves multiple strategies, including the introduction and release of exotic natural enemies, e.g., parasitoids. However, a risk assessment must be preliminarily conducted to evaluate possible non-target effects on local biodiversity of the introduced natural enemy after its establishment. For egg parasitoids, location of target and non-target hosts is firstly determined by effective responses towards odours emitted by plants as a consequence of herbivore attack (synomones), and/or by the different host instars (kairomones). Hence, evaluation of host-associated odour attractiveness during pre-release risk assessment can be crucial for determining the likelihood of parasitoid interaction with non-target species in open field conditions. In a quarantine laboratory, using Y-tube olfactometer bioassays, we investigated the ability of the Asian egg parasitoid Trissolcus mitsukurii (Ashmead) (Hymenoptera: Scelionidae) to exploit odours associated with the coevolved invasive pest Halyomorpha halys Stål (Hemiptera Pentatomidae) and with non-target stink bugs native to Southern Europe. Our results demonstrated attraction of T. mitsukurii towards plants exposed to feeding and egg deposition by H. halys and by the native pest Nezara viridula L., but not towards physogastric females or eggs alone. Noteworthy, T. mitsukurii was not attracted to the other non-target species tested and was repelled by plants bearing eggs of the beneficial predator Arma custos F. These laboratory studies contribute to a deeper understanding of the potential non-target risks of T. mitsukurii as a potential biocontrol agent, alternative to Trissolcus japonicus (Ashmead), against H. halys.

Side effects of some insecticides on two Halyomorpha halys egg parasitoids, Trissolcus japonicus and Trissolcus mitsukurii

Authors: Chiesa Serena Giorgia[2], Hoelmer Kim A.[3] and Angeli Gino[1], [1]Edmund Mach Foundation - Technology Transfer Center, Italy, [2]Fondazione Edmund Mach, Italy, [3]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States

Abstract: Halyomorpha halys is an invasive species native to eastern Asia accidentally introduced to America and Europe, causing severe damage in agriculture.

The egg parasitoid Trissolcus japonicus is the main natural enemy of H. halys in Asia, and adventive populations were discovered recently in USA and Europe. In Italy a second Asian egg parasitoid, Trissolcus mitsukurii, was detected parasitizing egg masses of H. halys. Both parasitoid species appear to be widely distributed in northern Italy. In Italy, the possibility for the application of a classical biological control program is currently being debated. A management approach involving the use of biological control in specialized crop cultures entails the need to determine the sensitivity of the parasitoids to commonly used agrochemicals and measure their persistence of these pesticides at levels harmful to the natural enemies over time.

Females and males of T. japonicus and T. mitsukurii used in our studies were obtained from lab-reared colonies using H. halys eggs as host. T. japonicus originated from the USDA Beijing colony, while T. mitsukurii was field collected in northern Italy. The insecticides whose selectivity was assessed in semi-field trials included Coragen (rynaxypyr; 0,2 ml/L), Steward (indoxacarb; 0,17 g/L), Delegate (spinetoram; 0,26 g/L) and Karate zeon 1.5 (lambda-cyhalothrin; 0,2 ml/L). An untreated control was added to the insecticide tests. The products were applied in the field on apple trees (Fuji variety) with a portable sprayer and the treated shoots were collected at three successive dates: T+0, T+5 and T+8 days after the treatment. The shoots were brought to the laboratory and placed in plastic cages. Ten females (3 replicates) were added to each cage, provided with honey, and incubated in a thermostatic cell (26±1 °C; 65% RH; 16:8 h light/dark).

Parasitoid mortality was assessed at 24 and 48 h (apparently insecticide-affected specimens were categorized as dead). The mortality values were transformed with the Schneider-Orelli formula to obtain the correct mortality rate. Results showed a low mortality of T. japonicus in the control that was always = 10%. On the same day of field application of the insecticides (T+0), Coragen and Steward showed good selectivity towards female T. japonicus, with a mortality rate of three and zero percent respectively. After 48 h of exposure, Coragen was confirmed to be quite selective, while Steward mortality increased significantly (87%). Similar results were observed when field-treated shoots were exposed to parasitoids after 5 or 8 days from treatment (T+5 and T+8). Karate Zeon and Delegate were shown to not be selective for T. japonicus from the start at T+0, with a mortality of 53 and 100% respectively. At T+5 and T+8 Delegate activity remained almost constant at high levels, while the toxicity of Karate Zeon tended to decrease over time. The same trends were observed for treated T. mitsukurii females and for males of both species.

Forensically Important Acari Associated with Rabbit Carcasses Placed at Four Different Ecoregions in Malaysia

Authors: Chin Heo Chong[1], N Azmiera[1] and A Mariana[2], [1]Faculty of Medicine, Universiti Teknologi MARA, Sungai Buloh Campus, Jalan Hospital, Sungai Buloh, Selangor, Malaysia, [2]Unit of Acarology, Infectious Diseases Research Centre, Institute for Medical Research @National Institutes of Health Malaysia, Seksyen, Malaysia

Abstract: Recent development in forensic acarology has raised the interest of researchers on the importance of Acari in death investigations. The understanding of how ecoregion differences could affect mites' diversity and abundance is important as they are useful as forensic indicators to detect location of death as well as minimum post-mortem interval (mPMI). Therefore, the aim of this study was to determine the diversity and abundance of forensically important mites at four different ecoregions in Malaysia. Three rabbit carcasses (n = 3) were placed at each different locality namely forest, highland, village, and oil palm plantation. One hundred gram of soil samples were collected from beneath and around the decomposing carcasses every three days until the carcasses reached the skeletonization stage (i.e., 40 days). The soils were then placed in the Berlese-Tullgren funnel for the extraction of mites and proceeded with slide mounting for family identification. The ambient temperature and the amount of precipitation for each location were recorded. The abundance of mites in the forest was significantly higher than the other study sites ($P < 0.05$) with the mean abundance of 7.47 ±7.52. Mites recovered from the highland (5.30 ±8.58) and oil palm plantation (4.23 ±5.49) were significantly higher than those from the village (1.92, ±3.52). The most abundant family of mites of forensic importance in the forest was Macrochelidae; Histiostomatidae on the highland, and Acaridae for both village and oil palm plantation. The soils samples collected from beneath and around the carcasses contain significantly more mites than those in the control soil ($P<0.05$). The introduction of carrion to the soil ecosystem has caused significant changes in the diversity and abundance of mites and further study is therefore needed to validate these changes as geographical and mPMI indicators in forensic investigations.

Temperature affects the wings area melanization of Idea leuconoe clara.

Authors: Ching Lin Chu[1], Li-Hsin Wu[1], [1]National Pingtung University of Science and Technology, Department of Plant Medicine, Taiwan

Abstract: Idea leuconoe clara, the large tree nymph, is known for its presence in Southeast Asia butterfly gardens because of its large wingspan and black and white colour contrast. The distribution of black spots and the degree of coarseness and melanization of the wings are usually adopted for species identification. Patterns of latitudinal and teperature variation in the phenotype or genotype of a butterfly may lead the wings of the same butterfly to have different coloration. There are several records of the melanized I. leuconoe in literature and specimens collections from Taiwan and Southeast Asia. To test the effects of the development temperature on melanization of the wings of I. leuconoe, we reared 600 larvae under six constant temperatures (15- 40 °C) and found only two melanized adults (67-80% of wings area) under 35 °C and 40 °C; The mortality is 99% under these two high temperature treatments. We further characterized heat/cold-shock-treatments on 100 individuals during their wandering stage for 12 days. In response to the 10 °C cold treatment, the degree of melanization of the wings was 59-69% (2 melanized adults); on the other hand, in response to the 35 °C treatment melanization of the wings was 66-75% (4 melanized adults), and in response to the lethal 40 °C could reach up to 79-82% (5 melanized adults). In wandering stage heat-shock treatment, 9 individuals were melanized, the melanization rate was raised to 12% because of extreme temperatures and the mortality rate of I. leuconoe was reduced to 33%. We conclude that wing colour patterns to extreme temperature treatments results from a combined effect worked precisely on wandering, early pupal stage. These mechanisms might have been exploited in the colour-pattern of I. leuconoe to prevent individuals from some specific rearing conditions like wet and hot season.

Monitoring of Auchenorrhyncha species known or potential vectors for phytoplasma, in grapevine from Romania

Authors: Chireceanu Constantina[2], Teodoru Andrei[1], Mihu Ghica[4], Podrumar Teodor[3], Pușcalău Marioara[4] and Dobromir Daniela[3], [1]Research and Development Institute for Plant Protection Bucharest, Romania,[2]Research Development Institute for Plant Protection, Romania, [3]The Vine and Wine Research and Development Station Miniş, [4]The Vine and Wine Research-Development Station Odobeşti

Abstract: The viticulture is one of the most important agroecosystems in Romania covering about 190 thousand hectares. The phytoplasmoses diseases and their associated insect vectors are a group of phytosanitary risk factors that increasingly threaten the grapevine agroecosystem. The aim of this work was to evaluate the presence and abundance of the Auchenorrhyncha species known in the literature as confirmed or potential vectors for the grapevine phytoplasmas. The survey was conducted from 2016 to 2018 in eighty vine plots located in vineyards from four viticulture regions, Banat, Crișana and Maramureș (Western Romania) and Moldova (Eastern Romania). The insects were monitored using yellow sticky traps of 30x20cm, which were replaced at two weeks interval, from June to October. A total of 38903 specimens belonging to twenty-one species confirmed or potential vectors for grapevine phytoplasmas were collected. The most abundant species was the leafhopper Scaphoideus titanus, the principal natural vector of the Flavescence doree phytoplasma in European grapevine, representing 46.9% of all captured insects. Other species with considerable abundance were Neoaliturus fenestratus (14.5%), Fieberiela florii (11.6%) and Reptalus quinqecostatus (6.5%) associated with Stolbur phytoplasma. For each species, the main ecological indices, abundance, dominance, constancy and indices of ecological signification were calculated.

Are insects sentient?

Authors: Chittka Lars[2], Perry Cwyn[1], Gibbons Matilda[2] and Sarlak Sajedeh[3], [1]Macquarie University, Australia, [2]Queen Mary University of London, United Kingdom, [3]University of Tehran, Iran

Abstract: Nobel laureate Karl von Frisch famously claimed that bees not only do not feel pain, but in fact lack basic nociception. There would have been enough evidence even 50 years ago to debunk this myth, but we now know that most if not all animals have nociceptors, mechanoreceptors specialised for damaging or at least potentially damaging stimuli. The question of whether bees (and other animals) subjectively experience suffering is formally impossible to answer, hence we need to reason by common sense, probability and analogy to other animals. Using the same criteria as for other animals such as lobsters and fish, my team explores whether bees have the subjective experience of pain. We have also in the past discovered a positive emotion-like state in bees. These experiments as well as those by other teams working on emotions in insects indicate that, by the same criteria as those used for vertebrate animals, bees must be counted as sentient animals.

How bees use scanning behaviour for visual pattern recognition

Authors: Chittka Lars[2], Guiraud Marie[2], MaBouDi HaDi[1] and Gallo Vince[2], [1]Department of Computer Science, University of Sheffield, United Kingdom, [2]Queen Mary University of London, United Kingdom

Abstract: Bumblebees have remarkable visual learning capacities and are a simple model for understanding visual processing in a miniature network. The mechanisms underlying bee visual discrimination are still poorly understood. Biederman's theory on human visual object recognition suggests that objects can be described by a combination of their simple components. Global visual perception in humans may be derived by eye saccades moving between local features. Accordingly, critical questions in bee vision are whether and how bees process localised elemental information within stimuli to generate a global perception. Here, we explore insights from Biederman's theory studying which visual features (vertices or edges) may be important for bees in the visual recognition and which strategy they may use to infer a holistic perception. After training bumblebees to discriminate a square and a triangle, bees were tested to identify triangles and squares with deletion of vertices or edges. We show that bees can still recognise these visual stimuli without either vertices or edges. Given the conditioned stimuli, different bees have distinctive preferences in using edges or vertices for pattern recognition. Using 3D video tracking, we discover that bees only scan the bottom of the presented shapes and focus on the left side of stimuli, which was also found in other sensory modalities in vertebrates. Our results suggest that bumblebees perceive the natural environment via local features as humans do. They then integrate these features to produce a global perception by flying between these elemental features. Additionnally, our results have been modelled into a virtual arena, which allow us to have a better understanding of the bee flight behaviour during a visual experiment.

The Mind of the Bee

Authors: Chittka Lars, University Queen Mary of London, United Kingdom

Abstract: Bees have a diverse instinctual repertoire that exceeds in complexity that of most vertebrates. This repertoire allows the social organisation of such feats as the construction of precisely hexagonal honeycombs, an exact climate control system inside their home, the provision of the hive with commodities that must be harvested over a large territory (nectar, pollen, resin, and water), as well as a symbolic communication system that allows them to inform hive members about the location of these commodities. However, the richness of bees' instincts has traditionally been contrasted with the notion that bees' small brains allow little behavioural flexibility and learning behaviour. This view has been entirely overturned in recent years, when it was discovered that bees display abilities such as counting, attention, simple tool use, learning by observation and metacognition (knowing their own knowledge). Thus, some scholars now discuss the possibility of consciousness-like phenomena in the bees. These observations raise the obvious question of how such capacities may be implemented at a neuronal level in the miniature brains of insects. We need to understand the neural circuits, not just the size of brain regions, which underlie these feats. Neural network analyses show that cognitive features found in insects, such as numerosity, attention and categorisation-like processes, may require only very limited neuron numbers. Using computational models of the bees' visual system, we explore whether seemingly advanced cognitive capacities might 'pop out' of the properties of relatively basic neural processes in the insect brain's visual processing area, and their connection with the mushroom bodies, higher order learning centres in the brains of insects.

Using drones to track bees

Authors: Chittka Lars[5], Oliver Tom[1], Reynolds Andy[4], Makinson James[3], Lim Jason[4] and Cross Paul[2], [1]Bangor University and Rothamsted Research, United Kingdom, [2]Bangor University, United Kingdom, [3]Hawkesbury Institute for the Environment, Western Sydney University, Australia, [4]Rothamsted Research, United Kingdom, [5]University Queen Mary of London, United Kingdom

Abstract: Insect telemetry involves the use of tracking technology to understand invertebrate movement and behaviour. Current techniques either rely on a battery powered tag which may impact the flight behaviour of the insect, or a lighter, passive tag used in tandem with a harmonic radar dish which has a tracking range of approximately 500m. Here we show how a piezoelectric tag used in conjunction with an antennae array carried by a drone can be used to track bees at a landscape scale. Through the use of the drone, it becomes possible to track bees over much greater distances compared to existing tracking techniques at a fraction of the cost. We present preliminary results using a prototype of the antennae array to track bees and discuss future applications of this novel tracking technology.

What can harmonic radar tracking reveal about the mating flights of honeybee drones and queens?

Authors: Chittka Lars[2], Woodgate Joseph[2], Reynolds Andy[3], Makinson James[1], Lim Jason[3] and Gallo Vince[2], [1]Hawkesbury Institute for the Environment, Western Sydney University, Australia, [2]Queen Mary University of London, United Kingdom, [3]Rothamsted Research, United Kingdom

Abstract: Honeybees (Apis mellifera) are arguably a domesticated species, with considerable economic and cultural importance, and have been kept for thousands of years. Nonetheless, there is much about their mating behavior that remains mysterious, since they mate in flight, away from the hive, making observation extremely difficult. Male honeybees (drones) gather in large numbers in areas known as Drone Congregation Areas (DCAs), presumably for the purposes of mating, and DCA locations are thought to persist for many years. Most of what is known about drone movements and DCAs comes from sampling drones approaching pheromone lures or tethered queens, which could potentially alter their behavior and does not allow tracking of individual flight paths. Virgin queen honeybees mate during short nuptial flights, but little is known about the structure or destination of these flights, or even whether mating takes place at DCAs, as commonly presumed. We used harmonic radar technology to track the flight paths of individual drones and virgin queens in an agricultural landscape, allowing us to examine for the first time the movements of individual bees in search of a mate. After attaching a lightweight transponder to the thorax of a bee, we scan across 360 degrees, locating the bee's position every 3 seconds. Using a dataset of hundreds of drone flights, collected over three years, we demonstrate that multiple drones converged on the same locations, even in the absence of pheromone lures and that these DCAs persisted over at least two years. Since no individual drones live overwinter, this demonstrates that the locations at which DCAs form must be defined by the landscape and that individual drones, from different hive locations, are capable of converging on the same spot. We will present findings on the structure of the orientation flights of drones and virgin queens and show how the flight paths of drones change with experience as they frequent DCAs. Finally, we ask whether the spatial structure of drone flights can provide any insight into where DCAs form and what features of the landscape bees use to locate them.

Genome-wide analysis of T. absoluta populations across South America

Authors: Chiu Joanna[3], Lewald Kyle[2], Tabuloc Christine[2], Perini Clerison[1], Zalom Frank[4] and Guedes Jerson[1], [1]Department of Crop Protection Universidade Federal de Santa Maria (UFSM), Brazil, [2]Department of Entomology University of California, Davis, United States, [3]Dept. of Entomology and Nematology, University of California Davis, United States, [4]University of California Davis, United States

Abstract: Tuta absoluta's recent expansion across South America currently represents a serious threat to the tomato agriculture industry. Massive pesticide use is the predominant method of control, and as a result, strong selective pressures have led to resistance development in populations of Tuta absoluta to various insecticides. In order to determine whether resistance developed in one population is likely to be genetically dispersed to other populations, it is necessary to first understand the population structure of Tuta absoluta. Previous analyses relied on microsatellite or mitochondrial sequences, which may lack power to discern distinct populations. Toward this end, we have sequenced whole genomes of 55 Tuta absoluta moths collected from sites across South America, as well as a collection site in Spain, to identify the populations in which gene flow is likely occurring. Analysis suggests the presence of three South American clusters which are clearly separated based on geography and genetic distance, although there is evidence of migration events between clusters. In addition, we conclude that the Spanish populations likely arose from a single population in Chile, confirming previous reports. In the future, this data can be used to inform growers on the best insecticides to use on their crops.

Molecular diagnostic assay to distinguish Tuta absoluta, Phthorimaea operculella, and Keiferia lycopersicella

Authors: Chiu Joanna[6], Agusti Nuria[7], Lewald Kyle[5], W. Song Ailsa[1], Perini Clerison[4], Guedes Jerson[4], Arnó Judit[2] and Evan Braswell W.[3], [1]Department of Entomology and Nematology, University of California, Davis, California, United States, [2]IRTA (Institute of Agrifood Research and Technology), Cabrils (Barcelona), Spain, [3]Center for Plant Health Science and Technology, USDA APHIS, Edinburg, Texas, United States, [4]Department of Crop Protection Universidade Federal de Santa Maria (UFSM), Brazil, [5]Department of Entomology University of California, Davis, United States, [6]Dept. of Entomology and Nematology, University of California Davis, United States, [7]IRTA, Spain

Abstract: In the past 15 years, the tomato pest Tuta absoluta has transformed from a regional pest of South America to a worldwide threat to tomato production. With current reports of Tuta absoluta presence across Europe, Africa, and sectors of Asia, there is a growing need to improve monitoring efforts in the United States to prevent introduction of this pest. A major challenge is the presence of morphologically similar moths Phthorimaea operculella and Keiferia lycopersicella, which prey on the same host plants as Tuta absoluta. Currently, identification requires dissection of adult moths, which can be labor intensive and requires a well-preserved intact specimen. This makes identification of Tuta absoluta presence in field traps difficult, especially when traps are left out for extended amounts of time. To tackle this, we used published draft genomes of the three species to identify two distinguishing loci, and developed a multiplexed quantitative PCR assay that can identify each species in a single reaction based on fluorescence from tagged oligonucleotide probes. This assay can reliably identify the three species with as little as 16 picograms of genomic DNA input. We tested sensitivity in an environmental collection setting by spiking local insect bycatch from traps with Tuta absoluta DNA; in all cases Tuta absoluta was positively identified. We expect this diagnostic to aid in monitoring and eradication efforts by allowing detection even when intact specimens are unavailable.

Risk-dependent brood parasitism by the predatory mite Neoseiulus californicus

Authors: Choh Yasuyuki[1], Janssen Arne[2], [1]Chiba University, Japan, [2]University of Amsterdam, Netherlands

Abstract: Two predatory mite species Neoseiulus califronicus and Gynaeseius liturivorus cooccur on the same plant individuals in crop fields, where they feed on the same prey species such as larvae of western flower thrips. In turn, the thrips prey on the predator eggs. In addition, the two mite species are reciprocal intraguild predators, attacking each other's juveniles. Although N. californicus is a stronger intraguild predator, eggs of both species are observed at the same oviposition sites such as leaf veins and hairs. Adult female G. liturivorus are known to reduce the predation risk of their eggs by thrips larvae by guarding their eggs. As a consequence, eggs of N. californicus close by guarded eggs of G. liturivorus might also be protected against attacks by thrips larvae. We therefore tested whether adult female N. californicus preferred ovipositing at sites where G. liturivorus had oviposited. N. californicus preferred laying eggs at oviposition sites with G. liturivorus eggs over sites without eggs but not at sites with eggs of conspecifics or another predatory mite species (Phytoseiulus persimilis) in the presence of thrips larvae. Moreover, such a preference was not found in the presence of two-spotted spider mites instead of thrips larvae as a food source. Although adult female N. californicus did not protect their eggs against thrips larvae, their eggs survived better from thrips larvae in the presence of G. liturivorus and its eggs. These results show that N. californicus reduces the predation risk of their eggs by ovipositing close to G. liturivorus eggs.

Classification of Culex pipiens complex using geometric morphometric

Authors: Choi Kwang Shik, Jeon Jiseung

Abstract: Traditionally, the D/V ratio of male genitalia and ommatidial number have been used to identify the Culex pipiens complex. However, it is difficult to identify the complex species due to morphological similarity. In this study, geometric morphometric (GM) was applied to the wings of Culex pipiens molestus and Culex pipiens pallens in the complex to supplement the traditional classification method before the molecular diagnostics step. Female mosquitoes were collected from nine regions in ROK between July and September 2021, and Cx. p. molestus and Cx. p. pallens were identified using the molecular markers. In addition, as an outgroup for comparison, Aedes albopictus was additionally collected and compared with Culex pipiens complex. As a result of morphometric analysis of Culex pipiens complex and Ae. albopictus, the morphological difference of the wings was revealed clearly. It was also shown that Cx. p. molestus and Cx. p. pallens, which are closely related to each other, were clearly separated. Therefore, it is expected that GM would be able to apply to various mosquito species that have difficulties in morphological classification.

Diagnostics development and species distribution of Culex pipiens complex in the Republic of Korea

Authors: Choi Kwang Shik, Ryu Jihun

Abstract: Culex pipiens complex, which is the most common in the urban area, has not yet caused a disease in the Republic of Korea (ROK) although Culex pipiens molestus and Culex pipiens pallens in the complex in ROK are known to have the vector competence. However, it is difficult to distinguish morphological differences between Culex pipiens complex species in ROK. Therefore, in this study, we collected from a total of 48 sites near residential areas in ROK, designed species-specific primers for the species, and analyzed the distribution of the Culex pipiens complex species. As a result, Cx. p. molestus and Cx. p. pallens were collected together in all of the study regions except Ullengdo where the number of collected samples were small (5 samples). Among the total of 1,063 individuals, 70.1% of the samples were Cx. p. molestus and 29.9% were Cx. p. pallens. Since there has been no research of these species distributions in ROK so far, the results of this study would be used as important data for the Culex pipiens complex research.

Receptor interference (Receptor-i) using small peptides to control the fire ant and slug

Authors: Choi Man-yeon[2], Vander Meer Robert[2] and Ahn Seung-Joon[1], [1]Mississippi State University, [2]USDA-ARS, United States,

Abstract: Insect pest management (IPM) is critical to prevent crop and livestock losses by Arthropod pests directly and indirectly by diseases vectored through arthropods, and to improve sustainable food production and security. Discovery of new insecticides has always been a goal in IPM, but it is a long iterative process with high risks and low chance of success. To discover potential insecticidal candidates screening is a critically important procedure. Insect G-protein coupled receptors (GPCRs) as a target for new specific class of pesticides holds great potential because GPCRs are involved in almost all physiological processes. We developed a novel GPCR-based screening method using a GPCR of neuropeptides, and successfully screened small bioactive peptides to be evaluated as control agents to manage populations of the fire ant and slug pest. Our research results provide an insight in the evolutional process with the neuropeptides and their receptors in the animal system. We also explore the feasibility and implementation of the novel screen technology for application to major economic pests.

First report of Pheromermis vesparum parasitic on Korean Vespa mandarinia

Authors: Choi Moon Bo[1], Kwon Ohseok[2] and Kim Seo Hyun[1], [1]Department of Plant Protection and Quarantine, College of Agriculture and Life S, [2]Kyungpook National University, South Korea

Abstract: We present this first report of an individual of the Mermithidae which was identified on V. mandarinia workers caught in a wasp trap in the Jirisan National Park in July 2021. This nematode was found to be parasitic on the abdomen of V. mandarinia, and because identification by appearance was impossible it was identified using molecular biology methods. A phylogenetic study based on sequencing of the 18S ribosomal RNA gene identified this nematode as Pheromermis vesparum. This is the first report of this species from Korea. In future research, we aim to analyze the frequency of their occurrence and host specificity to facilitate their use as a natural enemy for the biological control of V. mandarinia.

Foraging behavior of an invasive alien hornet (Vespa velutina) at Apis mellifera hives in Korea: foraging duration, attack attempts, and success rate

Authors: Choi Moonbo[1], Kwon Ohseok[1], [1]Kyungpook National University, South Korea

Abstract: The introduction of an invasive alien hornet (Vespa velutina) to Korea in 2003 has caused severe economic impacts on the beekeeping industry. We observed this hornet attacking honeybees at hives to develop control and management approaches for the species. We recorded duration of foraging attacks, number of attack attempts, and success rate from July to October, compared V. velutina attacks with those of a native wasp (V. simillima), and compared foraging behavior on a rainy day and a sunny day. The foraging success rate was 84.2% overall but exceeded 97% in September. V. velutina was a more efficient predator than V. simillima, with shorter attacks but a higher success rate. The data showed that local honeybees have not yet developed adequate defense mechanisms against predation by this new invasive species.

Temporal trend of species richness of macromoths across three southern mountains of South Korea

Authors: Choi Sei-Woong[1], Lee Jae-Young[1], An Jeong-Seop[3], Kim Nang-Hee[2], Na Sang-Hyun[1], [1]Mokpo National University, South Korea [2]National Institute of Agricultural Science and Technology, South Korea, [3]National Institute of Ecology, South Korea,

Abstract: The purpose of the study was to track the changes in species richness of macromoths in mixed deciduous and coniferous forests during the last decade. Macromoths were collected from 2003 to 2019 at 27 sites on three mountains in southern South Korea: 11 sites of Mt. Hallasan (HL, maximum height 1,950m), 11 sites of Mt. Jirisan (JR, maximum height 1,915 m), and five sites of Mt. Seungdalsan (SD, maximum height 333m). Ultraviolet light traps (22 Watt and 12 volts) were employed to collect moths from May to October and the collected samples were identified to the species level, if possible. We questioned that (1) Have moth communities in the Korean mountains been declined in the last decade?, (2) If moth communities have been declined, which taxonomic group and elevation zone were severely affected?, and (3) What factors were showing the higher correlation with the declining moth communities? We will show the trend of change in species richness and the causal factors of the change of moths in three mountain areas of southern South Korea.

Occurrence of Tomato Russet Mites, Aculops lycopersici Massee (Acari: Eriophyidae) in a Greenhouse and Selection of an Eco-friendly Organic Insecticide

Authors: Choi YongSeok, Bioenvironmental Division, Chungnam Agricultural Research and Extension Services, South Korea

Abstract: The first occurrence of the tomato russet mite, Aculops lycopersici Massee was in mid-late April, and the maximum occurrence was in mid-late June in 2013 and 2014. However, in 2015, the density of tomato russet mites increased in July. This pattern is thought to be attributed to temperature fluctuations, in which, low temperatures at night promoted their reproduction and long periods of high temperatures during the day promoted their dispersion. Comparison of the use of 11 Eco-friendly organic insecticides (EOIs) showed that, the mortality rates after application of 0.6% matrin(EOIMa) and 10% clove oil (EOICo) were 92.1% and 95.1%, respectively, when administered at 500-fold diluted concentrations. At 1,000-fold and 2,000-fold diluted concentrations, the mortality rates of EOIMa were 90.4% and 88.2%, respectively. In a field test, the mortality rates of EOIMa at the 1,000-fold diluted concentration and of EOICo at the 500-fold diluted concentration were 91.5% and 93.9%, respectively. In conclusion, theses two EOIs are sufficient to replace pesticides, and EOIMa seems to be particularly useful as a prophylactic given that it induced a mortality rate of 88.2% at a 2,000-fold diluted concentration.

Acute and residual toxicities of chordotonal organ modulator insecticides against two aphid species

Authors: Chong Juang, Clemson University Pee Dee Research & Education Center, South Carolina, United States

Abstract: Sucking insects, such as aphids and whiteflies, are major pests of ornamental plants grown in glasshouses and outdoor nurseries. Sucking pest management on ornamental plants have traditionally relied on neonicotinoids. As neonicotinoids face increased scrutiny due to their detrimental effects on pollinators, growers are replacing neonicotinoids with other chemistries, such as the chordotonal organ modulators, which include afidopyropen, pymetrozine and pyrifluquinazon (IRAC Group 9), and flonicamid (IRAC Group 29). No concerted efforts have been undertaken to compare the acute and residual efficacy of the four compounds. This study include 2 glasshouse and laboratory experiments to compare the acute and residual efficacy of afidopyropen (Ventigra), pymetrozine (Endeavor), pyrifluquinazon (Rycar) and flonicamid (Aria) against the potato aphid (Macrosiphum euphorbiae) and the chrysanthemum aphid (Macrosiphoniella sanborni). The products were applied to roses (for the potato aphid) and chrysanthemums (for the chrysanthemum aphid) at the lowest and highest label rates registered in the United States. In the first (acute toxicity) experiment, leaves infested with aphids were detached from plants grown in a greenhouse and dipped in insecticidal solutions. The leaves were then air-dried, and maintained in Petri dishes with the leaf petioles inserted into a cup of water through a hole drilled at the bottom of the Petri dishes (henceforth to be referred to as the observational arenas). The dipped aphid cohorts were monitored in the laboratory over 7 days to record mortality and population growth. Results suggested that afidopyropen resulted in the fastest reduction in the population of both aphid species, but all products achieved complete elimination of the aphid cohorts within 7 days. Application rates did not appear to influence of speed by which the aphid cohorts were eliminated. In the second (residual toxicity) experiment, the insecticides were sprayed to potted plants maintained in glasshouses. The aphid population on randomly selected leaves were recorded at 1, 3, 5, 7, 14, 21 and 28 days after treatment (Experiment 2A). One leaf was collected from each plant at 1, 3, 5, 7, 14, 21 and 28 days after treatment, and 10 adult aphids were introduced onto each leaf. The leaves were kept in the observational arenas, and monitored for 9 days after introduction (Experiment 2B). In Experiment 2A, both aphid species were eliminated from the treated plants (of all products and rates) within 7 days of introduction. The populations of both aphid species begin to rebound within 21 days of treatment, regardless of products and application rates. In Experiment 2B, introduced adult aphids were not killed by the residue on the leaves and continued to produce offspring. The offspring, however, die as soon as they began to feed on the leaves. This study generated recommendations on product selection and reapplication interval that can be utilized by growers.

RNA-Based biocontrols: the bio-delivery challenges

Authors: Christiaens Olivier[1], Lacombe Ruben[1], Coorevits Arnout[1], Dehertogh Astrid[1], Dewulf Nathalie[1], Begheyn Myriam[1] and Cappelle Kaat[2], [1]Syngenta Crop Protection LLC, [2]Syngenta Ghent Innovation Center, Belgium

Abstract: For most insect pest species tested so far, it has proven difficult to achieve a commercially relevant activity level using an insecticidal RNA-based biocontrol. Multiple loss mechanisms have been described, including external factors, such as the environment and feeding behavior, and internal factors related to the physiology of the insect. Generally, differences in RNAi efficiency are described only qualitatively, as it is not straightforward to obtain exact numbers and compare between different delivery methods, feeding behaviors etc.

In this work, the differences were quantified more precisely to increase our understanding of physiology-related loss mechanisms. Four species from diverse orders were selected for 1) being candidate targets for an RNA-based biocontrol product, and 2) showing a varying degree of RNAi efficiency. Using both injection and feeding delivery methods, lethal dose and lethal time were accurately specified and linked to the precise amount taken up using a feeding tracker. In addition, the QuantiGene Plex method, routinely used to quantify dsRNA expression levels in GM plants, was adapted to detect dsRNA in the insect body. A similar robust quantification method was developed to compare degradation rates in the insects' hemolymph and gut. Putting all this data together increased our understanding of the limitations of exploiting RNAi in these commercially relevant pests, and revealed some interesting discrepancies between RNAi efficiency and known loss mechanisms.

Defensive responses of rice cultivars resistant to Cnaphalocrocis medinalis (Lepidoptera: Crambidae)

Authors: Chuang Wen-Po[1], Liao Chung-Ta[2] and Guo Tzu-Wei[1], [1]National Taiwan University, Taiwan, [2]Taichung District Agricultural Research and Extension Station, COA, Taiwan

Abstract: Cnaphalocrocis medinalis (Guenée) (Lepidoptera: Crambidae) is an economically important pest of rice, Oryza sativa L. (Poaceae), throughout Asia, where damage caused by larvae, particularly during grain-filling stages, significantly increases yield losses. There is, therefore, a pressing need to develop cultivars that are resistant to C. medinalis. In this study, we assessed growth and mortality of first and third instar C. medinalis larvae fed on six rice cultivars that had previously been identified as resistant to the pest, and we quantified production of defense enzymes in plants exposed to herbivory. We found that mortality rates were highest in larvae fed on the resistant cultivars Baiqiaowan, Sasanishiki, Qingliu, and Kasalasu, while relative growth rates were lower for larvae fed on Baiqiaowan and Qingliu. Higher levels of phenylalanine ammonia lyase were expressed in the resistant cultivars. Qingliu plants exposed to herbivory by C. medinalis produced higher levels of jasmonyl isoleucine and salicylic acid (SA) than plants of the susceptible cultivar TN1, and levels of SA in Qingliu plants were intrinsically higher prior to feeding by C. medinalis.

Benefit of drought on a herbivore of herbaceous plants: Does drought create enemy free space and reduce competition?

Authors: Chuang Wen-Po[2], Lin Po-An[3], Felton Gary W.[1], Sun Cheng-Han[2], Liu Chia-Ming[4], Ho Chuan-Kai[2], Ou Jia-Ang[2] and Kinoshita Natsuko[5], [1]Department of Entomology Pennsylvania State University University Park, PA, United States, [2]National Taiwan University, Taiwan, [3]Pennsylvania State University, United States, [4]University of Tsukuba, Japan

Abstract: Drought stress is known to benefit insect herbivores in some instances; however, the mechanisms that lead to these benefits remain debated. To understand the impact of drought on quality of host plant and the interactions of insect herbivore with the arthropod community associated with host plant, we conducted a manipulative field study using a specialist herbivore Pieris rapae, and its host plant, Rorippa indica, in two populations. The results revealed that moderate water deficit increased the survival of P. rapae on R. indica, which was associated with reduced abundance of other herbivores and natural enemies. Water deficit increased the resistance of R. indica to most herbivores indicating by the reduced abundance in field and decreased relative growth rate of herbivore when fed with drought stressed R. indica. However, the performance of P. rapae larvae were not affected by changes in quality of R. indica, suggesting ability to utilize host plant with different quality. Our findings suggested beneficial impacts of drought to certain specialist herbivores, and in contrast, detrimental to most other herbivores. The present study provides insight to how drought may benefit insect herbivores and the importance of interactions among arthropods associated with plant in determining the impact of drought on insect herbivores.

The role of transmission dynamics mathematical models in guiding malaria vector control policy

Authors: Churcher Thomas, Imperial College London, United Kingdom

Abstract: The use of vector control to control malaria is complicated. There is no silver bullet to kill mosquitoes and different interventions will need to be layered together to adequately control the disease. Malaria is currently primarily controlled using long-lasting insecticidal nets and indoor residual spraying of insecticide though the rise of insecticide resistant mosquitoes and a proliferation of new bednets and alternative technologies means that it is very unclear how best to control the disease. The optimum and most cost-effective mix of interventions will vary from setting to setting according to its unique epidemiology and mosquito population. This complexity means that transmission dynamics mathematical models parameterised on entomological data are increasingly being used to guide decision making. The statisticians George Box and Norman Draper wrote that “All models are wrong; the practical question is how wrong do they have to be to not be useful”. This session will take a sober look at current evidence for the use of these models in guiding vector control policy and implementation. It will investigate in what situations they should be used and discus what needs to be done to make sure results are not overly interpreted.

TaxonWorks-powered Orthoptera Species File (OSF): An integrated web-based workbench for orthopterists

Authors: Cigliano Maria, Museo de La Plata, CEPAVE-CONICET, Argentina

Abstract: The Orthoptera Species File (OSF, http://orthoptera.speciesfile.org/) is the most up to date and complete taxonomic database of the world’s Orthoptera (grasshoppers, locusts, katydids, crickets), both living and fossil. Nowadays, the classification of Orthoptera shown in OSF is used worldwide as the general reference for the group. The field of cybertaxonomy represents the confluence of traditional taxonomic goals with new ones, powered by the full potential of digital technology, information science, and computer engineering. An introduction to TaxonWorks (http://taxonworks.org), the new platform that integrates the best features of Species File software with new ones will be presented. TaxonWorks is an integrated web-based workbench for taxonomists and biodiversity scientists. It is designed to capture, organize, and enrich data, share and refine it with collaborators, and package it for analysis and publication. This new platform, constituted by a collection of open source tools and services that cover all aspects of the taxonomic workflow will help to maximize the efficiency of taxonomic work allowing the exchange of data among the orthopterists’ community and helping to expand and enhance our knowledge of Orthoptera. The potential of using OSF for integrating many of the most recent cybertaxonomic tools will be discussed. The presentation will explore the status of OSF within TaxonWorks as it stands now, discussing the new features developed that will be used to add, explore, retrieve, and download data from OSF.

Symbiotic bacteria affect the clearance rate of a plant pathogen from its insect host

Authors: Civitello Dave[1] and Gerardo Nicole[1], [1]Emory University, United States

Abstract: Many insects form intimate, long-term associations, known as symbioses, with select microbes. Symbionts influence the ecological functions and evolution of insects, allowing them to exploit unique resources and occupy otherwise inaccessible niches. Work in several insect systems has shown that, in addition to direct benefits on host fitness, bacterial symbioses can affect the establishment and transmission of insect-vectored pathogens. The squash bug Anasa tristis is an agriculturally important pest of plants in the family Cucurbitaceae and a known vector of Serratia marcescens, the causative agent of Cucurbit Yellow Vine Disease (CYVD). Burkholderia species bacteria have a symbiotic relationship with A. tristis, significantly accelerating their development and increasing their survival. Furthermore, certain Burkholderia strains have been shown to suppress the growth of S. marcescens in vivo. We hypothesized that association with Burkholderia affects the establishment of S. marcescens in squash bugs. To test this, we reared insects aposymbiotically and with different Burkholderia isolates, infected them with a phytopathogenic strain of S. marcescens, then sampled them periodically to assess pathogen clearance. We observed variation in clearance rates among Burkholderia isolates, but by and large, squash bugs harboring Burkholderia cleared S. marcescens significantly faster than their aposymbiotic counterparts. Work in this system furthers our current understanding of how symbionts affect the vectoring of pathogens. We hope to leverage these results to design novel and effective vector control for this system.

Adaptation of diapause induction cue enables range expansion of a biological control agent across latitude

Authors: Clark Eliza[2], Stahlke Amanda[3], Bean Dan[1], Bitume Ellyn[4] and Hohenlohe Paul[3], [1]Colorado Department of Agriculture, United States, [2]Colorado State University, United States, [3]University of Idaho, United States, [4]USDA Forest Service, Hawaii, United States

Abstract:

Background

Eco-evolutionary theory predicts that species undergoing range expansions will evolve due to spatial sorting, genetic drift or selection in small edge populations, and adaptation to novel environments. For diapausing species, adapting to environmental cues that indicate seasonal change and vary across the range is crucial. Phenological mismatches in diapause timing can reduce the number of generations per year and reduce establishment. The northern tamarisk leaf beetle (Diorhabda carinulata), biological control agent for the invasive plant Tamarix spp. in the United States, originally failed to establish in southern latitudes due to mistimed diapause in response to shorter summer daylengths. In the past decade, however, the beetle has rapidly expanded its range to these areas without the aid of humans. This range expansion is uniquely situated to study the impacts of local adaptation during range expansions across heterogeneous environments.

Methods

Adaptation to daylength across latitude has been shown in D. carinulata at a population level. Here, we define a new trait, days until diapause at one daylength, to study adaptation to daylength at an individual level. We measured the heritability of days until diapause in one northern population in both home and away environments using a paternal half-sibling breeding design. To study adaptation to daylength across the entire range of D. carinulata, we measured days until diapause in both northern and southern environments for females from eight populations collected at varying latitudes.

Results

We found that days until diapause was highly heritable for the population in its home environment and not significantly heritable in a novel environment. When we compared populations across the range, we found significant differences between the diapause behaviors of northern core beetles and southern edge beetles in each environment. Northern populations in the northern environment took multiple days to enter diapause with lots of phenotypic variance, while northern populations in the southern environment entered diapause quickly with little phenotypic variance. Similarly, southern beetles in the southern environment took multiple days to enter diapause with lots of phenotypic variance, but most southern beetles in the northern environments did not ever enter diapause.

Conclusions

Heritability of days until diapause indicates that adaptive evolution of this trait is possible, but only when populations are near their home environment, indicating that the range expansion must proceed slowly enough that genetic variation on which selection can act is maintained. The number of days to diapause has evolved in populations across the range to better match the summer daylengths at their latitudes. These results can be used in conjunction with genomic studies on individuals to better predict the rate of range expansion and inform research on ecological factors important to range expansions.

DNA metabarcoding vs. Morphotaxomy methodologies to identify Arthropods and Non-Arthropods for biomonitoring of European rivers

Authors: Classen Silke[3], Nieminen Marko[2], Pujante Ana Maria[4], Antonio Villaescusa Juan[4], Jose Villena Maria[4], González Raquel[4] and Rojo Veronica[1], [1]Allgenetics, Spain, [2]Faunistica, Finland, [3]Gaiac, Germany, [4]Laboratorios Tecnológicos de Levante, Spain

Abstract: The present study has been developed under the Biowat kit_E!11892 project, which aims to validate a novel genomic tool for the identification of European freshwater macroinvertebrates and develop a protocol for its standard application in biodiversity assessments. The study has been carried out in rivers of Mediterranean Region (Spain), Continental Region (Germany) and Boreal Region (Finland). Two methods were used in parallel: the traditional morpho-taxonomy and metabarcoding tools. The genetic marker was selected according to a preliminary study comparing two commonly used mitochondrial marker regions: 16S and COI. A set of primers specific for 16S gene for arthropod and non-arthropod invertebrates were prepared. Results based on morphological and metabarcoding methods were compared. 93 macroinvertebrate families were identified by morphological (74 Arthropod and 19 Non-Arthropod). Of the families observed by both methods, metabarcoding observed 89% of the observations made by morphology. Of the total of Arthropod families only 8 were not identified with metabarcoding. In brief, the comparison of morpho-taxonomical and metabarcoding data for the studied rivers showed a good correlation. But some discordances were found between both methods due to the different level taxonomic resolution (family, genus, species). These discrepancies highlight the potential of DNA metabarcoding to provide more resolutive taxonomic inventories, as compared with morphological approach. The ecological status class (ESC) of the studied rivers were stablished based on both methodologies. Thus, in 75% of cases, remained the same with both approaches. In 13.9% of cases the ESC decreased by one class and increased by one class in 11.1% of cases.

10 Years of Operational Barrier Spraying in Panama City Beach, Fl. USA

Authors: Clauson James, None, United States

Abstract: With the advent of barrier sprayers that spray misting insecticides 30 feet and further, Beach Mosquito Control District incorporates this methodology in our integrated approach to controlling mosquitoes within our district. We utilize our high power misting sprayer (Buffalo Turbine) to access areas where mosquitoes harbor or rest. We use this technique in and around parks and schools. We have data that show positive results and feel this is a valuable tool in controlling adult mosquitoes.

Understanding the Australian termite diversity anomaly: how precipitation affects termite diversity in Northern Queensland

Authors: Clement Rebecca[2], E. Zanne Amy[3], A. Crandall Keith[1], Eggleton Paul[4], [1]Computational Biology Institute, The George Washington University, Washington, DC, United States, [2]Department of Biological Sciences and Computational Biology Institute The George Washington University Washington, DC., United States, [3]Department of Biological Sciences The George Washington University Washington, DC, United States, [4]The Natural History Museum London, United Kingdom

Abstract: Termites are critical components of tropical systems where they are thought to decompose up to 50% of plant organic material in litter, wood and soil. Termites have adaptations (e.g., the ability to scavenge and store water in their mounds) allowing them to thrive in habitats with variable rainfall and remain active during droughts. One frequently drought-affected area, the Australian tropics, is thought to show a unique pattern of termite distribution, with termite diversity and abundance lower in rainforests, peaking in drier savannah ecosystems. This pattern, if true, is opposite to what is found in tropical regions around the globe where termite diversity and abundance is highest in rainforests. Our study aims to survey termite turnover across a precipitation gradient and examine the causes and consequences of this anomaly. In five sites in Northern Queensland ranging from 600--5000 mm annual rainfall, we collected samples from 50 m transects and 50 m x 50 m plots and measured termite abundance and diversity, deadwood occupancy, and termite mound abundance. We analyzed turnover of feeding types and landscape types among sites with differing rainfall. We observed dramatic decreases in termite abundance in both mounds and deadwood corresponding to an increase in rainfall (107 mounds per ¼ hectare plot in the driest site, compared to 1 mound per plot in the wettest). Of the 18 termite species encountered in this study, none were soil feeders; litter-feeding termites were found only in the savannah sites, while wood feeders were found in both rainforest and savannah sites. These results support the termite diversity anomaly and point to turnover in feeding guild with greater diversity in savannah, suggesting that part of the anomaly lies in the adaptations to food resources across habitats. We found that presence of several common species of termites including Amitermes laurensis, Nasutitermes magnus, and Microcerotermes cerratus, corresponded more closely with habitat type than with distance from other sites. These results suggest that termite communities assemble in large part based on habitat type. Rainfall is an important factor in termite community assembly shaping the termite diversity distribution although why so few termites are found in the rainforest remains elusive.

Mechanisms of ecological and sexual divergence in the European corn borer

Authors: Coates Brad[4], Dopman Erik[2], Wanner Kevin[1] and Sappington Thomas[3], [1]Montana State University, United States, [2]Tufts University, United States, [3]USDA-ARS, Corn Insects & Crop Genetics Research Unit, United States, [4]USDA-ARS, United States

Abstract: The adaptation of pest arthropod species to local environments and producer control practices pose challenges to crop production across agroecosystems. The European corn borer, Ostrinia nubilalis, is a pest of cultivated maize in North America and Eurasia, and a model for elucidating the genomic interactions underlying differentially-adapted subpopulations. Sympatric strains that differ in sexual communication system can also vary in response to temperature and photoperiod via adjustments to diapause traits causing latitudinal differences in number of annual mating generations (voltinism). Distinct phenotypes persist despite relatively high reciprocal gene flow and hybridization. Specifically, pheromone strain variants differ in the ratio of E and Z isomers of the sex pheromone produced by females and preferentially responded to by males of the same strain. The autosomal pheromone gland fatty acyl-reductase (pgfar) gene controls strain-specific E and Z isomer ratios in female pheromones, and male pheromone response phenotype (Resp) maps to a suite of neurogenesis-related genes on the Z-chromosome. Linkage disequilibrium between strain specific alleles at pgfar and Resp suggest sexual co-selection for compatible sexual communication traits at the population level. Additionally, the genetic architecture of diapause duration involves functional interaction (epistasis) between co-adapted alleles on the Z-chromosome of major genes influencing circadian rhythm: period (per) and pigment dispersing factor receptor (pdfr). A segregating non-recombining Z-chromosome inversion also contributes to the maintenance of “optimal” co-adapted allelic combinations at per and pdfr, as evidenced by maintenance of the inversion at higher frequencies between populations differing in pheromone and diapause traits. Cyclical changes in allele frequency at per and the autosomal cryptochrome 1 gene are correlated with population transitions across regions of one, two, and three generations, demonstrating a possible genetic basis of latitudinal plasticity in voltinism traits. These genomic and ecological interactions contribute to the distribution of European corn borer variants, phenotypic plasticity, and capacity to adapt to changing environmental conditions.

Certain botanical nematicides also show repellency against ticks.

Authors: Coats Joel[5], Robertson Alan[1], Pouliot Claire[2], Wong Colin[3], Tylka Greg[4], Klimavicz James[5], Barizon Jefferson[4] and Martin Richard[1], [1]Dept. Biomedical Sciences Iowa State University Ames, Iowa, United States, [2]Dept. Entomology Iowa State University Ames, Iowa, United States, [3]Dept. Entomology, Pesticide Toxicology Lab, Iowa State University, Ames, IA, United States, [4]Dept. Plant Pathology & Microbiology Iowa State University Ames, Iowa, United States, [5]Iowa State University, United States

Abstract: Our lab has explored the multiple bioactivities of monoterpenes from plants, and we have shown some of them to be insecticidal, acaricidal, repellent, or synergistic with conventional insecticides. This presentation will report on the nematicidal activity of a range of monoterpenoids that are plant-volatiles. Data from bioassays on the plant-parasitic soybean cyst nematode (Heterodera glycines) and the free-living nematode (C. elegans) will reveal that several volatile monoterpenes have nematicidal activity. Our investigations of a nicotinic acetylcholine receptor from the animal-parasitic swine roundworm (Ascaris suum) have demonstrated that some of the volatile monoterpenoids have inhibitory activity at that receptor. A natural terpene oral parasiticide could have potential as a therapeutic for swine. As we evaluate results from these three anti-nematode studies, we are alert for any patterns or consistent trends regarding which specific monoterpenes or classes of terpenes (e.g. aromatics, cyclics, bicyclics, or acyclics) (e.g. functional groups) are most active.

Citronella Oil Derivatives and Their Repellent Properties

Authors: Coats Joel[1], Corona Caleb[1] and Klimavicz James[1], [1]Iowa State University, United States

Abstract: The field of mosquito control has long been searching for molecules that can be used as mosquito repellents to fight against the spread of vector-borne diseases. A breakthrough was made while researchers were examining the essential oil associated with lemongrass (Cymbopogon nardus). Citronella oil was extracted from the plant and was proven to be an effective oil for repelling mosquitoes, especially in short-term evaluations. The multiple components of this oil have also been extracted and screened for their ability to repel mosquitoes. Citronellol, a major component of citronella oil, has proven to be quite effective when used as a spatial repellent. Our lab has now used citronellol as a parent molecule to which we have been able to make a series of derivatives. These biorational derivatives have shown high levels of efficacy when screened against multiple genera of mosquitoes in our laboratory spatial repellency assays in both short and long-term situations.

Terpene Repellents: Beyond Amides and Pyrethroids

Authors: Coats Joel[3], Corona Caleb[2], Wong Colin[1] and Klimavicz James[2], [3]Iowa State University, United States, [1]Dept. Entomology, Pesticide Toxicology Lab, Iowa State University, Ames, IA, United States, [2]Iowa State University, United States

Abstract: Amide repellents, such as DEET, picaridin, and IR-3535 dominated the repellent market for years/decades. Recently the pyrethroid permethrin has shown utility as a contact repellent on clothing and other fabrics, and most volatile pyrethroids have activity as spatial repellents. Amides and pyrethroids are both useful, but both also have limitations. Terpenes are emerging as a promising third class of repellents; certain monoterpenoids in citronella oil and other plant essential oils show repellency, but they don't show much residual efficacy. The one newer botanical product on the market is the monoterpenoid p-menthane-3,8-diol, which shows modest activity as a contact repellent and minimal activity as a spatial repellent. Certain sesquiterpenoids show good activity, and provide better residual time. Many questions still remain: how broad-spectrum is their activity? Do they work against ticks? Do they have the same mechanism of action as amides or pyrethroids? Can biorational analogues and derivatives offer enhanced activity or residual times? The traditional amide-type repellents lack strong efficacy against ticks, but several terpene repellents and biorational derivatives of them show excellent potency against the black-legged tick (deer tick) Ixodes scapularis and the American dog tick Dermacentor variabilis. Comparisons in repellency in the lab will be reported between classes of commercial repellents, specific terpenoids, and between species of ticks.

Does the rearing of Telenomus remus Nixon in the laboratory, for successive generations, changes its characteristics for Spodoptera frugiperda (J.E. Smith) biological control?

Authors: Coelho Jr. Aloisio[2], de Paula Pedro[2], P. Parra José Roberto[1], [1]Department of Entomology and Acarology, Luiz de Queiroz College of Agriculture (ESALQ)/University of São Paulo (USP), Brazil, [2]ESALQ-University of São Paulo, Brazil

Abstract: We evaluated whether rearing the egg parasitoid wasp Telenomus remus Nixon for successive generations in the laboratory alters its characteristics as a biological control agent of Spodoptera frugiperda (J.E. Smith). The experiment began with collection of a population with characteristics close to the wild insects. A pool of three different strains were released in a cornfield, and S. frugiperda egg masses were placed on corn plant leaves. The presumably parasitized egg masses were brought to the laboratory, and the parasitized eggs were selected and reared at 25°C and 75% RH; after emergence, adult wasps were offered only S. frugiperda eggs and pure honey. The wasps' biological characteristics were assessed at generations F1, F6, F11 and F17, including the short-range flight capacity, parasitism and life span. The flight test unit consisted of a PVC pipe 15 cm in diameter and 20 cm long, covered inside with black paper. The pipe was closed with a clear plastic cap, with entomological glue inside to catch flying T. remus, and a 0.5 cm-wide glue ring around the inside of the pipe at a height of 3.5 cm from the bottom, to capture walking parasitoids. Parasitism was evaluated by counting the number of dark (parasitized) eggs of S. frugiperda egg masses offered daily; female wasps were monitored until they died. T. remus flight capacity decreased from generations F1 to F17, with the proportion of flyers changing from 60% in F1 to 40% in F17. Parasitism capacity was similar across generations, 250 eggs on average, except in F17, which was lower, 97 eggs. The F1 and F6 life spans were similar, around 12 days; F11 was four days shorter and wasps in F17 lived only two days on average. In conclusion, laboratory rearing of T. remus over successive generations changes its flight ability, longevity and parasitism in relation to wild populations. The mechanisms of this change are unknown; perhaps laboratory rearing selects for individuals adapted to artificial conditions, considering that for haplodiploids parasitoids as T. remus inbreeding (endogamy depression) do not occurs.

Effects of a lipid-enriched diet on adults of Trichogramma pretiosum Riley

Authors: Coelho Jr. Aloisio[3], P. Parra José Roberto[2] and Raynard Yoan[1], [1]Agrocampus Ouest, France, [2]Department of Entomology and Acarology, Luiz de Queiroz College of Agriculture (ESALQ)/University of São Paulo (USP), Brazil, [3]ESALQ-University of São Paulo, Brazil

Abstract: The use of lipids in rearing has long been neglected. Parasitoids such as Trichogramma pretiosum Riley, as with most hymenopteran parasitoids, are unable to synthesize lipids de novo, differing from phytophagous insects, which can synthesize lipids in the adult stage. Lipid reserves are essential for fueling oogenesis and somatic functions. For parasitoids such as T. pretiosum the lipids contained in the host eggs will provide the needed energy for the wasp embryo to develop, and therefore are essential for viability. Adult female wasps can obtain lipids by consuming part of the host egg yolk (host feeding), and in this way stimulate oogenesis. However, the energy invested in producing eggs depletes lipid reserves faster than they can be renewed. It is believed that providing lipids from an alternative source, through the adult diet, would stimulate egg production and thus the capacity for parasitism, which is desirable since this is a biological control agent. Here, females of T. pretiosum were continuously fed with acacia honey enriched with 10% vegetable oils with a fatty-acid profile similar to that of Anagasta kuehniella (Zeller) eggs, by thermal process (water bath at 70°C). Females fed with honey enriched with oleic acid-rich vegetable oil parasitized 10% more eggs than females fed only pure honey, in 72 hours. However, the parasitoids' life span was reduced by about 40%. Neither the flight performance nor the quality of the offspring of parasitoids fed a lipid-rich diet was adversely affected. These results reveal the potential of a lipid-rich diet to increase lipid allocation to reproduction. Presumably, providing lipids from a plant source could rapidly renew the female's fat reserves and allow her to invest more energy in egg production. However, the increase in parasitism capacity occurred only under certain experimental conditions. Simply mixing vegetable oil in honey at room temperature (25°C) had no significant impact on the number of parasitized eggs. The use of an organic solvent, DMSO (5%), was also inconclusive. Therefore, the method of incorporating the lipid source into the diet (honey) is critical and needs to be explored. Further research into lipid supplementation is needed to determine which fatty acids can cause an increase in parasitism. Today, honey-only is used as a food source to rear this oophagous parasitoid. As Trichogramma species are now widely used in biological control programs, adding lipids to the diet of adults of this parasitoid could be of great interest to biological control companies.

South American Spodoptera Complex: Biology, Thermal Requirements and Ecological Zoning

Authors: Coelho Jr. Aloisio[2], P. Parra José Roberto[1], Gomes Garcia Adriano[3], Dourado Neto Durval[3], G. C. Bajonero-Rugno Johanna[3] and de Andrade Moral Rafael[4], [1]Department of Entomology and Acarology, Luiz de Queiroz College of Agriculture (ESALQ)/University of São Paulo (USP), Brazil, [2]ESALQ-University of São Paulo, Brazil, [3]Luiz de Queiroz College of Agriculture (ESALQ), University of São Paulo (USP), Brazil, [4]National University of Ireland Maynooth, Ireland

Abstract: Species of the Spodoptera Guenée complex, Spodoptera frugiperda (J.E. Smith), S. eridania (Stoll), S. albula (Walker) and S. cosmioides (Walker) are serious crop pests worldwide. All these species have a wide range of host plants as well as a high biotic potential. Satisfactory control of this pest complex might be achieved through Integrated Pest Management (IPM). Optimal use of IPM requires knowledge of bioecological aspects and the population dynamics of each species in the different producing regions.

Considering the importance of the Spodoptera pest complex for agriculture, the present study determined the biology, thermal requirements and ecological zoning of these species, considering the agricultural calendar of three highly important crop plants worldwide and in Brazil, soybean, corn (first and second crops) and cotton.
Pupal development of S. albula did not occur at 18°C and of S. eridania at 34°C. Egg-adult viability of S. frugiperda and S. eridania was higher at 25°C, and of S. cosmioides and S. albula was higher at 28°C. Pupae originated from larvae reared at lower temperatures were heavier than pupae originated from larva exposed to higher temperatures, except for S. albula, which had lighter pupae at 18°C. A higher proportion of deformed pupae was recorded at lower temperatures. The duration of the egg-adult period was inversely proportional to the temperature up to 32°C, above which the larval periods of S. cosmioides, S. frugiperda and S. albula were prolonged. The fertility of S. frugiperda, S. eridania and S. albula was lower in extreme temperatures, while S. cosmioides showed a decrease in fertility only at high temperatures. The thermal requirements were: S. frugiperda, Temperature threshold– Tt= 13.04°C and Thermal constant– K=390.06 Degree Days (DD); S. eridania, Tt=11.90 and K=495.96 DD; S. cosmioides, Tt=13.23, K= 462.02 DD and S. albula, Tt=13.19°C, K=478.49 DD. Using the lower threshold temperature and the thermal constant, we estimated the number of generations of each species in three crops (corn – 1st and 2nd harvests, soybean and cotton) grown in different Brazilian municipalities, considering their crop calendar. We used the ArcMap application in ArcGis Pro to organize and represent the estimated number of generations for each Spodoptera species in each crop and municipality. The number of generations was higher in municipalities in the North and Northeast regions where temperatures are highest. S. frugiperda had the highest number of generations in all crops, indicating that it is best adapted to temperature conditions in Brazil. Corn supported the highest number of generations of all species, because it is grown over a longer period.

Rearing Systems as Ecological Niches: The Interplay of Genetics and N-Dimensional Hypervolumes

Authors: Cohen Allen, Allen Carson Cohen, Program Coordinator & Research Professor Insect Rearing Education & Research Program North Carolina State University, Unit 2, United States

Abstract: Insect rearing systems are treated here as artificial niches. As with all ecological niches, there is a dynamic interplay between genetic potential and environmental conditions. Understanding this interplay in the rearing environment is important to designing rearing systems to meet the expectations of the rearing systems' purpose. Drawing from examples from mulberry silkworms (Bombyx mori) rearing (the oldest rearing systems) through modern highly automated processes such as those designed for pink bollworms (Pectinophora gossypiella) and boll weevils (Anthonomus grandis), the interplay of genes and the rearing environment is explored. In accord with treating the rearing process as an n-dimensional (Hutchisonian) hypervolume, the interplay of rearing system components can be explored, helping to shed light on where phenotypic outcomes match or depart from genetic potential. In this presentation, several examples of how rearing system components may succeed or fail in matching the genetic template. These examples are taken from nutritional and environmental factors as they interplay with genetic bases of immunology and life history. One of the most illuminating examples will be the responses to oxidative stress in silkworms and waxworms (Galleria mellonella L.). Other examples of "niche/gene matching" are taken from mass-rearing systems developed for tarnished plant bugs (Lygus Hesperus), green lacewings (Chrysoperla rufilabris), and cactus moths (Cactoblastis factotum).

Vibratory communication in a complex world: the role of media and the use of communication with signals of different modalities in insects.

Authors: Cokl Andrej[1] and Alberto Laumann Raúl[2], [1]Department of Organisms and Ecosystems Research National Institut of Biology, Slovenia, [2]Embrapa Genetic Resources and Biotechnology, Brazil

Abstract: Communication holds insect societies together and among many tasks enables mating females and males of solitary species to find each other in the field. The process from recognition and location to copulation runs through complex calling, courting and rivalry phases by information exchange with chemical, mechanical and visual signals, transmitted through different media. Plants represent for majority of insects the most natural and common surroundings where they find shelter, feed and mate. Local air currents, different architecture and specific mechanical properties of plants restrict communication by visual, chemical, airborne and contact mechanical signals to short distances. The majority of insects use the substrate-borne vibratory component of signals produced by different mechanisms to exchange information at longer distances along the plant. Plants as non-inert transmission medium change transmitted vibratory signal's amplitude, temporal and frequency characteristics. The amplitude decreases non-linearly with the distance, signal duration increases by echoes at the air/substrate phase border and frequency spectra change according to resonance properties of the substrate. Insects tune their vibratory emissions with mechanical properties of plants by incorporating information into signal's parameter less influenced by impacts of the transmission medium and environmental noise. During evolution they developed specific high sensitive receptors and underlying neuronal network, adapted to extract the relevant information from modified vibratory signals. Phytophagous and plant-dwelling stink bugs of the subfamily Pentatominae (Heteroptera: Pentatomidae) represent an instructive group of insects with well investigated multimodal communication running at different distances through air and substrate. Plant-borne communication represents just the intermediate phase of information exchange between long range chemical communication in the field and short range communication on a plant by visual and contact chemical and mechanical signals. Adaptation of vibratory signal characteristics, produced by different mechanisms and tuned with mechanical properties of plants are correlated with characteristics of group mechanosensory system and discussed in view of their function during species recognition and isolation, courting and social conflicts, reflected in female and male rivalry.

Trichoderma harzianum strain T22 enhances indirect plant defenses against stink bug egg deposition

Authors: Colazza Stefano[2], Alinc Tugcan[2], Antonino Cusumano Antonino[2], Peri Ezio[2], Torta Livio[2] and Guarino Salvatore[1], [1]Institute of Biosciences and Bioresources (IBBR - CNR), [2]University of Palermo, Italy

Abstract: In the recent years, there is increasing evidence showing plant growth-promoting fungi such as Trichoderma spp. do not only promote plant growth, but also direct and indirect plant defenses against a wide range of pests, such as herbivore insects. However, no information up to now is available on the role played by plant growth-promoting fungi in mediating egg parasitoid attraction to plant induced by stink bug oviposition. To fill this gap, a multitrophic model system consisting of tomato plant, Solanum lycopersicum, southern green stink bug, Nezara viridula, egg parasitoid, Trissolcus basalis and plant growth-promoting fungi, Trichoderma harzianum strain T22 was used. In olfactometer experiments, it has been found that root colonization by T. harzianum strain T22 enhanced T. basalis attraction towards oviposition-induced plant volatiles (OIPVs) released by tomato plants in response to egg laying by N. viridula. In fact, the egg parasitoid preferred OIPVs emitted by tomato plants inoculated with the beneficial soil microbe compared with OIPVs emitted by non-inoculated plants. Then, the chemical nature of OIPVs to attempt to explain which compounds could mediate parasitoid olfactory responses we analyzed.

Social immunity in fungus-farming termites

Authors: Cole Erin Louise[2], Poulsen Michael[2], Silue Simon[3], Bell-Roberts Louis[1], Jensen Nikolaj[2], Kolhorn Frederik[2] and Kone N’golo[3], [1]New College, [2]The University of Copenhagen, [3]Université Nangui Abrogoua

Abstract: As epitomized by epidemics and pandemics throughout human history, including the ongoing SARS CoV-2 pandemic, social life carries risks of substantial and rapid spread of infectious diseases. Social insects, including termites that live in pathogen-rich environments have evolved remarkably robust social immunity mitigation strategies that effectively prevent diseases from spreading within colonies. However, experiments have been conducted on only a small portion of the vast diversity of termite species, with most work being on soil- and wood-dwelling species. Consequently, it is currently unknown to what extent mound-building termites face the same pathogenic pressures and exhibit the same social immune behaviours, strategies and immune responses as their wood-dwelling counterparts. Using the mound-building fungus-farming termite Macrotermes bellicosus, we identified and characterized ecologically relevant entomopathogens. We also performed a behavioural experiment and two survivorship experiments to test the hypotheses that M. bellicosus exhibits a sophisticated, and caste-specialized pathogen defense system. Here we present preliminary analyses, and more broadly discuss the evolution of termite immunity and the implications of social life for robust defence.

Tick-tock: New repellency strategies needed for the changing times

Authors: Cole Lacey[1], Kuhns Emily[1] and Bedoukian Robert[1], [1]Bedoukian Research, Inc, United States

Abstract: Ticks are one of the most devastating vectors of human pathogens, but they are often eclipsed by their flashier “cousins”, mosquitoes. Ticks vector Borellia, Anaplasmosis, Babesiosis, Erlichiosis, Powassan, Francisella, Rikettsia pathogens, and were responsible for 59,349 reported human illnesses in the US in 2017. This number greatly underestimates the number of illnesses due to ticks because of the challenge in diagnosing tick-borne illness. Additionally, the geographic range of native and invasive ticks is expanding. In one example, in 2017 a new species of tick was reported in the United States for the first time, Asian longhorned tick. It has since been detected in 13 US States. In the natural range, these ticks have transmitted pathogens to humans, it is still unclear what the domestic threat will be. All of these outcomes have a serious impact on human health, medical burden, and quality of life, and will require a multi-pronged approach to control the impact of these diseases, including better diagnostics, surveillance, treatment and intervention. Here we present a new set of active ingredients as topical repellents to protect humans from ticks.

Characterization of the circadian clock in the Pea Aphid

Authors: Colizzi Francesca Sara[1] and Foerster Charlotte[1], [1]Biocenter - University of Würzburg, Germany

Abstract: Aphids are strongly photoperiodic insects. They reproduce parthenogenetically in spring and sexually in autumn, and this change is controlled by the shortening of day length. The involvement of the circadian clock in photoperiodism has already been established in mammals, plants, and fungi, but it is still controversial in insects. To answer this question, we began by characterizing the neuroanatomy of the aphid circadian clock and localizing the clock-related neuropeptides. Using immunohistochemistry with antibodies against the clock proteins Period and Cryptochrome, we found that the clock consists of four neuronal clusters that oscillate daily. By doing a 3D reconstruction of the CRY-positive neurons, we found that they project toward the Pars Intercerebralis, where also insulin-producing cells are located. Furthermore, we used antibodies against neuropeptides that are clock related in Drosophila melanogaster and found that IPNamide, Diuretic Hormone 31, and Allatostatin A are expressed in some aphid clock neurons, suggesting that they may also be associated with the clock in aphids. Briefly, we have found that the expression pattern of neuropeptides can be very different in different insect species, even if the peptide sequence itself is highly conserved. This laid the groundwork for future functional analysis of the aphid clock neurons and neuropeptides.

Predatory Mirids as Crop Pests: Importance of Host Plants, Prey Type, and Endosymbiotic bacteria

Authors: Coll Moshe, The Hebrew University of Jerusalem, Israel

Abstract: Omnivory, the feeding on both plant and prey materials, is common in agroecosystems. Understanding the feeding habits of omnivorous consumers is particularly important for mirid bugs, because several biological control agents in this family may also inflict economic damage to crop plants. In recent studies, we explored the influence of plant genotype, availability of various prey types, and the presence of bacterial endosymbionts on plant-feeding and fitness components of several mirid bugs. Results show that compared to wild genotypes, commonly cultivated tomato is more suitable for the development, survival and reproduction of Nesidiocoris tenuis. However, the oviposition preference for the cultivated genotype is lost in the presence of prey. In another system, plant-feeding and crop damage were found to be influenced differentially by the presence of various prey species on pepper plants; red spider mite, sweet potato whitefly, western flower thrips, and moth eggs differed in their nutritional suitability for Creontiades pallidus which in turn affected level of fruit damaged by the bug. Finally, an on-going study suggests that two Rickettsia species, R. bellii and R. Limoniae, influence the ability of Macrolophus pygmaeus to exploit both plant and prey materials. These bacteria are highly abundant and probably fixed in bug populations, and are found in distinctly different cells in parts of the gut and in Malpighian tubes. Taken together, these results demonstrate the great challenge faced by biological control practitioners that employ omnivorous natural enemies. It seems that elaborate, specific research is needed of each mirid-cropping system combination if we are to maximize pest suppression and at the same time prevent bug-inflicted crop damage.

Ecology of native Drosophila parasitoids in Central Europe

Authors: Collatz Jana[2], Wolf Sarah[4], Trivellone Valeria[3], Barmettler Elias[4] and Romeis Jörg[1], [1]Agroscope, Research Division Agroecology and Environment, Zurich, Switzerland, [2]Agroscope, Switzerland, [3]Illinois Natural History Survey, Prairie Research Institute, University of Illinois at Urbana-Champaign, United States, [4]Research Division Agroecology and Environment, Agroscope, Switzerland

Abstract: The alien vinegar fly Drosophila suzukii calls for landscape-level control because it can re-infest orchards from semi-natural habitats that provide year-round food resources, oviposition sites and refuges. In Central Europe, several species of native pupal parasitoids have been identified that are able to utilize pupae of D. suzukii for reproduction. These parasitoids could help to reduce populations of the invasive pest on a landscape level.

To unravel the ecology of these parasitoids we first performed field collections in agricultural and semi-natural habitats with sentinel traps that contained pupae of four native Drosophila species. Subsequent laboratory experiments with the three most common parasitoid species, Pachycrepoideus vindemmiae, Trichopria drosophilae and Spalangia erythromera, were conducted to investigate host choice in the presence of D. suzukii. To validate our findings, we finally released the three parasitoid species in a semi-field experiment and evaluated their parasitization of D. suzukii and two native Drosophila species. Our results show that the parasitoid species differ in their host finding and host choices but that D. suzukii is among the preferred hosts. We discuss our findings in the light of efficacy and potential non-target effects and point to the challenges that still lay ahead in the use of native parasitoids for D. suzukii control.

Climate change adaptation strategies in Latin America as part of a Resilient Agricultural production system

Authors: Colmenarez Yelitza[3], Vasquez Carlos[5], Torres Luis[4], Corniani Natalia[1], Edgington Steve[2], [1]CAB International (CABI), Brazil, [2]CAB International (CABI), United Kingdom, [3]CABI Brazil Centre Director, Brazil, [4]INIA, Peru, [5]Universidad Técnica de Ambato, Ecuador

Abstract: Climate change is affecting the agricultural production in Latin America, and represents a challenge for agricultural production and plant protection, since it favours the movement of pests to new areas due to the increase in temperature and change in climatic conditions. Climate conditions have an important influence in the development of pests, diseases and biological control agents. Biological control plays an important role as part of Integrated Pest Management and sustainable production. Therefore, is important to investigate the effect of the abiotic condition changes, such as the increment of temperature, humidity, flooding and drought conditions on the distribution range of both agricultural pests and their biocontrol agents. This study presents the different strategies putting in place, and join efforts looking forward to have a more Resilient Agricultural production system, evaluating the effects of climate change on the pests and biological control agents and using sustainable practices and tools as part of the adaptation process to climate change. The Climate Smart Agriculture approach will be discussed as a possible way of facing some of the current challenges in the region and increasing sustainable production in Latin America.

Bottom-up and top-down effects on insect herbivore fitness under global change

Authors: Comerford Mattheau[2], Murphy Shannon[2], Vidal Mayra[1], [1]Syracuse University, United States, [2]University of Massachusetts Boston, United States

Abstract: Insect herbivores can be affected by selective forces from natural enemies (top-down) and host plants (bottom-up). The quality of plants as food for insect herbivores as well as the potential pressure by natural enemies can vary directly and indirectly with environmental factors such as temperature, water and nutrient availability, atmospheric gases, etc. Many of these environmental factors are already and will continue to rapidly change due to global environmental change. The different environmental factors that are changing can have variable effects on insect herbivore fitness via top-down and bottom-up forces, which makes the response of insect herbivores to global change hard to predict. For instance, some plants can respond positively to some environmental changes (e.g., nutrient pollution), which can result in positive effects for herbivores. However, other environmental factors can have a negative effect on plant quality (e.g., drought), resulting in an indirect negative effect on herbivores. Natural enemies are likely going to be negatively affected by many environmental changes (e.g., change in precipitation, temperature), which may result in enemy release and a positive effect for herbivores. We conducted a meta-analysis to synthesize the current knowledge on the indirect effects of global change on insect herbivores via bottom-up and top-down forces. We tested the overall effect that global change has on top-down and bottom-up forces on insect herbivore fitness. We further tested the effects of different types of global change on the responses of insect herbivores to top-down and bottom-up forces, and how these responses can vary with insect guild, type of habitat where the experiments were performed, type of fitness measure taken, and type of natural enemies (e.g., parasitoids vs. predators). Knowing the many possible effects that global change can have on top-down and bottom-up controls of insect herbivore can help with conservation efforts and pest controls.

Genome-wide macroevolutionary signatures of key innovations in butterflies colonizing new host plants

Authors: Condamine Fabien[4], KERGOAT Gael[1], Cotton Adam[7], Clamens Anne-Laure[1], Nabholz Benoit[4], Sperling Felix[2], Chomicki Guillaume[3], Pérez-Escobar Oscar[6], Allio Rémi[5] and Wanke Stefan[5], [1]Centre de Biologie pour la Gestion des Populations, France, [2]Department of Biological Sciences, University of Alberta, Canada, [3]Department of Bioscience, Durham University, United Kingdom, [4]Institut des Sciences de l'Evolution de Montpellier, France, [5]Institut für Botanik, Technische Universität Dresden, Germany, [6]Royal Botanic Gardens, Kew, United Kingdom, [7]Tambon Nong Kwai, Hang Dong, Chiang Mai, Thailand

Abstract: The exuberant proliferation of herbivorous insects is generally attributed to their associations with plants. Yet, despite numerous studies on insect-plant interactions, a rigorous integration of the macroevolutionary and genomic consequences of the evolutionary dynamics of host-plant shifts has not been achieved. The arms race between swallowtail butterflies and their host plants provides a preeminent model for addressing this gap. Here we show that host-plant shifts are associated with genome-wide adaptive molecular evolution, followed by repeated bursts of higher speciation rates. We find that this antagonistic insect-plant interaction began 55 million years ago for the ancestor of swallowtails and a highly toxic plant group, the birthwort genus Aristolochia, both of which occurred in a northern region centered on the Bering Land Bridge. Despite strong host-plant conservatism, several ancient shifts to new plant families now allow repeated tests of genome-wide signatures of macroevolutionary changes and estimation of diversification rates across their phylogeny. Phylogenetic branches with host-plant shifts had more genes under positive selection and faster diversification, contributing to an increase in global diversification through time. Our study links ecological changes, genome-wide adaptations and macroevolutionary consequences, lending support to the importance of ecological interactions as evolutionary drivers over long time periods.

Mechanisms of herbivore-induced plant responses and perspectives for improvement of stink bug biocontrol

Authors: Conti Eric[2], Rondoni Gabriele[1], Chierici Elena[1] and Bertoldi Valeria[2], [1]DSA3, University of Perugia, Italy, [2]University of Perugia, Italy

Abstract: Several stink bugs, such as Halyomorpha halys and Nezara viridula, are serious crop pests globally. Classical and conservation biological control, combined with other sustainable control methods, are considered effective solutions for management of these stink bugs. Future strategies might target plant resistance, focusing on indirect defences (attraction of egg parasitoids) and direct defences (antibiosis and antixenosis). The aim of this presentation is to review the current knowledge related to physiological and molecular aspects of bi-trophic and tri-trophic plants – stink bugs – parasitoids communication. Egg deposition combined with feeding punctures and walking activity by different stink bug species induces in plants the emission of volatiles that recruit stink bug egg parasitoids, thus preventing eggs from hatching. Furthermore, combinations of biological and molecular investigations indicate that naturally laid eggs and/or adult feeding by H. halys are perceived as a warning signal by faba bean and tomato plants, which activate a mechanism of enhanced direct defence that affects the developing progeny and repels nymphs. Indeed, higher expression of jasmonic acid-dependent genes was detected in oviposition-experienced plants compared to control plants when challenged by nymphs. The magnitude of plant response and/or the type of pathway activated by the herbivore attack may change with the stink bug species, plant species and type of plant-herbivore interaction. Understanding how plants modulate stink bug-induced responses is important for the development of management strategies based on improving plants' indirect and direct defences in combination with biocontrol.

The learning curve: specialist and generalist insect response to ozone-altered floral scents.

Authors: Cook Brynn[2] and Roulston T'ai[1], [1]University of Virginia, Blandy Experimental Farm, United States, [2]University of Virginia, United States

Abstract: Plant volatiles can act as important long-distance signals for host-searching insects. However, some air pollutants, which have increased dramatically following the industrial revolution, may react with volatiles and alter these cues. In following with emerging studies, we find that the air pollutant ozone causes floral scents to become less attractive to a pollinating moth, Manduca sexta, as well as two cucumber beetles Acalymma vittatum and Diabrotica undecimpucntata. However, some insects may be equipped to use behavioral plasticity to overcome ozone-induced changes in evolved signal-cue matching by learning the altered floral scents. Here we find that M. sexta can readily learn the ozone-altered plume, even when the ozone-altered plume and reward are temporally decoupled, as they would be in a field setting. Somewhat more surprisingly, given the dearth of literature on specialist-insect olfactory cue learning, the specialist beetle A. vittatum was also able to learn the ozone-altered plume via association. This work thus demonstrates both the potential threat of air pollution to insects as well as the importance of considering insect learning and learning abilities in future studies investigating how insects respond to anthropogenically-altered signals.

Not just a ‘dirty needle’: the influence of Stomoxys calcitrans on lumpy skin disease

Authors: Cook Charlotte[3], Moffat Katy[1], Greaves David R. [4], Darpel Karin [1] and Beard Pip[2], [1]The Pirbright Institute, [2]The Pirbright Institute; The Roslin Institute, [3]The Pirbright Institute; University of Oxford, [4]University of Oxford

Abstract: The poxvirus lumpy skin disease virus (LSDV) is mechanically transmitted by haematophagous arthropods including stable flies (Stomoxys calcitrans), causing severe systemic disease in cattle. Arthropod vectors that transmit viruses mechanically are regarded as playing little role in disease beyond transmission. We examined this theory by studying S. calcitrans and LSDV. Addition of S. calcitrans secreted saliva to LSDV had no impact on viral survival or replication in vitro. The impact of S. calcitrans on LSD was examined using an experimental LSD bovine model. Three groups of ten cattle were inoculated intradermally with 1x106 pfu of LSDV. Group 1 received virus alone, group 2 received virus mixed with 10ug S. calcitrans saliva, and group 3 received virus inoculated into a site that S. calcitrans had spot-fed on. Fewer cattle in group 2 developed LSD (3/10) than group 1 (6/10) and group 3 (7/10), indicating that S. calcitrans saliva inhibits LSDV infectivity in vivo. Cutaneous lesions and viraemia appeared more rapidly in group 3 than group 1, revealing that pre-feeding S. calcitrans on inoculation sites accelerates disease kinetics. S. calcitrans are therefore more than a simple conduit for virus transmission: through bite trauma and saliva deposition they influence LSDV infection and disease.

The Final Solution: Preventing Stable Flies from Developing in Vegetable Crop Residues

Authors: Cook David, Department of Primary Industries and Regional Development Western Australia, Australia

Abstract: Post-harvest residues of most leafy vegetables rot within days after harvest and provide an ideal environment for stable flies to complete their development. The resultant adult flies that emerge seek blood meals several times a day and significantly affect livestock and rural residents nearby. Numerous methodologies have been tried to reduce stable fly development from vegetable crop residues left in situ after harvest but have either had limited success or are neither practical nor economically viable for vegetable producers to adopt. Our research clearly confirmed the best method for managing and having a major impact on stable fly development from vegetable crop residues involved 2 simple steps: (1) Burial of crop residues using either a mouldboard plough, stone burier or a deep, slow rotary hoe; followed by (2) Compaction of the sandy soil using a fixed landroller at rates equivalent to 5t/m2. Compacting sandy soil almost totally prevented adult stable fly emergence from the soil. The hard barrier of soil near the surface prevent the newly-emerged adults from digging their way to the soil surface. Burying and compacting sandy soil over the crop residues provides key production benefits to growers including: (i) retention of all the organic matter from the residues (ii) less soil wind erosion from moist, compacted sand (iii) no need to use insecticides to control stable flies. The option of burying crop residues and compacting the sandy soil above the residues offers a unique physical solution to preventing the emergence of adult stable flies from the residues without the need to use pesticides.

Biology and chemical ecology of spotted lanternfly

Authors: Cooperband Miriam, Otis Laboratory USDA-APHIS-PPQ-S&T, United States

Abstract: In the five years since the discovery of Spotted Lanternfly in Pennsylvania, in the United States, it has spread to neighboring states and populations have multiplied unchecked. At the onset, we had few tools for monitoring and detection of this pest. We set out to improve our understanding of the biology and behavior of this species, with the ultimate goal of identifying strong attractants or semiochemicals that could be used in survey, detection, and control. We now know much more about its host preferences, host suitability, basic biology, adult phenology, have identified approximately 15 kairomones, and have found evidence that they may use pheromones. This talk will summarize our research and results in the context of Spotted Lanternfly biology and chemical ecology.

Population ecology of a forest insect with prolonged quiescence and its consequences on classical biological control

Authors: Corley Juan, Bariloche Institute of Research in Forestry, Agriculture and Livestock (IFAB, INTA-CONICET) and Ecology Department, Comahue National University, Bariloche, Arg, Argentina

Abstract: Prolonged or extended diapause is a life history feature of many forest insects living in unpredictable environments. It is considered an adaptive risk-spreading strategy, as it creates heterogeneity within populations by extending the life cycle of a fraction of individuals. Developmental quiescence can vary largely among species in kind, duration, stage and triggering factors. However, it can have dynamic consequences on single populations and on species interactions. I analyze the population dynamics of a forest insect pest that undergoes prolonged quiescence and through simple modeling, explore its significance on the interaction with parasitoids. I illustrate my case with a system involving a major forest pest, the woodwasp Sirex noctilio and two of its parasitoid species that have been introduced into different geographical regions through classical biological control programs. Recent work has provided evidence for prolonged developmental quiescence at the egg stage or early larval stage correlated to the ambient temperature in the Sirex wasp. A consequence of this is a variable, multi-year life cycle in some invaded regions. Through simple models, I show how multi-year cycles may affect population outbreaks. Because delayed emergence can also affect adult size, and consequently longevity, fecundity and dispersal potential the consequences are likely to be more complex. I also suggest that the physiological relationship between the parasitoids and the development patterns of its host, can have an impact on the success of classical biological control programs deployed. I conclude that for given environments and in the light of climate change, multi-year emergence and the way in which it affects population growth, should be carefully pondered to understand observed population patterns of forest insects and spread rates of invasive species. In turn, how parasitoids deal with host development under given climatic conditions, should be considered with other selection criteria of natural enemies of alien pests.

The standing challenges for the successful management of insect pests in plantation forestry in Argentina

Authors: Corley Juan, Bariloche Institute of Research in Forestry, Agriculture and Livestock (IFAB, INTA-CONICET) and Ecology Department, Comahue National University, Bariloche, Arg, Argentina

Abstract: Plantation forestry in South America is dominated by non-native tree species. A likely consequence of this, is that most pest issues are also non-native, largely arriving accidentally from native or previously invaded ranges. In contrast with most food or fodder producing crops, tree plantations cover larger spatial and temporal scales and so pest issues require management practices that consider their spatial and temporal dynamics. This, and the fact that many pests are non-native, are probably the reasons why classical biological control is often the practice used in plantation forestry.

In pine and eucalypt plantations in Argentina, thirty-five alien forest insects have established populations and only 23% (eight species) are exclusively found there; the rest being shared with a least one neighboring country. Despite the fact that information on the distribution changes, population dynamics, and spread of established forest insects in commercial forests of Argentina is limited, many probably cause still little damage. For all those alien species present that cause some impact (6), classical biological control plans are in course or else planned. For none however, population size prior to management and the economic impact have been estimated nor the efficacy of control actions has been quantified. To improve our knowledge on the factors underlying success or failure of pest management practices against established pests of plantation forests in Argentina, population information is urgently needed. A key matter is understanding those issues that favour the arrival and population growth of alien insects, including the relative roles of top-down vs bottom-up regulating factors and identifying the main mortality factors present. The development of sensitive, cost-efficient and repeatable monitoring protocols is thus a necessary step in this direction, as are, cross border pest databases of pests and natural enemies, that include geographical information. Considering the observed changes in global climate, detailed climate matching studies based on physiological studies of potential natural enemies, may improve the chances for success.

Plant-insect-entomopathogen interactions: Do host plants have a role in the outcome of mixed pathogen infection and successful pathogen transmission?

Authors: Cory Jenny[1], Deschodt Pauline[1], Dang Brandon[1] and Hercus Jess[1], [1]Simon Fraser University, Canada

Abstract: Plants can play a major role in the interaction between insects and their pathogens. Differences in plant quality can have significant impacts on insect growth and condition, which can affect their susceptibility to pathogen infection either directly or indirectly. Moreover, insects are commonly challenged by multiple pathogen species, yet little is known about how nutrition affects the outcome. Different host plants could influence pathogen co-infection in terms of host survival, pathogen replication and subsequent pathogen transmission to uninfected hosts. Additionally, traits that enable a pathogen to be a good competitor within the host on a specific host plant might not be the same as those that are needed for successful transmission within the host population. Our earlier work has shown that host nutrition significantly affects host survival to infection, as well as pathogen replication within the host and the outcome varies with pathogen type.

In a spray assay, using the cabbage looper, Trichoplusia ni, its nucleopolyhedrovirus (TnSNPV) and the entomopathogenic fungus, Beauveria bassiana, and two of its host plants, broccoli and tomato, we asked whether host plant species and mixed infection could alter pathogen efficacy in controlling the cabbage looper. Then using the same host plants, we measured pathogen transmission within T.ni populations. We challenged T.ni larvae with either a single pathogen species, two pathogens simultaneously or two pathogens asynchronously. Before death, randomly selected challenged larvae were transferred onto caged host plants (broccoli and tomato). After death, 20 healthy larvae were added to each plant. Using destructive samplings 1, 3 and 5 days after introduction, collected larvae were then reared on artificial diet until death or pupation to estimate pathogen transmission.

We hypothesized that the likelihood of healthy larvae being infected by a pathogen in the field will vary depending on; host plant architecture, plant nutrient composition and secondary chemicals; spatial structure of pathogen transmission stages as well as temperature and humidity. The results showed that host likelihood of being infected is highly dependent on the host plant and pathogen infection pathway. The results presented give insight into the complex interactions which can modulate pathogen transmission in the field.

Vector Control Products and Approaches: Contributions from the U.S. National Institute of Allergy and Infectious Diseases

Authors: Costero-Saint Denis Adriana[1] and Ghenbot Ghiorghis[1], [1]National Institute of Allergy and Infectious Diseases, National Institutes of Health, United States

Abstract: The National Institute of Allergy and Infectious Diseases (NIAID) part of the National Institutes of Health (NIH) in the U.S. Department of Health and Human Services (DHHS) provides funding (competitive grants) and resources (preclinical services) to investigators interested in basic and translational research leading to vector control approaches and products. The Vector Biology Program at NIAID supports over 100 grants on all aspects of basic research on arthropod vectors of human pathogens and snail reservoirs of Schistosoma parasites. Vectors currently supported include: mosquitoes, sand flies, black flies, tsetse flies, triatomine bugs, ticks and snails. Research projects range from physiology, pathogen/vector interactions, vector immunity, vector microbiome, to ecological and epidemiological studies, including clinical trials of vector interventions to assess their impact on disease transmission. The translational component of the Program supports the generation of evidence that allows investigators to reach out to funders to advance their product development efforts and for support to scale up; and to regulatory agencies to register the products. Examples of successful products that have followed this path will be presented and include ZAP Males (MosquitoMate) for dengue control and Ivermectin for malaria control.

Nutritional ecology, infection and immune defence — exploring the mechanisms

Authors: Cotter Sheena[2] and Al Shareefi Ekhlas[1], [1]University of Babylon, Iraq, [2]University of Lincoln, United Kingdom

Abstract: Many insects have been shown to switch diets after infection, to ones that improve the outcome of infection, known as self medication. However, how diet improves infection outcomes is often unclear. Diet can impact the outcome of parasitic infection in three, non-mutually exclusive ways: 1) by changing the physiological environment of the host, 2) by enhancing the immune response and 3) by altering the presence of host microbiota. We show that there are no clear patterns in the effects of diet across taxa and that good evidence for the mechanisms by which diet exerts its effects are often lacking. More studies are required to understand the mechanisms of action if we are to discern patterns that can be generalised across host and parasite taxa.

Sci-comics for #scicomm

Authors: Couret Jannelle[1] and Rothwell Aya[2], [1]University of Rhode Island Department of Biological Sciences, United States, [2]University of Rhode Island, United States

Abstract: Sci-comics are a product of graphic/comic art and compelling story-telling that primarily aim to educate, but also entertain. We present the tragicomic life-story of a mosquito larva in order to demystify the step-by-step process of creating a sci-comic inspired by published research articles, as well as highlight the important ground-rules for successful collaborations between graphic artists and scientists. This and other sci-comic success stories suggest that this genre has broad potential to enhance the impact of other forms of science communication. A preliminary study of the impact of sci-comics in an undergraduate entomology course demonstrates that students improved their understanding of research results when primary literature was accompanied by related sci-comics than when articles were read alone. The collaborative vision for sci-comics presented here is fun and rewarding, and creates products that can memorably capture and convey scientific concepts and research results.

The more you know: Targeted social media #scicomm for different demographics

Authors: Coyle David, Department of Forestry and Environmental Conservation, Clemson University, Clemson, South Carolina, United States

Abstract: Social media is exponentially increasing in its use as a scientific communication (#scicomm) tool. Many people, including professionals and non-professionals, are using social media to talk about the natural world. As an educator, especially one in an academic setting (e.g. Cooperative Extension in the U.S.), time and resources are seemingly on a continual decline. AS such, it is imperative that we maximize our time, energy, and resources. Social media is a great way to reach a lot of people, but it is important to know your audience in order to maximize the efficacy of your message. Different demographics gravitate towards different social media platforms. Knowing who uses what, and then using targeted messages, can greatly increase the chances that your #scicomm is effective. This talk will discuss different social media platforms and common demographics associated with them in an effort to help attendees more efficiently use social media.

Studies on the host diversity of the spiraling whitefly (Aleurodicus rugioperculatus Martin) and the physiological and biochemical changes accompanying the fly infestation in Cocos nucifera L.

Authors: CR Arunkumar[1] and Job Joseph[2], [1]Department of Botany St.Berchmans College Changanassery Kerala India, India, [2]Division of Plant Physiology and Biochemistry Department of Botany University of Calicut Kerala India, India

Abstract: Aleurodicus rugioperculatus Martin. was an important agricultural pest, known as spiraling whitefly which was found to be present mainly in agricultural crops. The whitefly infestation on crop plants was always associated with black sooty mold. The objectives of the present study were the preparation of an inventory of the host diversity of the fly and the determination of the physiological and biochemical changes in the coconut plants(Cocos nucifera L.) due to whitefly infestation . The fly was found to be inhabiting all most all of the crop plants and natural vegetation of the study area. The infestation made several biochemical changes in the infected plants. Mainly the stress related compounds were produced in higher amounts in the infected coconut leaves. Significant increase was noted in the contents of flavonoids, proline, total sugar, amino acid and total protein. It was also observed that the reactive oxygen species were formed at an elevated rate in the infected tissue. The enzymatic antioxidants such as catalase, ascorbate peroxidase and sod and non-enzymatic antioxidants such as glutathione, ascorbate and phenol were also detected in higher amounts in the infected leaves. As a result of the infection there was a significant decline in the contents of chlorophyll a, chlorophyll b, total chlorophyll and carotenoid. Consequently the activity of photosystem I and II were also reduced in the infected leaves.

Identification of the Bactrocera white pupae (wp) gene provides new opportunities for developing genetic sexing strains for SIT

Authors: Crisp Peter[2], Baxter Simon[5], Caceres-Barrios Carlos[1], Ward Christopher[3], Amanda Choo Dr.[3], Fung Elisabeth[4] and Nguyen Thu[3], [1]Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, International Atomic Energy Agency, Austria, [2]South Australian Research and Development Institute, Australia, [5]University of Melbourne, Australia, [3]University of Adelaide, Australia, [4]University of Adelaide, South Australian Research and Development Institute, Australia

Abstract: Suppression or elimination of insect pest populations can be achieved using the Sterile Insect Technique (SIT). The release of sterilized males, rather than bi-sex releases, requires genetic sexing strains with the ability to selectively eliminate females and this can be achieved using dimorphic pupal color phenotypes. Here we report a recessive gene mutation in Bactrocera dorsalis that causes the white pupae (wp) phenotype by preventing the puparium from developing into wild type brown colors. The B. dorsalis wp- locus was introgressed into the genetic background of a related species, B. tryoni (brown pupae), over twelve generations to produce a wp- Bactrocera introgression line. Whole genome sequencing identified a 2.5 Mb region in the introgression line containing 81 genes from B. dorsalis that controlled the wp phenotype. One of these genes was highly expressed during pupal development, however, wp- flies contained a 37 bp truncating mutation predicted to cause a total loss of protein function. CRISPR/Cas9 mutagenesis in B. tryoni provided functional support for a role in pigmentation, as injected individuals developed mosaic white and tan puparium colors, and progeny with recessive white pupae phenotypes were subsequently produced. Gene technology has the potential to engineer white pupae phenotypes in a range of Tephritids, although the construction of a genetic sexing strain will require insertion or translocation of a functional copy of the wp+ gene to the male Y-chromosome for dimorphic pigmentation.

Manipulating pollen macronutrient ratios to improve honey bee (Apis mellifera) resilience to pesticide stress

Authors: Crone Makaylee[2], Grozinger Christina[1], Biddinger David[3], [1]Distinguished Professor of Entomology at Pennsylvania State University Director of the Center for Pollinator Research, United States, [2]Ecology Ph.D. Candidate in the Department of Entomology at Pennsylvania State University Center for Pollinator Research, United States, [3]Entomology, Penn State Fruit Research & Extension Center, Biglerville, PA, United States

Abstract: Many stressors are known to contribute to a decline in honey bee (Apis mellifera) health. One of the best ways bees can combat these stressors is by consuming pollen from multiple sources. A diet lacking in pollen quality or quantity has been shown to decrease the survival of bees parasitized by the ectoparasite Varroa destructor, increase the level of viral loads present, and increase pesticide susceptibility.

Our study sought to determine whether the protein or lipid portion of pollen contributes most to pesticide resilience by feeding groups pollen of varying protein to lipid ratios and challenging bees with the pesticide stressor chlorpyrifos. We also examined the differential expression of genes associated with diet and overall health by using qRT-PCR to determine the mechanisms responsible for differences in survival between dietary treatment groups. The goal of this study is to determine the most beneficial diet for honey bee health to inform beekeepers and land managers of best practices for supplementing floral resources for bees.

Impact of elevated CO2 on insect-plant interactions in a forest ecosystem.

Authors: Crowley Liam[1], Pritchard Jerry[1], Sadler Jon[1] and Hayward Scott[1], [1]University of Birmingham, United Kingdom

Abstract: Elevated atmospheric concentrations of carbon dioxide (eCO2) is a key driver of global climate change. Increasing CO2 can also profoundly alter insect-plant interactions via its effects on plant biochemistry, physiology and ecology. The full extent of these potential impacts, however, remains unclear specially in complex ecosystems such as forests. The new Birmingham Institute of Forest Research (BIFoR) Free Atmosphere Carbon Enrichment (FACE) facility provides a unique opportunity to investigate these responses in a mature, temperate woodland.

Insect herbivory and insect-mediated pollination are two key ecological process affecting nutrient flow and plant reproductive success within forested ecosystems. Thus, understanding the responses of insect herbivores and pollinators to eCO2 is critical to predicting the consequences of future climate scenarios for the wider ecosystem.

Leaf-mining insect larvae are a useful feeding guild to study these responses in a forest ecosystem as they are sessile, abundant and leave a clear trace of their life history. Here we present data showing the impact of eCO2 on leaf-miner species abundance, distribution and feeding rate. The details of how plant-pollinator interactions may be altered under future climate conditions are also discussed, using common Bluebell, Hyacinthoides non-scripta, and its pollinators as a model. Associated variables are measured in both interactions in an attempt to provide a mechanistic understanding of the driving force behind observed trends.

Ploidy levels regulate cell fate during metamorphosis in Drosophila melanogaster

Authors: Cruz Josefa [1], Martín David[3], Franch-Marro Xavier[3], Franch Marro Xavier[2], Subirana-Bonet Jordi[1], [1]IBE (CSIC-UPF), [2]IBE (UPF-CSIC), [3]Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: Tissue remodeling is an important process during morphogenesis. In insects, organ remodeling takes place during the metamorphosis. At the metamorphic transition larval cells die, whereas imaginal cells survive and differentiate into the cells of the adult organism. Remarkably, we found that both processes (death and differentiation) depend on the presence of the ecdysone-dependent transcription factor E93. E93 expression in the prothoracic gland (PG), the main endocrine larval organ, induces its degeneration by apoptosis and autophagy. In contrast, in wing imaginal cells, E93 promotes cell differentiation. The molecular context that determines the fate of the larval cells and the adult precursors upon activation of E93 remains unknown. One of the main features that distinguish these two populations of cells is their DNA content. Whereas imaginal cells are mainly diploid, larval cells, as those of the PG, shows a high grade of polyploidy. Interestingly, conversion of PG polyploids cells into diploid by depleting Fzr impaired the degeneration of the organ. In contrast, polyploidization of wing imaginal cells resulted in an increase in cell death during metamorphosis in the adult wing. Altogether, our results indicate that E93 induces either cell death or differentiation depending on the DNA content of larval and imaginal cells.

Suppression of prophenoloxidase activation is required for vector competence for a persistent plant virus

Authors: Cui Feng[1], Wang We[1], Lu Hong[1], Yu Jinting[1], Kang Le[1] and Chen Xiaofang[1], [1]Institute of Zoology, Chinese Academy of Sciences, China

Abstract: Rice stripe virus (RSV) is the cause of one of the most destructive rice disease epidemics in eastern Asian countries. This virus is transmitted by the small brown planthopper in a persistent-propagative mode. However, factors associated with vector competence for RSV remain elusive. Here, we reported that the proteolytic activation of prophenoloxidase (PPO) played a role in vector competence for RSV transmission.

Neopolyploidy in plants and its impact on insect herbivore communities

Authors: Cure Anne[2], Porturas Laura[1] and Segraves Kari[2], [1]Pennsylvania State University, [2]Syracuse University, United States

Abstract: Insect herbivores are a key component of many ecosystems, having a major impact on plant community composition and structure. A common yet overlooked factor that could affect patterns of insect herbivory is the evolution of whole-genome duplication (WGD) or polyploidy in plants. Newly formed polyploids, or neopolyploids, often have physiological and morphological changes that might cause cascading effects in the associated herbivore community. Despite these potential linkages between WGD and herbivory, we know little about how WGD alters herbivore-plant interactions. Here we determined how insect herbivores respond to neopolyploid hosts by examining if the community of insect herbivores change in response to neopolyploidy, and in turn, if neopolyploidy alters patterns of attack by insect herbivores. We tested the effects of WGD on insect communities by placing diploid and neopolyploid red clover (Trifolium pratense) in a common garden and assessed insect community composition, abundance, and attack rates.

Estimation of developmental thermal parameters of the Chilean leafroller, Proeulia auraria (Clarke) (Lepidoptera: Tortricidae), using non-linear models.

Authors: Curkovic Tomislav[2], Arraztio Diego[2], Leiva Flaminio[2], Solis Gabriela[2], Neira Jose[2], Morales Luis[2], Gutierrez Pablo[3] and Tapia Roberto[1], [1]Agriculture and Livestock Service Dept. Agriculture, Chile, [2]University of Chile, Chile, [3]University of O´Higgins, Chile

Abstract: Proeulia auraria (Lepidoptera: Tortricidae) is a native to Chile leafroller, affecting fruit orchards and vineyards yields. Besides, historically it is the sixth species in terms of quarantine rejections during post-harvest inspections to our fruit for exports. Thus, our group has worked to develop a phenological model as a predictive tool for precise pest management under field conditions. P. auraria larvae, pupae, and eggs were collected in severely infested vineyards, brought to the lab, and reared on artificial diet. Once adults were obtained, couples were placed in courtship arenas where females laid eggs. 0-12-hours eggs were taken to climatic chambers set at constant temperatures (8 temperatures between 8 and 34º C). Development (days) was checked every 2-3 days, for over 100-130 individuals/stage or instar, in each temperature regime, determining the time when eggs hatched, and larvae and pupae molt. Most phenological models developed to date for insect species, have estimated thermal parameters (lower threshold and degree-days) using linear models fitted to data (developmental rate vs. rearing temperatures, at several thermic regimes). However, the linear approach is not able to estimate the upper threshold nor the optimal range of temperature. On the other hand, the use of non-linear models (we used those published by Briere, Kontodimas, Ratkowsky among others) has been reviewed most recently, having the advantage of estimating both, the threshold and optimum, but not the respective degree-days. Our work estimated all four thermal parameters with a new approach for calculation of degree-days, using several of these non-linear models, by computing the derivative of development rate with respect to temperature, and obtaining the mean positive value between the lower and upper thresholds. These parameters were used later for validation in field tests, where the development was checked daily, and the canopy temperature was periodically registered, to estimate the actual degree-days experimented by the individuals. Those were contrasted with predictions based on the thermal parameters, obtaining significantly better predictions when parameters obtained with the non-linear models were used.

Molecular identification of Irish mosquitoes via direct and indirect sources

Authors: Curran Thomas[3], McDevitt Allan[5], Browett Samuel[6], O'Neill David[6], Ruiz Arrondo Ignacio[1], John McMahon Barry[4], O'Hanlon Aidan[2], O'Reilly Catherine[6], Harrington Andrew[6] and O'Meara Denise[6], [1]Centre of Rickettsiosis and Arthropod-Borne Diseases, Hospital San Pedro–CIBIR,, [2]National Museum of Ireland, [3]South East Technological University, Ireland, [4]University College Dublin, [5]University of Salford, [6]Waterford Institute of Technology

Abstract: Ecosystem services provided by insects include soil aeration, plant pollination and pest control. Insects also pose concern, particularly vectors for disease, such as some of the 3500 mosquitoes that occur worldwide. Across Europe, cases of mosquito borne diseases have been recorded and are associated with anthropogenic changes. Mosquito monitoring is vital to create informed mitigation measures in advance of potential disease outbreaks. Morphological identification of mosquito larvae and adults requires a high level of expertise and is susceptible to error. Here, we demonstrate the application of DNA technology to identify mosquitoes from larvae, adults and indirectly from the diet of bats using a combination of DNA-based techniques including Sanger sequencing, DNA metabarcoding and real-time PCR (qPCR). Sanger sequencing facilitated the identification of previously unrecorded mosquito species in Ireland (Culex torrentium). Using DNA metabarcoding on bat faecal pellets a highly diverse diet was revealed and included the identification of four mosquito species, one of which was also previously unrecorded in Ireland, (Culex quinquefasciatus). Finally, species-specific qPCR assays were designed and optimised and allowed for the rapid detection of mosquitoes. The combination of these molecular techniques have facilitated the identification of mosquito species occurring in Ireland via direct and indirect approaches.

From lab bench to tailgate – the state of molecular diagnostics in invasive species surveillance and early detection

Authors: Cusson Michel[4], HAMELIN Richard[1], Cui Mingming[2], Roe Amanda[6], Capron Arnaud[7], Boyle Brian[3], Porth Ilga[5] and C. Levesque Roger[5], [1]Department of Forest Sciences University of British Columbia Vancouver, Canada, [2]Department of Wood and Forest Sciences, Laval University, Canada, [3]IBIS - Laval University, Canada, [4]Laurentian Forestry Centre, Natural Resources Canada, Quebec City, QC, Canada, [5]Laval University, Canada, [6]Natural Resources Canada, Canadian Forest Service, Great Lakes Forestry Centre, Canada, [7]University of British Columbia, Canada

Abstract: Vigilant biosurveillance is necessary to protect our forests from invasive alien species. Early detection is critical to effective control and management, but is challenging due to the diversity of pests and their pathways of spread, as well as the difficulty in assessing their risk of establishment. Genomics can provide powerful solutions to these biosurveillance challenges and can tell us the story of invasion. One exciting prospect is the development of genomic tools that can be used outside the laboratory environment. These 'point of need' approaches unshackles molecular diagnostics from the laboratory bench and releases them into the wild. We provide emerging examples of these field-based molecular diagnostics for several high risk forest invasive species.

Genomics-based tools for biosurveillance of Asian gypsy moths

Authors: Cusson Michel[2], Hamelin Richard[1], Djoumad Abdelmadjid[3], Nisole Audrey[3] and Stewart Don[3], [1]Department of Forest Sciences University of British Columbia Vancouver, Canada, [2]Laurentian Forestry Centre, Natural Resources Canada, Quebec City, QC, Canada, [3]Natural Resources Canada, Laurentian Forestry Centre, Quebec City, Quebec, Canada

Abstract: Genomics-based approaches are becoming increasingly relevant for the design of assays aimed at detecting, identifying and monitoring forest invasive alien species. A good example of this type of application is provided by the Asian gypsy moth (AGM). Indeed, AGM ranks high on the list of unwanted alien pests in North America, and measures to prevent its accidental introduction and establishment are given high priority by plant protection authorities. Several features of AGM make it a particularly rewarding research subject from both fundamental and applied science perspectives. “AGM” designates a complex of difficult-to-distinguish Lymantria dispar subspecies and closely-related Lymantria species, some of which appear confined to Japan (L. dispar japonica, L. umbrosa, L. albescens, L. postalba), while the most widely distributed one, L. dispar asiatica, is found over most of mainland Asia. Its range overlaps with that of the European gypsy moth (EGM; L. dispar dispar) at its western-most limit, where the two subspecies appear to interbreed. EGM is already present in North America, following an accidental introduction in 1869. However, it has a narrower host range than AGM and, unlike the latter, its females are flightless, reducing its ability to spread rapidly in newly invaded habitats.

Research conducted by our group has involved the development of molecular tools that help distinguish EGM from AGM-complex species and subspecies in egg samples intercepted on foreign vessels entering North American ports, as well as in moths caught in pheromone traps. To this end, we carried out comparative mitochondrial genomics, which enabled the identification of markers suitable for the development of diagnostic TaqMan assays. In parallel, we initiated a study focused on the identification of genome-wide SNPs that can be used to identify the geographic origins of intercepted samples; this type of information is useful in characterizing introduction pathways. Do date, a proof-of-concept study based on eight populations sampled from across the range of L. dispar showed strong population structure and a high success of assignment of unknowns to source populations. A full scale study involving ~80 sampling sites and 25+ countries is now almost completed.

AGM-EGM hybrid populations in eastern Europe often feature females that display strong flight capability while bearing an EGM mitochondrial genomic signature. Because such specimens could be wrongly identified as flightless EGM on the basis of mitochondrial markers, and fail to be screened out during ship inspection, we recently set out to identify the genomic determinants of female flight capability in gypsy moths, using three analytical approaches in parallel; it is hoped that flight capability genes can be used to identify all specimens originating from populations with flight-capable females.

Insights into the role of insulin-like peptides in aphid photoperiodism

Authors: Cuti Paolo[1], Martínez-Torres David[1] and Barberà Miquel[1], [1]Institute for Integrative Systems Biology. University of Valencia, Spain

Abstract: Aphids were the first animals to be described as photoperiodic due to their seasonal response characterized by a reproductive switch. During the favourable seasons (spring and summer), aphid’s populations consist of viviparous parthenogenetic females, whereas during the harsh seasons (autumn and winter) they switch to produce a single sexual generation of oviparous females and males that mate and lay diapausing cold-resistant eggs that can overcome the unfavourable environmental conditions. Aphids exhibiting the complete cycle are called holocyclic, but there are also anholocyclic lineages that represent natural mutants, which have lost the ability to respond to photoperiodic changes and thus can help us study how the process is regulated. Previous studies have demonstrated that the main elements of a putative photoperiodic clock are located in the aphid brain, especially in the medial region comprising the pars intercerebralis and pars lateralis areas. Moreover, the insulin-signalling pathway could be involved in the seasonal response, as it has been described in other insect species. In order to shed some light on the role of this mechanism, we analysed Acyrthosiphon pisum brains at the embryonic and adult stages by immunohistochemistry (IHC) to locate ILP4 (Insulin-Like Peptide 4), a neuropeptide previously shown to be differentially produced under diverse photoperiods. A possible link between the circadian clock and photoperiodism was also investigated by quantifying the expression of ilp1 and ilp4 genes by RT-qPCR during a time-course experiment along one day and a half. A similar experimental design was used to quantify ILP4 protein levels by IHC by measuring the intensity of cell’s fluorescence signal under a confocal microscope. Our results clearly show that ILP4 is synthesized in two groups of four cells in the pars intercerebralis and then it is axonally transported to the ventral region of the brain, possibly to the corpora cardiaca or corpora allata, where it could potentially modulate the secretion of some downstream hormones implicated in the photoperiodic response. Although no evident rhythmicity behaviour was observed, ILP1 and ILP4 change their expression patterns along the day and between long and short photoperiods in the holocyclic strain. On the other hand, no statistical differences were observed in ILP1 and ILP4 transcripts and proteins in anholocyclic aphids. In conclusion, our results highly support an active role of insulin-like peptides in the aphid seasonal response.

Strategic information provision in social insects

Authors: Czaczkes Tomer, Animal Comparative Economics lab, Department of Zoology University of Regensburg, Germany

Abstract: Social information use is extremely widespread throughout the animal kingdom, and how animals choose to use information has been extensively studied. However, for information to be used, it must be provided. The study of strategic information provision has been comparatively neglected. Foraging eusocial insects, such as ants and bees, famously communicate the availability of resources to their fellow foragers. Foragers have to make critical decisions about whether to communicate, and if so, how much. To do this, they need to integrate a wide variety of inputs in order to ensure successful foraging by their fellow foragers. At a basic level foragers need to decide whether a resource is worth recruiting to, and this depends on the resource quality other foragers are finding. Moreover, foragers need to tune their recruitment to the need for navigational help. At lower light levels, when individual navigation is hindered, ants deposit more pheromone. Foragers can even use their subjective experience of information need to tune recruitment: ants which make mistakes when trying to relocate a food source deposit more pheromone once they eventually find it. Even more intriguingly, foragers may tune their recruitment to their degree of certainty – ants which are about to make an error deposit less pheromone than ants which will go on to make correct decisions. Foraging social insects are in the rare situation of all being in the same boat – unlike predator-prey or mate communications, the foragers all have basically the same role, and so are in an ideal position to know what information is needed, and help each other based on their own experiences

VectorNet – A European network for medical and veterinary entomology

Authors: Czwienczek Ewelina[2], Braks Marieta A.H. [3], Briet Olivier[1], [1]European Centre of Disease Prevention and Control (ECDC), [2]European Food Safety Authority (EFSA), Italy, [3]National Institute of Public Health and the Environment, Netherlands

Abstract: Public and animal health authorities face many challenges in surveillance and control of vector-borne diseases (VBDs). Those challenges are principally due to the multitude of interactions between vertebrate hosts, pathogens and vectors in continuously changing environments. VectorNet, a joint project of the European Food Safety Authority (EFSA) and the European Centre for Disease Prevention and Control (ECDC) facilitates risk assessments of VBD threats through the collection, mapping and sharing of distribution data for ticks, mosquitoes, sand flies and biting midges that are vectors of pathogens of importance to animal and/or human health in Europe. We describe the development of the network that celebrated its 10th anniversary in 2020 and the value of its most tangible outputs, the vector distribution maps, that are freely available online.

Effects of organic farming and landscape structure on biological pest control in Flemish apple orchards

Authors: Daelemans Robin[1], Hulsmans Eva[1] and Honnay Olivier[1], [1]KU Leuven, Belgium

Abstract: Relying on natural predator-prey dynamics, biological pest control is often seen as a key element to achieve sustainable farming. Determining the potential of biological control for the suppression of pests, however, requires a profound understanding of how communities of pests and their natural enemies are influenced by local farming practices and landscape characteristics. Here, we used piecewise structural equation modelling to test direct and indirect effects of landscape composition, landscape configuration and local management practices on natural enemy communities, the pest control service they provide and ultimately pest infestation and crop damage. We sampled arthropods in 24 organic or Integrated Pest Management (IPM) orchards as well as in hedgerows bordering semi-natural grasslands to provide benchmark predator communities that developed free of pesticides and fertilizers. Pest control levels were quantified using sentinel eggs of codling moth and pest infestation as well as pest damage were estimated during harvest. Our results show higher predator abundance and richness in organic orchards relative to IPM orchards, but no higher predation levels. Biological control by natural enemies did not affect pest infestation in either of the management types, indicating that biological pest control alone seems to be an ineffective means to guarantee crop protection.

A role for Aedes aegypti Gr34 in sugar homeostasis

Authors: Dahanukar Anupama[3], Akbari Omar[2], Maekawa Emi[1], Li Ming[4] and Ohsawa Shizue[1], [1]Group of Genetics, Division of Biological Science, Graduate School of Science, Nagoya University, Japan, [2]UCSD, United States, [3]University of California Riverside, United States, [4]University of California San Diego, United States

Abstract: Mosquitoes are vectors of deadly human diseases in the world, and vector control remains a crucial part of the arsenal for disease prevention. Female mosquitoes feed not only on blood from vertebrate hosts but also on nectar from flowers and plants. It is known that nectar components such as sucrose and glucose are essential for survival, and as an energy source for flying, and for reproduction in female mosquitoes. Female mosquitoes must control the consumption and metabolism of dietary carbohydrates to achieve sugar homeostasis. Previous studies have shown that Drosophila Gr43a functions as a nutrient sensor in the brain that is important for sensing levels of fructose in circulating hemolymph. Loss of DmGr43a results in dysregulation of feeding behavior control by internal fed and starved states. Interestingly, Gr43a is among few gustatory receptors that are highly conserved, and found in most insect species. We therefore investigated the role of the yellow fever mosquito Aedes aegypti ortholog of DmGr43a, AaegGr34, by generating a mutant using CRISPR/Cas9 gene editing. We will present results of physiological and behavioral analysis of AaegGr34 mutants, which indicate a role for this receptor in carbohydrate homeostasis.

The ionotropic receptor IR56d is selectively required for perception of medium-chain fatty acids

Authors: Dahanukar Anupama[2], Keene Alex[1], Brown Elizabeth[1] and Shah Kreesha[1], [1]Department of Biological Science, Florida Atlantic University, United States, [2]University of California Riverside, United States

Abstract: Fat represents a calorically potent food source that yields approximately twice the amount of energy as carbohydrates or proteins per unit of mass. The highly palatable taste of free fatty acids (FAs), one of the building blocks of fat, promotes food consumption, activates reward circuitry, and is thought to contribute to hedonic feeding underlying many metabolism-related disorders. Despite a role in the etiology of metabolic diseases, little is known about how dietary fats are detected by the gustatory system to promote feeding. Neurons expressing the Ionotropic Receptor 56d (IR56d) are required for reflexive feeding responses to the medium-chain fatty acid, hexanoic acid. Short-, medium-, and long-chain fatty acids are appetitive to flies, but the role of IR56d in detecting these classes of fatty acids remain unknown. To determine the selectivity of the IR56d receptor, we generated IR56dnull flies and measured their response to a panel of fatty acids representing each of these classes. We find that that IR56d is required for medium-chain fatty acid taste perception, but not for perception of short- or long-chain fatty acids. Conversely, functional imaging reveals that neurons expressing IR56d are responsive to short-, medium- and long-chain fatty acids, suggesting the presence of additional receptors that are selective to short- and long-chain fatty acids. To determine whether flies can differentiate between different classes of fatty acids, we measured taste discrimination using an aversive taste memory assay. Flies are unable to discriminate between different medium-chain fatty acids, but are able discriminate between medium- and short-chain as well as medium- and long-chain fatty acids. Taken together, these findings suggest that the IR56d receptor is selective for medium-chain fatty acid taste perception. Further, these findings reveal that flies are capable of distinguishing between tastants of the same modality through neurons that are broadly tuned to short, medium, and long chain fatty acids.

Getting chased up the mountain: high elevation stress may limit ability of montane insects to respond to climate change

Authors: Dahlhoff Elizabeth[1] and Rank Nathan[2], [1]Santa Clara University University of California, White Mountain Research Center, United States, [2]Sonoma State University University of California, White Mountain Research Center, United States

Abstract: Climate change is expected to shift species distributions as populations grow in favorable habitats and decline in harsh ones. Montane animals escape warming conditions at low elevation by moving upslope, but may be physiologically constrained by conditions there. Losses of individual insect species along altitudinal gradients are likely to have profound effects on terrestrial communities, especially in montane environments where species diversity is low. Effects of high elevation were studied for montane populations of the leaf beetle Chrysomela aeneicollis, where allele frequencies at nuclear genes and the mitochondrion vary along latitudinal and altitudinal gradients. A population presence survey conducted along a steep altitudinal transect (1600-3800 m) from 1981 to 2018 revealed that populations expand to low elevation following wet winters and retreat during drought. Quantitative surveys of a 45-site population network conducted from 2012-2018 along multiple altitudinal transects shows that when beetles are abundant, population size peaks at 3135 m, highest altitude populations are at the southern edge of the range, and populations decline and extirpate during drought, especially at low elevation. To examine effects of elevation on measures of performance and fitness, beetles from a genetically-introgressed population (Bishop Creek- BC) were examined. In nature, fecundity of females transplanted along natural altitudinal transects was measured, as was activity of the electron transport enzyme cytochrome c oxidase (CytOx). To examine effects of environmental hypoxia independent of other factors limiting persistence at high elevation, larval development and metabolic rates were measured for larvae reared under otherwise common garden conditions at low (1250 m) and high (3800 m) elevation. In nature, fecundity declined with increasing elevation, independent of air temperature. CytOx activity was higher at high than low elevation, especially for individuals possessing genotypes of southern origin. Laboratory-reared larvae with southern mitochondrial haplotypes developed equally well at both elevations, but larvae with northern haplotypes developed more slowly at high elevation. Metabolic rates showed a similar pattern, suggesting that slower development rates at high elevation may be due to reduction in metabolic rate. These findings suggest that physiological effects of environmental hypoxia may contribute to other factors known to restrict insects' ability to persist at high elevation, ultimately disrupting associated ecological communities (e.g. loss of specialist beetle predators and other enemies). However, some populations may possess genetic variation that allows for local adaption to high elevation.

Genetic control of molting and metamorphosis in the silkworm

Authors: Daimon Takaaki, Kyoto University, Japan

Abstract: The number of larval instars in insects varies greatly across insect taxa, and can even vary at the intraspecific level. However, little is known about how the number of larval instar is fixed in each species or can be changed depending on the environment. The silkworm, Bombyx mori, would provide unique bioresources to elucidate this question, as there are several “moltinism” strains that exhibit variations in the number of larval molts. We have been working on moltinism mutants of Bombyx, and identified the genes responsible for the dimolting (mod) mutant and Molitinism (M) locus. We are hopeful that our studies will pave the way for a greater understanding of physiological control, developmental plasticity, and evolutionary history of the number of larval molts in insects, which may reflect adaptive strategies of insects to diverse environmental conditions.

Hox-mediated repression of ecdysone biosynthesis confers intraspecific variation in the number of larval instars in Bombyx

Authors: Daimon Takaaki, Kyoto University, Japan

Abstract: In insects, the number of larval molts varies inter- and intra-specifically, and it is widely accepted that the variation in the number of larval molts is an adaptive response to diverse environmental conditions. However, the molecular mechanism that underlies the variety and plasticity in the number of larval molts is largely unknown. In the silkworm, Bombyx mori, there are strains that molt three, four, or five times, and these numbers are determined by allelic variation at a single autosomal locus, Moltinism (M). Here, we demonstrate that the Hox gene Sex combs reduced (Scr) is responsible for the phenotypes of the M locus. Our results suggest that Scr represses the biosynthesis of molting hormones in the PG, thereby regulating the incremental increase in body size during each larval instar. While the role of Hox genes in conferring segmental identify along the body axis and in molding segment-specific structure later in development has been well-established, our study identifies an unexpected role of Hox gene in hormone biosynthesis. This new role means that in addition to shaping segment-specific morphology, Hox genes also drive the evolution of life history traits by regulating animal physiology.

DIPA-CRISPR is a simple and accessible method for insect gene editing

Authors: Daimon Takaaki[3], Shirai Yu[3], Piulachs Maria-Dolors[1], Belles Xavier[2], [1]Institute of Evolutionary Biology (CSIC-Univ. Pompeu Fabra), Barcelona, Spain, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain, [3]Kyoto University, Japan

Abstract: Current approaches for insect gene editing require microinjection of materials into early embryos. This severely limits the application of gene editing to a great number of insect species, especially to those whose reproduction systems preclude access to early embryos for injection. To overcome these limitations, we here develop a simple and accessible method for insect gene editing, termed Direct Parental CRISPR (DIPA-CRISPR). We show that injection of Cas9 ribonucleoproteins (RNPs) into the haemocoel of adult females efficiently introduces heritable mutations in developing oocytes. Importantly, commercially available standard Cas9 protein can be directly used for DIPA-CRISPR, which makes this approach highly practical and feasible. DIPA-CRISPR enables highly efficient gene editing in the cockroaches, on which conventional approaches cannot be applied, and in the model beetle Tribolium castaneum. Furthermore, we show that DIPA-CRISPR-mediated targeted gene knock-in can be achieved in beetles by co-injection of single-stranded oligodeoxynucleotides (ssODNs) with Cas9 RNPs. Due to its simplicity and accessibility, DIPA-CRISPR will greatly extend the application of gene editing technology to a wide variety of insects.

Integrated Pest Management in UK Forestry

Authors: Dainton Katrina, Forest Research, Northern Research Station, Scotland, United Kingdom

Abstract: Forests are essential to the health of the planet. They support biodiversity, provide ecosystem services, sequester carbon, mitigate climate change, and promote human health and wellbeing (Sing et al., 2018). Insect pests that damage and kill trees can drastically alter landscapes and ecosystems. Bark beetles, for example, have killed millions of hectares of forest across Europe and North America (Hlásny et al., 2019). In the UK, where forests are smaller and less contiguous, tree damage and mortality tend to be more localised, although several diseases (i.e. Dutch elm disease, Ash dieback and Phytophthora ramorum) have had widescale impacts on specific tree species.

To mitigate the negative effects on trees and landscapes it is necessary to manage these tree health threats. Different management options are available, some of which can themselves directly impact landscape scale change, e.g. felling and removing trees. Integrated pest management (IPM) approaches promote the use of preventative measures to protect trees from pests whilst reducing the need for more drastic reactive methods.

In this presentation I will introduce and share preliminary results from my PhD project (supervised by University of Edinburgh, Scotland's Rural College and Forest Research) which aims to evaluate and enhance IPM awareness and use in UK forestry. This research will assess the methods being used to manage insect pests in UK forestry. It will also investigate forest manager perspectives on the opportunities and challenges of taking an IPM approach. Identifying current challenges, including if there is a gap for new practices, will inform the focus of a case study, including laboratory and field trials.

Insect conservation on golf courses: Integrating recreational land management and urban biodiversity conservation

Authors: Dale Adam[2], Cope Grace[2], Daniels Jaret[1] and Perry Rebecca[2], [1]Florida Museum of Natural History University of Florida, United States, [2]University of Florida Entomology and Nematology Department, United States

Abstract: Urbanization is the leading form of land use change and driver of biodiversity loss. As urbanization progresses, habitats are fragmented and vegetation is replaced with impervious surfaces. Golf courses are among the largest, most ubiquitous maintained green spaces within many urban areas. Although their primary function is recreation, a large portion of golf course land is primarily aesthetic, which presents opportunities to create more ecologically functional space and provide valuable urban conservation services. Many courses around the world are converting out-of-play areas to naturalized or wildflower habitats, but few do so using evidence that maximizes their conservation benefit. Based on previous research, we know that factors commonly associated with golf courses, like elevated nutrient content and reduced plant diversity may affect conservation efforts. Here, we aim to develop evidence-based guidelines that maximize the conservation benefits of golf course out-of-play areas. First, we ask if flowering plant species richness influences the effect of wildflower habitats on solitary bee and natural enemy conservation. Then we determine if this effect translates to biological control of key golf course pests in adjacent in-play areas. Finally, we test the hypothesis that soil nitrogen availability, associated with golf course turfgrass fertilization, affects host plant quality and butterfly fitness, and if that effect depends on plant species richness. Our results indicate that golf courses can provide valuable resources for urban pollinators and other beneficial insects, both flying and ground-dwelling. Interestingly, plant species richness does matter for beneficial insect conservation, but is not as important in translating to insect pest control. Nitrogen is an important factor that must be considered when evaluating the effects of urbanization on insect conservation efforts. Thus our results have important implications for tailoring insect conservation practices to golf courses and other urban green spaces to maximize their ecological value.

The association of symbiotic Rickettsia with omnivorous mirid bugs (Hemiptera)

Authors: Dally Maria, Hebrew University, Israel

Abstract: Bacterial symbionts are common in arthropods, where some of them are known to influence host nutrition and diet breadth. It was therefore interesting to explore the involvement of symbionts in the nutritional ecology of omnivorous insects, consumers that feed on both prey and plant food sources. Like most other insects, omnivorous consumers harbor symbiotic bacteria in their body. Omnivorous bugs of the genus Macrolophus (Heteroptera: Miridae) are mainly predatory but may also feed on plants. M. pygmaeus and M. melanotoma (=M. caliginosus) are key natural enemies of various economically important agricultural pests. To test for possible involvement of symbiotic bacteria in plant feeding habits of M. pygmaeus and M. melanotoma, we first determined that the microbiome of all tested individuals is dominated by Wolbachia (reported to induce cytoplasmic incompatibility), and two Rickettsia species, R. bellii and R. limoniae. FISH analyses revealed that in both M. pygmaeus and M. melanotoma, females Rickettsia species are found in the germarium, the apical end of the ovarioles within the ovaries, a location that suggests vertical transmission. In both Macrolophus species, the two Rickettsia species mostly occupied separate epithelial cells both in the mid-gut and its unique outgrowth, caeca-like organs, and in the Malpighian tubules. Yet, each Rickettsia species had a unique distribution along the digestive system, a pattern that differed between the two Macrolophus species. These species-specific Rickettsia distribution patterns may suggest a different roles in host nutrition, allowing it to derive nutrients from both prey and plant materials.

Deciphering moth sex pheromone biosynthesis pathways and biotechnological production in yeast

Authors: Dam Marie Inger[2], Löfstedt Christer[2], Holkenbrink Carina[1] and Borodina Irina[1], [1]Biophero ApS, [2]Lund University, Sweden

Abstract: The larvae of moths (Lepidoptera) are key agricultural pests, causing significant economic loss on major and valuable crops such as rice, soybean, tomatoes and apples. There is a pressing need to find alternatives to conventional insecticide control, because of human and environmental toxicity, governmental restrictions and resistance development. The use of insect sex pheromones is a sustainable method with a growing market within integrated pest management, working to control moth population in a species-specific manner by either trapping and eliminating male moths in the crop area or preventing them from locating females and thereby achieving mating disruption. This method is already successful at large scale in organic fruit farming, vineyards and in control of certain deciduous forest pest, and to a smaller extent in the production of cotton, rice and cabbage. Chemical synthesis of these pheromones can be complicated and involve harmful chemicals and waste products, whereas with biotechnological production in yeast or plants we can take advantage of enzymatic specificity and cheap renewable feedstocks. With the discovery of pheromone biosynthesis pathways and -genes in the pest insect, “cell factories” can be engineered to produce insect pheromones in the same way we use microbes for production of for example drugs, enzymes, biofuel and industrial chemicals and food additives. We have demonstrated yeast production of pheromones for pests on maize, rice, cotton and cruciferous crops, including the rapidly expanding fall armyworm (Spodoptera frugiperda) and the globally distributed diamond back moth (Plutella xylostella).

Incompatible Insect technique feasibility to control Aedes invasive mosquitoes in Europe

Authors: Damiani Claudia[1], Moretti Riccardo[2], Calvitti Maurizio[2], Fabbri Giulia[3], Lampazzi Elena[2], Serrao Aurelio[1] and Lombardi Giulia[3], [1]BiovecBlok srl and University of Camerino, [2]ENEA Biotechnology and Agroindustry Division, [3]University of Camerino, Italy

Abstract: Incompatible Insect Technique (IIT) is a genetic control strategy based on the exploitation of a natural phenomenon of egg inviability induced by an opportune infection of the endosymbiotic bacterium Wolbachia. Establishing an artificial Wolbachia infection in a species that is uninfected, or naturally infected by a different Wolbachia strain, enables to mass produce and release mosquito males that may sterilize wild-type females without the recourse to any preliminary treatment. Thus, this strategy assures full preservation of male fitness and simpler mass rearing protocols compared to other genetic control strategies as like SIT.

Biovecblok S.r.l., in collaboration with ENEA and the University of Camerino, is exploring the feasibility of proposing IIT as a suppression tool against Aedes albopictus and other Aedes mosquitoes. The present work reports on preliminary studies addressed to test efficiency, safety, and sustainability of applying this strategy on a large scale both in the European context and in Tropical regions where arboviral diseases are endemic. Obtained results are encouraging and allow to be optimistic regarding the future development of this approach.

Plant phenological sensitivity to warming elevates herbivory

Authors: Davis Charles[1] and Davies Jonathan[2], [1]Harvard University, United States, [2]University of British Columbia, Canada

Abstract: Species interactions can drive ecosystem processes and are thus a major focus of global change research. Some of the most consequential interactions expected to shift with climate change are between insect herbivores and plants, both of which are highly sensitive to temperature. Historically, insect herbivores and their host plants display varying levels of synchrony that could be disrupted or enhanced by climate change. Here, with herbarium specimens of 26 plant species collected from 1900 to 2015, we show that plant species whose phenology is more sensitive to warming are more likely than co-occurring, insensitive species to incur elevated levels of insect damage or ‘herbivory’ in warmer years. Our results point to a scenario in which warming lengthens growing seasons for phenologically sensitive plant species, exposing their leaves for longer periods of time to herbivores. Mounting evidence indicates that, in the short-term, plant species that are able to track changing temperatures have a fitness advantage over coexisting species that are less sensitive. However, we show that plants that are sensitive to warming are also exposed to elevated herbivory when temperatures are warmer, which may affect plant fitness and thus community composition and ecosystem function over longer timescales.

Hemoglobin genes are present and expressed throughout Hexapoda

Authors: Davis Steven[1], Herhold Hollister[1] and Grimaldi David[1], [1]American Museum of Natural History, United States

Abstract: The tracheal system of insects, comprised of intricate cuticular invaginations branching within the body, provide direct access to tissues for gas exchange. Although notable exceptions exist, such as the well-known reddish hemolymph of chironomid midges and recently discovered hemoglobins in a handful of taxa, insects have long been thought to not require respiratory proteins and thus lack hemoglobins. Hemoglobins, however, have been shown to be ancient in origin and are ubiquitous among animals and plants. A comprehensive analysis of transcriptomes across Hexapoda has revealed the expression of hemoglobin genes in all 32 orders of hexapods, including all 29 recognized orders of insects. Discovery and identification of 1333 putative hemoglobins was achieved with target gene BLAST searches of the NCBI TSA database, verification of the presence of functional residues, secondary and tertiary structure predictions, and machine learning-based localization predictions. While the majority of these proteins are intracellular, extracellular hemoglobins were also recovered in a handful of specimens. Hemoglobin gene trees were constructed via multiple-sequence alignments and phylogenetic analyses. These investigations into sequence evolution indicate probable duplication events and adaptive function/significance. Future work involving genome comparisons to transcriptome results and comparative investigations of morphology and ecology will further illuminate the possible roles of these hemoglobins in insects.

Can artificial diets support cost-effective mass production of omnivorous predators?

Authors: De Clercq Patrick, Laboratory of Agrozoology, Department of Plants and Crops, Belgium

Abstract: The use of arthropod predators in augmentative biological control programs necessitates the availability of cost-effective mass rearing systems, allowing the production of large numbers of beneficials at the lowest possible price. Many of these predators are polyphagous to some degree, but it does not necessarily follow that they can be produced on a wide choice of easily reared prey. In addition, several species are omnivores and benefit from or need plant materials to acquire moisture or supplementary nutrients, or they may require plant substrates for oviposition, complicating their mass rearing and shipping. Good success has been obtained with the use of factitious (unnatural) prey for the commercial production of some predatory heteropterans, coleopterans, and neuropterans (e.g. lepidopteran eggs, brine shrimp cysts), as well as several species of predatory mites (e.g. various storage mites). In contrast, despite several decades of research, artificial diets have hardly been used in the commercial mass production of polyphagous predators, with a diet for lacewings being one of the few exceptions. The reasons for the limited success with artificial diets for the production of predatory arthropods as well as potential research avenues will be discussed.

Managing stink bugs on soybean/maize crop systems in the Neotropics

Authors: de Freitas Bueno Adeney, Researcher in Entomology of Embrapa Soybean, Brazil

Abstract: Alternating cultivation of soybean (summer crop) and maize (fall/winter crop) favors population growth and permanence of some stink bug species feeding on crop plants, mainly due to the constant food supply ("green bridge"). Among these species, Euschistus heros and Dichelops melacanthus stand out with their high abundance and injury potentials. Although E. heros causes lower damage on maize than D. melacanthus, growers frequently control both species in these crops. The most important control strategy is the use of insecticides. However, these should only be applied when economic thresholds are reached. Moreover, other control strategies such as the mass release of the egg parasitoid Telenomus podisi should be adopted. Studies have shown that this parasitoid has high parasitism rates on both E. heros and D. melacanthus eggs, and high field performance. In addition, research results indicate that D. melacanthus does not develop well when feeding only on maize seedlings. Therefore, crop remains (soybean seeds dropped on the ground, dry pods, volunteer soybean) and the presence of invasive plants (such as Commelina sp.) play an important role in the development and reproduction of these pests in the production system and should be avoided in order to manage stink bugs in the soybean/maize crop systems. In fact, only a combination of different stink bug management strategies in soybean integrated pest management (IPM) as a whole can be effective against the pest. In the state of Paraná, Brazil, where IPM is adopted, growers are able to successfully manage these pests with a greatly reduced use of insecticides (around 50%).

Quis custodiet ipsos custodies? Hesperomyces virescens, a potential biocontrol agent against the invasive ladybird Harmonia axyridis

Authors: de Groot Michiel[1], Haelewaters Danny[2], [1]Ghent University, Belgium, [2]Ghent University, Czech Republic

Abstract: Harmonia axyridis is an invasive alien ladybird in North America and Europe. Studies show that natural enemies are starting to use Ha. axyridis as a new host. No studies have focused on the effects of simultaneous infections of multiple natural enemies on Ha. axyridis. We hypothesized that high thallus densities of the ectoparasitic fungus Hesperomyces virescens on a ladybird weaken the host's defenses, thereby making it more susceptible to infection by other natural enemies. We examined mortality of the North American-native Olla v-nigrum and Ha. axyridis co-infected with He. virescens and an entomopathogenic fungus – Beauveria bassiana or Metarhizium anisopliae. Laboratory assays revealed that He. virescens-infected O. v-nigrum are more susceptible to entomopathogenic fungi, but not Ha. axyridis. In another experiment, both fecundity and hatchability were significantly lowered in female ladybirds when co-infected with Spiroplasma bacteria and He. virescens. Considering these results, we can start asking how He. virescens affects survival against other pathogens that previously had little impact on Ha. axyridis.

Citizen science records to complete global distribution patterns of both Harmonia axyridis (Coleoptera, Coccinellidae) and its parasite Hesperomyces virescens

Authors: de Groot Michiel[2], Haelewaters Danny[3], Hiller Thomas[6], Christou Maria[5], Pan Jeffrey Y.[4] and Santamaria Brianna[1], [1]Ghent University, [2]Ghent University, Belgium, [3]Ghent University, Czech Republic, [4]Northeastern University, [5]The Cyprus Institute, [6]University of Hohenheim

Abstract: Harmonia axyridis (Coleoptera, Coccinellidae) is a globally invasive ladybird. It was intentionally introduced in many countries as a biological control agent and it has been unintentionally released in many other countries. For a long time, no published reports were known from Central America. Searching through online photographs available from the citizen science project iNaturalist and the photo-sharing platforms Flickr, we reported Ha. axyridis from Costa Rica, Guatemala, Honduras, Panama, and Puerto Rico. The biotrophic microfungus Hesperomyces virescens causes mortality of its ladybird hosts, which makes it a potential biological control agent of Ha. axyridis. Again, photographic records have been obtained from iNaturalist, Flickr, and BugGuide.Net to map the distribution of He. virescens associated with Ha. axyridis in North America and Europe. A social media campaign is in progress to encourage European citizen scientists to contribute photo-records. A dedicated He. virescens–Ha. axyridis project was launched on iNaturalist and distribution maps of curated records will be made available through https://beetlehangers.org/. We stress the need for citizen science projects to assess the presence of alien invasive species and their natural enemies.

Why Open Biodiversity Data matter for equitable and fair share of benefits defined by the Nagoya Protocol

Authors: De Prins Jurate, Royal Belgian Institute of Natural Sciences, Brussels, Belgium; Science Committee, Global Biodiversity Information Facilities, Belgium

Abstract: The Convention of Biological Diversity (CBD), and its supplementary agreement of the Nagoya Protocol which has now been ratified by 113 UN member states and the EU, firmly established the territorial sovereignty over all genetic resources and conditioned the rights of scientists to use such resources without the permission of the relevant government authorities. The Protocol was agreed in 2010 and the entomological community has to comply with the fair access and benefit sharing regulations defined by the Protocol and to learn to work in different ways, with different thinking and different reasoning. Despite the guidelines being clear, the implementation of the legislation and the translation of the Nagoya Protocol into laws is a very slow, complicated and diverse process, full of legal and practical uncertainties. Furthermore, a deep and non-consensual split along North-South governmental lines is formed for meeting the benefit-sharing obligations defined by the Nagoya Protocol. Though all parties acknowledge that knowledge sharing and exchange in the form of Open Access that document successes and failures is one of the best practices, it does not solve the goals of benefit sharing defined by the Nagoya Protocol. The recently (10 May 2019) adopted Code of Conduct and annexed best practices of the CETAF, uniting the major European Insect Collections and depositories, has the intention to show a way of successful development of community-based approaches and non-monetary sharing of benefits inside the European Union.

Global Biodiversity Information Facilities aggregates biodiversity data on a global scale and strongly focuses on the integration of a variety heterogeneous data into a synergetic framework of biodiversity data across different domains. Here it is suggested that the global non-monetary, free and open access to biodiversity data, through sharing of datasets under open licence and aggregation through intergovernmental collaborative network composed of governmental bodies and international organizations from countries of all global regions and of all income levels, could be helpful in the context of the current discussions within CBD. The GBIF community is dedicated to the vision of free and universal access to biodiversity data, for science, society and a sustainable future. The opening of primary biodiversity data obtained globally and processed by FAIR principles can assist to remove barriers that prevent institutions and individuals from sharing data, due to a wide range of factors including professional, cultural, institutional, legal and economic concerns. The non-monetary sharing of biodiversity data via global mega data aggregators such as GBIF can serve as a common ground to solve the disagreements related to the benefit-sharing applications between biodiversity rich and economy rich countries as well as stimulate the international cooperation on biodiversity research beneficial for all parties involved.

Medication in monarch butterflies: the role of plant toxins and host microbes

Authors: de Roode Jacobus, Emory University, United States

Abstract: Parasites pose major threats to their hosts' fitness, and hosts can protect themselves against infection through innate immune responses, anti-infection behaviors and microbial defenses. Monarch butterflies are specialist feeders of milkweed host plant species, which vary in their toxicity of secondary chemicals called cardenolides. Monarchs are commonly infected with a protozoan parasite, and infected females preferentially lay their eggs on high-cardenolide species of milkweed, which reduce infection in their offspring. While previous work suggests that these cardenolides directly interfere with parasite infection, current studies also indicate that milkweeds alter the monarch gut microbiome, and that the altered microbiome contributes to parasite resistance. I will summarize the medication behaviors of monarchs and discuss the role of plant chemicals and the gut microbiome in determining parasite resistance.

Management of Plant-Parasitic Nematodes by The Use of Three Saturated Hydrocarbons

Authors: Deepika[1], Lakshmi[1] and Kumar Archna[1], [1]Amity University Noida Uttar Pradesh India

Abstract: The plant parasitic nematodes (PPNs) cause major loss in food production globally. According to an estimation it is 12.3% annually. Among PPNs, Root-knot nematode (RKNs), Meloidogyne spp, group is a problematic soil pest which is distributed worldwide. Presently no full proof strategy is available for control of this pest. Practices that are commonly prioritized by farmers to check the population of these RKNs are chemical based. Thus, the concept of integrated pest/crop management includes a threshold concept for the application of pest control measures and reduction in the amount/frequency of pesticides applied to an economically and ecologically acceptable level. Therefore, research is focused on how to use of straight chain hydrocarbons presents in plant extracts with hexane solvent. In vitro analysis, two concentrations of pure hydrocarbons were applied over a counted number of nematodes. In this study Undecane, dodecane, tridecane were used to check the mortality of Meloidogyne spp. at 1 PPM and 10 PPM. Mortality status of nematode population by counting the live as well as dead individuals after applying a 500 µl of extract was recorded at different time durations i.e., 24h, 48h, and 72h. Undecane seems a promising source for eco-friendly management of Meloidogyne spp.

Nutritional composition, growth and development performance of black soldier fly (Hermetia illucens) prepupae reared on seaweed-enriched substrates

Authors: Defilippo Francesco[1], Roberta Cazzola[2], Porta Matteo Della[2], Paolo Gigante[3], Annalisa Grisendi[3], Matteo Ottoboni[2], Bonilauri Paolo[3], Giovanni Pupillo[3] and Francesca Selmin[2], [1]Sperimental Zooprophilactic Institute of Lombardia and Emilia- Romagna, Italy, [2]University of Milan, Italy, [3]Zooprophilactic Institute of Lombardia and Emilia-Romagna, Italy

Abstract: Larvae of the black soldier fly (BSF) are able to convert organic waste such as animal feces and kitchen waste into high-quality biomass, which can be processed into animal feed. However, the influence of marine substrate on BSF life cycle traits, as well as nutritional composition of deriving prepupae have not been thoroughly investigated. Accordingly, the aim of this study was to evaluate the effect of inclusion of brown algae (Ascophyllum nodosum) in BSF growing substrate on nutritional composition of deriving prepupae and insect life cycle traits.

The larvae were reared on two different substrates: i) Gainesville diet used as control substrate (CTR) and ii) Ascophyllum nodosum diet (AN30%) in which Ascophyllum nodosum meal was included in substitution of alfalfa meal (300 g·kg-1 of dry substrate).
Eggs collected from a stable colony of BSF were placed for hatching on two experimental substrates CTR and AN30%. All experiments were carried out under dark condition, at 25°C with 70% relative humidity, and repeated for three consecutive generations. Both rearing substrate and deriving prepupae were analyzed for proximate and fatty acid composition. Results were expressed on dry matter basis (DM). Percentage of mortality in each stage, development period (days required to reach pupa stage), larvae weight, percentage of adult formation, percentage of adult emergence were also recorded.
With regard to nutrient composition mean protein content was 536 g·kg-1 DM in CTR and 446 g·kg-1 DM in AN30% group. Considering fatty acid composition of both CTR and AN30% prepupae were dominated by saturated fatty acids (74.76±2.72% and 83.04±0.48%, respectively). Despite the inclusion of seaweed in the rearing substrate, the concentrations of unsaturated fatty acid were not incremented in AN30% prepupae compared to CTR prepupae. However, a slight increase in eicosapentaenoic acid in in AN30% prepupae compared to CTR ones has been observed. Considering early stages survival, during the larval and pupal stages, no significant differences in mortality were observed between larvae reared on CTR and AN30% substrate. In contrast, BSF development period was lower ($P<0.05$) in CTR than in AN30% group (29.5 vs 43 days, respectively). Finally, no differences were observed between CTR and AN30% pupae in term of weight. Combining obtained results BSF larvae can be grown on media containing up to 30% Ascophyllum nodosum with limited detrimental effect on growing performances. However, further investigations are required for understanding the effect of the composition of the feeding media on the nutritional value of deriving larvae in order to produce BSF meal more suitable for specific feed or food purposes.

Effect of propagule pressure and temperature on establishment success of Bactrocera zonata

Authors: Delatte Helene[2], Moquet Laura[2], Gledel Corentin[1], Terblanche John S.[3], Saccaggi Davina[3], Papadopoulos Nikolaos[4], [1]CIRAD, [2]CIRAD, France, Réunion, [3]Stellenbosch University, [4]University of Thessaly

Abstract: The peach fruit fly, Bactrocera zonata (Diptera: Tephritidae) is a major pest of mango, peach and guava. It is of Asian origin, and is currently present in southern Asia, the Middle East and north eastern Africa. It is of concern to areas where it is not yet established, and is listed as a quarantine pest in Europe, Australia and the Americas. Preventing the establishment of B. zonata in new areas relies on understanding the factors influencing its population establishment potential. The two most influential factors for successful establishment of new populations has been shown to be environmental suitability and propagule pressure – that is, the number of founding individuals, and the timing and frequency of introduction events.

This study aimed to determine the influence of, and interaction between, the size of the founding population, number of introduction events and environmental temperature on the establishment success of B. zonata colonies in a laboratory experiment. Bactrocera zonata colonies were initiated by introduction of founding individuals to 3L plastic containers providing ample space and food for colony growth. Five different founding population sizes (n=2, 4, 8, 16 and 20) introduced at four different introduction rates (all at once or incrementally) were tested. This was repeated at three different temperatures (20°C, 25°C and 30°C) to determine the influence of ideal (25°C) or adverse (20°C and 30°C) temperatures on establishment success. We considered establishment to be successful if adult emergence in the F1 generation was greater than the number of founding individuals. We found that adverse hot and cold temperatures resulted in significantly increased mortality and decreased establishment success of B. zonata colonies. Increasing the number of introduction events and the size of founding population also increased successful establishment, especially at adverse temperatures.

The results obtained highlight the factors important for establishment of B. zonata, and give insight into factors and interactions that may be important for establishment and invasion of fruit fly pests in general.

Interspecific interactions between a new invasive Tephritid fruit fly, Bactrocera dorsalis, and other resident species in an insular context

Authors: Delatte Helene[2], Moquet Laura[2], Jobart Benoît[1], Payet Jim[1] and Glenac Serge[1], [1]CIRAD - French Agricultural Research Centre for International Development, France, [2]CIRAD, France, Réunion

Abstract: The impact of biological invasions of insects considered as pests has important negative impacts on the economy and the environment, partly because invaders can affect the structure of the community through direct and indirect effects on resident species.

Since the detection, in April 2017, of one of the most harmful pests of fruit and vegetable crops worldwide, Bactrocera dorsalis, Reunion island counts nowadays nine pests species of Tephritid fruit flies of economic importance. Despite the presence of a biological control agent, Fopius arisanus (Braconidae) originally introduced for controlling Bactrocera zonata, B. dorsalis was found to have a high infestation rate and an extreme polyphagia (over 50 host-plant species). Since its invasion, the structure of the fruit fly community has changed: the most abundant species on the island, B. zonata, has almost disappeared, and the host range of other polyphagous species (C. capitata and C. quilicii) has been modified.

To understand the invasion process of B. dorsalis and the impact of this newly introduced fruit fly on the community structure of the resident Tephritid species, and the parasitoid, F. arisanus, it is necessary to study interactions experimentally. We assessed both direct and indirect interactions among polyphagous fruit flies and F. arisanus: i) by analysing interspecific competition among fruit flies, considering competition among female adults for oviposition, and competition among larvae for food resources; ii) by observing host species preference of F. arisanus according to plant species; and iii) by testing the effects of indirect interactions among fruit fly species mediated by F. arisanus.

Bark beetles, drought and tree mortality: Examples from California and Southwest Germany

Authors: Delb Horst[1], Fettig Christopher[2], [1]Dept. of Forest Protection, Forest Research Inst. of Baden-Württemberg, Germany, [2]Research Entomologist and Team Leader Forest Service Pacific Southwest Research Station, Davis, CA, United States

Abstract: Bark beetles (Coleoptera: Curculionidae, Scolytinae) are important disturbance agents in conifer forests of temperate and boreal ecosystems, and several notable species are capable of causing significant amounts of tree mortality. Trees of all species, ages and size classes may be colonized and killed, but each bark beetle species exhibits unique host preferences, life history traits and impacts. Mechanisms contributing to outbreaks are complex, poorly understood, and include density-dependent and density-independent factors. In recent years, climate change has contributed to some bark beetle outbreaks in North America and Europe due to shifts in temperature and precipitation that influence both the beetles and their hosts.

Applying anchored hybrid enrichment to study gene flow in the Himalopsyche martynovi species complex (Trichoptera: Rhyacophilidae)

Authors: Deng Xiling[2], Favre Adrien, H. Lemmon Alan[1] and Pauls Steffen, [1]Department of Biological Science, Florida State University, United States, [2]Germany

Abstract: The caddisfly genus Himalopsyche contains 56 species, including 3 species complexes which show variation on both genotype and phenotype within species complex. In the Himalopsyche martynovi species complex there is striking phenotypic diversity among groups of individuals, but previous phylogenetic data was unable to resolve relationships within this clade. We use a comprehensive dataset (791 loci, 655,236 bp, average locus length of 750 bp) generated from anchored hybrid enrichment to study the phylogenetic relationships among individuals of H. martynovi species complex (H. martynovi: 5 males; H. epikur: 2 males, 1 larva; H. viteceki: 2 males) and 1 male of H. immodesta as outgroup. The phylogenetic reconstruction based on the filtered dataset presents highly consistent gene and species trees with strong node support. The concatenated analysis reveals that H.viteceki is sister to H. martynovi + H. epikur. H. martynovi and H. epikur are not fully resolved: H. martynovi species complex splits into two lineages (from hereon group 1 and group 2), where group 2 forms a clade with H. epikur. Groups 1 and 2 also differ slightly in male genitalia, but group 2 is morphologically distinct from H. epikur. To better clarify the species delimitation, we apply D-statistics and DFOIL to detect the introgression among clades. The results indicate a high probability of gene flow among all three nominal taxa.

Molecular and functional characterization of masculinizer gene in Helicoverpa armigera

Authors: Deng Zhongyuan[3], Li Xianchun[2], Zhang Yakun[1], [1]Chinese Academy of Agriculture Science, China, [2]University of Arizona, United States, [3]Zhengzhou University, China

Abstract: Bombyx mori Masculinizer(BmMasc) gene is known to control sex development and dosage compensation in B. mori. It remains unclear whether its orthologues also exist and play the same roles in Helicoverpa armigera. To address this question, we used BmMasc protein sequence to blast against the reported transcriptome datasets of H. armigera and retrieved a partial sequence of Masc from H. armigera (HaMasc). Subsequent 5’/3’ RACE, full-length RT-PCR cloning and BLAST search against the male genome of H. armigera showed that HaMasc contains 12 exons and transcribes into two alternative transcripts that differ in the transcription start site and splicing of its 1stintron. Genomic qPCR showed that HaMasc copy number was 2.24-2.40 fold greater in males than in females. RT-qPCR analysis revealed that HaMasc transcripts were significantly more abundant in the embryonic stage, head, and males than in the other stages, other body parts and females, respectively. Transfection of a mixture of 3 siRNAs of HaMasc into aH. armigera male embryonic cell line resulted in reduction of HaMasc transcripts, appearance of the female-type transcript of doublesex gene, and greater transcription of 13 out of the 15 tested Z chromosome genes. Feeding male neonates with the mixture of the 3 HaMasc siRNA for 3 days caused HaMasc knockdown, upregulation of Z chromosome genes, and reduction in the sizes and weights of male pupae testes and male pupae body. These results demonstrate that HaMasc also locates on Z chromosome and regulates sex determination and dosage compensation in H. armigera.

Can the genetic structure of Malus sylvestris impact the feeding behavior and fitness of the rosy apple aphid pest Dysaphis plantaginea?

Authors: Denoirjean Thomas[2], Doury Géraldine[4], Remoué Carine[3], Rousselet Agnès[3], Falque Matthieu[3], Chen Xilong[3], Hance Thierry[1], Ameline Arnaud[4] and Cornille Amandine[3], [1]UCLouvain, Belgium, [2]UMR CNRS 7058 EDYSAN, Université de Picardie Jules Verne, France, [3]Université Paris Saclay, INRAE, CNRS, AgroParisTech, GQE, France, [4]University of Picardie Jules Verne - UMR CNRS 7058 EDYSAN (Écologie et Dynamique des Systèmes Anthropisés), France

Abstract: Apple production can be highly impacted by one of its major aphid pest, the rosy apple aphid (RAA, Dysaphis plantaginea). Surprisingly, the trophic interaction between the RAA, the domesticated apple tree Malus domestica and its crop wild relatives remains unexplored. The European crabapple Malus sylvestris has been one of the main genetic contributors of the apple tree domestication therefore representing a potential source of interesting genetic traits. We assessed the potential resistance of M. sylvestris to RAA by measuring life history traits (aphid weight, daily fecundity and survival of aphid adults) and recording the aphid feeding behavior (electropenetrography technique) within three European populations of M. sylvestris (intraspecific comparisons). Interspecific comparisons were also performed using a Malus domestica pool of seedlings.

Regarding life history traits, there was no or little intraspecific or interspecific differences. Aphid feeding behavior emphasized that M. sylvestris resistance was exclusively linked to phloemian factors and highlighted varying levels of resistance between M. sylvestris populations. Interspecific comparisons showed that one population of M. sylvestris was as sensitive as M. domestica, thus being able to act as RAA reservoir. Depending on the chosen populations, M. sylvestris, could therefore represent an interesting genetic source to confer RAA resistance in apples.

Wing morphological disparity to better understand the patterns of odonate biodiversity in Paris region

Authors: Deregnaucourt Isabelle[1], Julliard Romain, Béthoux Olivier[1], Fontaine Benoît[2], Bardin Jérémie[1] and Villier Loïc[1], [1]Centre de Recherche en Paléontologie – Paris (UMR 7207 – Sorbonne University, MNHN, CNRS), France, [2]Centre d'Écologie et des Sciences de la Conservation (UMR 7204 – MNHN, CNRS, Sorbonne University), France

Abstract: The recent alarming loss of species induced by human activities is regarded as the premises of a sixth mass extinction, in reference to the past five major crises evidenced by the fossil record. However, formal comparisons of the Recent with the Fossil remain very few due to analytical limitations. The fossil datasets are subject to sampling biases, and the metrics of diversity are particularly difficult to compare. We propose to apply morphology-based metrics to investigate anthropic pressure on diversity and to compare its effects to past mass extinctions.

Although differing in their respective, underlying causes, the past five major mass extinctions share similar properties, including a major drop of taxonomic richness affecting all types of ecosystems at a global scale. Several studies suggest a change in extinction selectivity during these events. While extinction risk of a given taxon is related to its ecology and to changes in environmental conditions, selectivity decreases during mass extinction events. All types of ecology undergo extinction but, in surviving groups, ecological diversity is often preserved. A measure of morphological diversity can be used to summarize ecological diversity of a group and to test selectivity of diversity loss.

Initiated by S. J. Gould and further developed by M. Foote and colleagues, metrics aiming at quantifying morphologic diversity (disparity) have been developed and tested on the fossil record. The notion of disparity is used to express morphological diversity and body plan variety, as opposed to taxonomic diversity. The corresponding metrics are expected to be much less sensitive to sampling heterogeneity than species richness. The contrast between morphological and taxonomic diversity has been used to describe the properties of extinction events in the fossil record.

To test the proposed approach we analysed diversity and disparity patterns of odonates in several sites, from pristine to highly artificialized environments in the Ile-de-France area, including Paris. Assessment of taxonomic richness is based on standardized data from the Steli, a citizen science program for odonate diversity monitoring in France. Disparity was measured based on selected morphological features of odonate wings which could be taken into account using morphometric approaches. A morphospace encompassing all odonate species recorded in Ile-de-France was derived. Disparity values were computed for each individual site.

Our results have shown a correlation between disparity and diversity. More importantly, they highlighted sites of interest, in the most artificialized areas, with really low diversity but high disparity. However there is no evidence of more tolerant species and there is no clear impact of artificialization on odonate disparity. Streams have been found to be more conductive to odonate disparity. In the case of the disappearance of threatened species, the loss of diversity linked to a constant disparity support a scenario of non-morphologically selective extinction.

Extreme genome reduction in the minute tomato pest Aculops lycopersici

Authors: Dermauw Wannes[2], Van Leeuwen Thomas[1], Kant Merijn[3], Wybouw Nicky[1], M. Clark Richard[4] and Greenhalgh Robert[4], [1]Department of Plants and Crops, Ghent University, Belgium, [2]Flanders research institute for Agriculture, Fisheries and Food (ILVO), Belgium, [3]Institute for Biodiversity and Ecosystem Dynamics (IBED) University of Amsterdam (UvA), Netherlands, [4]School of Biological Sciences, University of Utah, United States

Abstract: The tomato russet mite, Aculops lycopersici, is an extremely small metazoan species, with a length of merely 150 micrometer. This specialized mite belongs to the Eriophyoideae (Arthropoda: Chelicerata: Acari: Acariformes) and is a destructive priority pest on tomato and able to manipulate the defense response of its host. The tomato specialist A. lycopersici has the smallest genome yet reported for an arthropod, together with the lowest total number of genes. Along with a reduction of intergenic distance and transposable elements, we report extraordinary intron loss, with more than 80% of coding genes having no introns. As compared to a generalist mite herbivore, the two-spotted spider mite Tetranychus urticae, gene families associated with detoxification - cytochrome P450 monooxygenases, carboxyl/cholinesterases and glutathione S-transferases - and chemosensory perception, which are known or implicated in the interaction of herbivores with their plant hosts, are extremely reduced. However, reductions in nearly all gene families were observed. Our work provides a unique insight into the genomic changes associated with arthropod host specialization, as well as that associated with extreme physical miniaturization in metazoans. Furthermore, it provides a molecular basis for investigating the interaction between A. lycopersici and its Solanaceae host.

Does dim Artificial Light At Nigh affect physiological, life-history and behavioural traits in a parasitoid wasp?

Authors: Desouhant Emmanuel[1], Gomes Elisa[1] and Amat Isabelle[1], [1]Université Claude Bernard Lyon 1, Laboratoire de Biométrie et Biologie Evolutive, UMR CNRS 5558, France

Abstract: Artificial Light At Night (ALAN) is a widespread phenomenon impacting nocturnal species, mostly in a negative way, at several biological levels. Insects are not spared, with potential dramatic consequences on many species, some of them being involved in ecosystem services such as pollination or biological control. However, the impact of ALAN on diurnal species is still rarely studied. Yet, lengthening of the photophase due to ALAN is likely to modify the activity patterns of diurnal organisms, with potential consequences on their behaviour and fitness.

We investigated the effects of ecologically relevant ALAN intensities on the diurnal parasitoid Venturia canescens. First, we examined if ALAN modified the diel activity patterns of insects in terms of foraging for hosts and food, and thus impacted their lifetime reproductive success. Recording the daily survival and offspring production also allowed us to have an insight into both actuarial and reproductive senescence in this species, and to determine if it differed between different light pollution regimes. Secondly, we studied more specifically the behavioural responses of parasitoid females to ALAN in relation to their energetic reserves, at both intra- and between-generation levels. We focused on the decision to search for hosts (immediate fitness gain) or food (delayed fitness gain) that is involved in the state-dependent trade-off between current and future reproduction. The decision-making was modified by ALAN, but without involvement of the energetic reserves.

Our results clearly demonstrate that ALAN has consequences on a diurnal parasitoid species, and therefore raise the question of the effects of light pollution on biological control efficiency.

Influence of bacterial symbionts on host niche and ecological diversification: an integrative approach in a whitefly model

Authors: Desouhant Emmanuel[4], Calevro Federica[1], Heddi Abdelaziz[3], Vavre Fabrice[4], Rahioui Isabelle[2], Mouton Laurence[4], Da Silva Pedro[2] and Banhamou Sylvain[4], [1]UMR 203 INRA/INSA Lyon - BF2i, France, [2]UMR0203, Biologie Fonctionnelle, Insectes et Interactions (BF2i); Institut National des Sciences Appliquées de Lyon (INSA Lyon); Institut National de Recherche, [3]Univ. Lyon, UMR 203 INRAE/INSA-Lyon BF2i, F-69621, Villeurbanne Cedex, France, [4]Université Claude Bernard Lyon 1, Laboratoire de Biométrie et Biologie Evolutive, UMR CNRS 5558, Villeurbanne, France

Abstract: Symbiosis has been associated with major evolutionary innovations. For instance, the acquisition of nutritional obligate symbionts allowed phytophagous insects to feed on plant sap. The whitefly Bemisia tabaci (Hemiptera: Aleyrodidae) is a major economic pest forming a species complex with many biotypes. In addition to the nutritional primary symbiont Portiera aleyrodidarum, most individuals are infected by secondary symbionts (S-symbionts). Symbiotic composition is biotype-specific and may be associated with biological and ecological features such as plant range adaptation. This raises the possibility that S-symbionts play a role in the adaptation of their host to the ecological niche, and in B. tabaci diversification. Genomic studies suggest that S-symbionts could profoundly influence their host metabolism acting as sources and/or sinks of metabolites, and contribute to niche specificity in a nutrient-contrasted environment. To investigate B. tabaci niche exploitation abilities, we first analyzed the amino acid content (by HPLC) of plants this insect is adapted to, and pointed out that they represent a nutritionally-contrasted environment. We then used B. tabaci biotypes harboring different S-symbionts to determine: (i) their free amino acid content and (ii) their life-history traits as physiological state indicators. Our results reveal significant plant-dependent variations in the insects' traits suggesting that plant nutrient properties could be critical for their development. A biotype-dependant plant utilization was also observed. To decipher whether plant utilization is S-symbiont-mediated, efforts are now focused on producing genetically-homogeneous individuals harbouring differents S-symbionts. Investigating the adaptive value associated to symbionts will contribute to elucidate mechanisms of diversification and speciation of insects.

Experience, brain maturation and cognitive flexibiliy in honey bees: from plasticity to metaplasticity

Authors: Devaud Jean-Marc, Research Center on Animal Cognition Center for Integrative Biology Paul Sabatier University/CNRS Toulouse, France

Abstract: Learning allows individuals to make reliable predictions about connected events in their environment, and is thus a crucial factor for behavioural plasticity. While the honey bee is a model species for understanding learning and memory processes, most studies dedicated to their neural bases have focused on elemental olfactory learning tasks, whose simplicity contrasts with the complexity of the situations to which honey bees are likely to experience while foraging, particularly due to the time-limited availability of food provided by flowers and the complexity of their aromas. Importantly, the ability to solve such complex tasks, as assessed under controlled laboratory conditions, depends on the maturation of specific brain circuits that are required for such tasks, particularly in the mushroom bodies. In addition, mushroom body circuits are shaped by experience at different moments of the bee's lifetime. Recent results showed that the experience-dependent maturation of mushroom body synaptic organization is correlated to the animal's capacity to display complex task abilities, in particular cognitive flexibility.

Challenges for the field-ready deployment of new vector surveillance and control tools

Authors: Devine Gregor[1], Johnson Brian[1], Rasic Gordana[1], [1]QIMR Berghofer Medical Research Institute, Australia

Abstract: Entomological monitoring is an obvious requirement of vector control programmes but the techniques that we use for these purposes are unwieldy, inaccurate and were never designed for application to an ever increasing number of target environments and vector complexes. New trap types and automated counting and species identification systems that offer alternatives to human landing catches and traditional taxonomy would be of tremendous value. Similarly, an ability to characterise the age of mosquito populations could provide compelling entomological evidence for the risks of transmission and the likely epidemiological impacts of vector control tools. We'll discuss why, despite considerable activity around their development, few of the myriad iterations of these tools are field-ready.

The vector-control management agenda is formidable, involving billions of humans at risk, countless stakeholders and a multiplicity of landscapes, mosquito behaviours and ecologies. Despite substantial research efforts, the key elements of most control programs have changed little over the past 50 years. Particularly for arboviral diseases, the lack of innovation is in part due to issues of governance, the acceptance of poor efficacy among existing tools and a failure to co-opt communities into the decision making and deployment process. It is also true that the tremendous costs of epidemiological trials for new tools, which are required to gain a WHO recommendation and subsequent endorsement from National Control Programs, slow the rate at which new techniques and products can be prioritised and tested. To illustrate this point, we'll look at the development of two new paradigms in vector control; spatial repellents and the release of Wolbachia-infected Aedes aegypti.

Changes in Stonefly (Plecoptera) Assemblages in the Midwest of USA Using Museum and Contemporary Specimen Data

Authors: DeWalt Edward[1], Robinson Jason[1] and Grubbs Scott[2], [1]Illinois Natural History Survey, United States, [2]Western Kentucky University, United States

Abstract: The Midwest USA region suffers from agriculture and urbanization so that as much as 75-95% of total landcover is occupied by agriculture and urban areas. Because of this, the use of contemporary samples from reference quality streams is insufficient to characterize the stonefly fauna of the region. We must depend upon museum specimens to set the baseline of distribution across the region. Early (the 1860s through 1950s) work on stoneflies in the region resulted in significant holdings of stonefly specimens at 25 institutions. Our collection efforts and those of others continued through the 20th and into the 21st centuries, adding many more specimens to museums. We have identified all these specimens to the current taxonomic state of the art, digitizing and georeferencing nearly 40,000 specimen records. Sampling strongly suggests that species richness (156 species) is saturated across the region. Eastern, wooded, and unglaciated drainages hold the greatest species richness. Northern drainages suggest a wrap-around the Great Lakes recolonization pattern. Prairie drainages hold many fewer species. Cluster analysis suggests three assemblages that are mainly governed by proximity to eastern post-glacial dispersal pathways and glacial history. Two species have been extinguished from the region, another 4 are nearly extirpated, and 30 have severe range reductions compared to historical distributions. Data are now being used to conduct state and national conservation status assessments. This study demonstrates the usefulness of museum specimen data for answering broad ecological and conservation questions.

Pitfalls and progress in Collembola phylogeny

Authors: D'Haese Cyrille, MECADEV, UMR 7179 CNRS/MNHN Muséum national d'Histoire naturelle, France

Abstract: Among the three entognathan classes of hexapods (Protura Diplura and Collembola), springtails are arguably the most important both in terms of diversity and ecology. However, traditional views on collembolan relationships based on morphology and taxonomy has had a turbulent history. Their relationships have been debated since the early 20th century and despite recent attempts to solve their phylogeny, both from morphological and molecular data analyses, relationships among the main lineages and the very position of Collembola within Hexapoda remain unclear. Multiple molecular loci for a broad taxonomic sampling are analysed to address the phylogeny of the four orders Neelipleona, Symphypleona, Entomobryomorpha and Poduromorpha, along with the familial relationships within the orders. Ambiguities and lack of resolutions will be discussed.

Adaptive and maladaptive contemporary evolution of thermal tolerance and performance within cities

Authors: Diamond Sarah, Case Western Reserve University, United States

Abstract: Cities have expanded globally over the last century. These replicated urban heat islands provide an unprecedented opportunity to explore how populations cope with rapid increases in temperature. Within-generation phenotypic plasticity is one possible coping strategy, but there is growing evidence that contemporary evolution of temperature-sensitive traits is more common than previously appreciated. Here, I examine the evolution of thermal tolerance and performance in response to urban heat islands using an acorn-dwelling ant species. In a majority of cities, but not all, acorn ants have evolved higher heat tolerance, but lost their tolerance of cold temperatures. These changes were not due to indirect effects of body size, which showed no evolutionary divergence between urban and rural populations, nor maternal effects, as the phenotypic patterns of population divergence persisted from F1 to F2 generations. The evolution of higher heat tolerance appears to be adaptive owing to evidence of positive directional selection on heat tolerance coupled with evidence of local adaptation. In particular, urban populations produced more sexual reproductives under warmer laboratory rearing temperatures, whereas rural populations produced fewer under these conditions. Despite these adaptive shifts, other traits including whole-colony metabolic rate exhibit potentially maladaptive evolutionary divergence, with urban populations exhibiting a higher metabolic rate compared with rural populations. The results of this work highlight how cities can be used to explore contemporary convergent evolution of thermal traits in response to a common agent of selection, the urban heat island effect, but also potential constraints on thermal adaptation.

In a nutshell, a reciprocal transplant experiment reveals fitness trade-offs in response to urban evolution in an acorn-dwelling ant

Authors: Diamond Sarah[1], Martin Ryan[1], [1]Case Western Reserve University, United States

Abstract: What is the evidence for adaptive evolution over contemporary timescales? Although there is widespread evidence for local adaptation in response to environmental variation, how these responses play out over more rapid, recent timescales is unclear. Cities provide an unparalleled opportunity to explore local adaptation in response to contemporary environmental change. Acorn ants (Temnothorax curvispinosus), inhabiting forested urban patches have evolved greater heat tolerance but lower cold tolerance when compared to nearby rural populations. These earlier findings led us to ask how these relatively rapid evolutionary changes have affected fitness and local adaptation. We performed a multi-year reciprocal transplant between replicated rural and urban habitats located in and near Cleveland Ohio, USA across an urbanization gradient to explore local adaptation in response to urban heat in acorn ants. In the case that local adaptation is present, we expected urban ants to have the highest fitness in their 'home', i.e. urban environment, and rural ants to have highest fitness in their 'home', i.e. rural environment, with crossed pairings of the 'away' environment for each population to have relatively low fitness. We broadly find evidence for local adaptation, however, the magnitude of the response appears to be dependent on the season under which fitness is assessed. While rural populations appear to have a relatively equal probability of colony failure throughout the year, urban populations appear to have a much higher probability of colony failure during the coolest portions of the year. Previous evidence of evolved increases in heat tolerance and losses in cold tolerance might leave urban populations vulnerable to cold temperature stress events, even in relatively warmer urban environments. Although a few other urban evolution studies in plants have explored the potential for local adaptation in cities, the acorn ant system appears to be one of the first systems to demonstrate evidence for local adaptation to city life, albeit with some potential maladaptive shifts in cold tolerance responses.

Two new species of Dentigaster Zettel, 1990 (Hymenoptera, Braconidae, Cheloninae) from Brazil.

Authors: Dias Manoel[1] and Dias Angélica[1], [1]Federal University of Sao Carlos

Abstract: Dentigaster Zettel, 1990 has nine neotropical species described. Two new species from Brazil are presented here. Dentigaster sp. nov. 1: type material,16 females from Atlantic forest; this new species has the color pattern similar to Dentigaster erythrothorax Zettel, 1992, but it's morphologically different; has metasoma noticeably narrower, longer and first tergite with anterior prominent median knob. Dentigaster sp. nov. 2: type material, 12 females from savannah and caatinga; yellow and dark brown color, with more or less expanded yellow in different individuals; yellow head with brown spot on face and vertex; brown mesoscutum with two yellow longitudinal bands; brown metasoma with yellow sides, which may be reduced or absent in the second and third tergites in some individuals.

Endosymbionts of members of the third trophic level manipulate chemical ecology among four trophic levels

Authors: Dicke Marcel[1], Cusumano Antonio[1] and Poelman Erik[1], [1]Laboratory of Entomology, Wageningen University, Wageningen, Netherlands

Abstract: Parasitoids harbour a diversity of microbial symbionts including viruses, bacteria, and fungi. In contrast to symbionts of herbivorous and hematophagous insects, parasitoid symbionts do not provide nutrients. Instead, they are involved in parasitoid reproduction, suppression of host immune responses, and manipulation of the behaviour of herbivorous hosts. Moreover, our data show that parasitoid symbionts such as polydnaviruses may also influence plant-mediated interactions among members of plant-associated communities at different trophic levels such as herbivores, parasitoids and hyperparasitoids. This implies that these symbionts have a much more extended phenotype than previously thought. I will highlight this with recent data on the chemical ecological effects of endosymbionts in plant-herbivore-parasitoid-hyperparasitoid interactions and the effects on direct and indirect species interactions and the consequences for community ecology.

Honeydew from aphids feeding on plants whose seeds were coated with neonicotinoids enhances mortality of beneficial insects

Authors: Dicke Marcel[3], Heimpel George[4], Calvo-Agudo Miguel[2], Tena Alejandro[1], Gonzalez-cabrera Joel[5], Dregni Jonathan[4], [1]Instituto Valenciano de Investigaciones Agrarias, Spain, [2]IVIA, [3]Laboratory of Entomology, Wageningen University, Wageningen, Netherlands, [4]University of Minnesota, United States, [5]University of Valencia, Spain

Abstract: Soybean is a major crop worldwide and its seed is commonly treated with neonicotinoids to control the soybean aphid Aphis glycines. It has been recently demonstrated that neonicotinoids, either sprayed or applied via the irrigation system, reach and kill beneficial insects when they feed on honeydew. Here, we tested whether honeydew excreted by A. glycines under field conditions contained the neonicotinoid thiamethoxam and whether it was toxic for the dipteran predator Aphidoletes aphidimyza and the parasitic wasp Aphelinus certus when the aphids fed on soybean plants grown from: i) untreated seeds, seeds treated with ii) thiamethoxam or iii) thiamethoxam + three fungicides.
A. glycines honeydew was collected 30-43 days after sowing (DAS) in July 2019. Honeydew collected in plots seed-treated with thiamethoxam or thiamethoxam + three fungicides contained 10 times higher levels of thiamethoxam than honeydew collected in the untreated plots. In addition, honeydew collected in plots seed-treated with thiamethoxam or thiamethoxam + three fungicides reduced the longevity of the dipteran predator and parasitic wasp compared to control honeydew. The results show, for the first time, that neonicotinoids can reach beneficial insects via honeydew when they are applied as seed coating. This route of exposure is likely to affect a much wider range of beneficial insects and crops.

Mass rearing insects as mini-livestock: effects of environmental factors

Authors: Dicke Marcel, Laboratory of Entomology, Wageningen University, Wageningen, Netherlands

Abstract: With the expected growth of the human population towards 9-10 billion people by 2050, an increase in global food production of at least 60 percent above 2006 levels is required. However, the food system is a major driver of climate change, reason that dietary changes are needed as well as reductions in food loss and waste. A major challenge is to produce sufficient animal proteins in a sustainable way. Several insect species, such as the yellow mealworm (Tenebrio molitor), the buffalo worm (Alphitobius laevigatus), the house cricket (Acheta domesticus) and the black soldier fly (Hermetia illucens) are now reared as mini-livestock. The mealworm, buffaloworm and cricket are especially used as food for humans and the black soldier fly but also the yellow mealworm as feed for livestock.
For a novel circular and sustainable approach to protein production, insects provide excellent opportunities because various species can be reared on organic waste streams. Insects are now reared in large volumes by big companies as well as in smaller volumes by smallholder farmers across the globe. The new insect sector provides animal proteins through a sustainable production process, with low-value input, high-value output and low environmental impact. Insect production can, therefore, become an important component of a circular economy, by closing nutrient and energy cycles, fostering food security while minimising climate change and biodiversity loss.
Important questions in developing the production of insects as source of protein include effects of substrate quality, densities, competition, pathogens and ethical aspects. These aspects influence insect health and welfare as well as economic value in the context of sustainable and circular agriculture. In this contribution I will focus on such aspects of insect rearing. I will conclude on the opportunities for rearing of insects as mini-livestock.

Plant-microbe-insect interactions at the roots

Authors: Dicke Marcel, Laboratory of Entomology, Wageningen University, Wageningen, Netherlands

Abstract: Plants are members of complex communities, both aboveground and belowground. They are exposed to a wide diversity of insect herbivores that are in turn attacked by a wide diversity of carnivorous enemies. Plant responses to herbivore attack modify plant phenotype and, consequently, interactions with community members and community composition. Microbes in the rhizosphere, especially plant-growth promoting rhizobacteria (PGPR), influence both direct and indirect induced defence of plants against insects. These PGPR are supported by plants through root exudates. Upon insect herbivory, plant hormone profiles and subsequently root exudate profiles are altered. Modified root exudation may influence the community of rhizobacteria that colonize plant roots, with consequences for insects herbivores feeding on the roots or shoots. Here, I will present recent developments focussing on insect-plant-microbe interactions at the roots including underlying mechanisms. Such knowledge is instrumental for novel developments in sustainable crop protection strategies.

Pollinator decline – a case study of the need for transformative change to avert biodiversity loss

Authors: Dicks Lynn, University of Cambridge, United Kingdom

Abstract: Decline in pollinating animals has become a prominent example of how biodiversity loss can affect humanity, usually with reference to the potential impacts of pollinator decline on food production. This talk will provide an overview of the state of knowledge on pollinators, including their conservation status, drivers of pollinator declines, and the policy responses underway through national and international strategies and action plans. I will present a global assessment of the relative importance of direct drivers of pollinator decline and ten consequent risks to human well-being, based on a formal expert elicitation process. Our results indicate that policy responses should focus on reducing pressure from changes in land cover, land management and pesticides. We reveal how the risks from pollinator decline differ among regions, with perceived risks substantially higher in the Global South. I will argue that the focus on food production, while providing an important economic argument for looking after some pollinators, does not address all aspects of the problem. Rather, addressing and reversing pollinator declines requires a multi-scale, hierarchical response that tackles both direct and indirect drivers of decline, and takes into account the many values of pollinating animals, beyond their direct contributions to food production.

When management facilitates invasion: the case of Nipeacoccus viridis in Florida citrus

Authors: Diepenbrock Lauren, University of Florida Citrus Research and Education Center, United States

Abstract: Human movement and trade routes are well documented in the spread of invasive species. As such, regulations regarding movement of people and goods are monitored and precautionary measures taken to minimize risk while at the same time, agricultural and trade related organizations continually assess risk of unwanted species to arrive.

Anthropogenic disturbances in the form of land use changes can further exacerbate the potential for adventive species to gain a foothold once introduced. Such is the case for a recently established invasive mealybug, Nipaecoccus viridis Newstead in Florida citrus. N. viridis is a common pest in many citrus-producing regions of the world where it is often managed with minimal chemical input due to ability of natural enemies to suppress the pest before populations reach damaging levels.

After nearly two decades of intense chemical management for Diaphorina citri Kuyawama, the primary vector for citrus greening, many growers in Florida are now reducing their chemical inputs from 14+ applications a year to 6-8 applications targeted at periods where research has shown the greatest potential for management success. In the years since D. citri was found in Florida, followed soon after by citrus greening, citrus habitats have experienced 2 abrupt shifts: (1) focus on IPM with primary reliance on biological control to intense management, and more recently (2) a swift reduction in chemical inputs. These and other changes in management have opened the door for adventive species to successfully establish and cause damage in part due to the lack of abundant generalist predators present in the system.

Why honeybees are poor pollinators of a mass-flowering plant

Authors: Diller Carolina[1], Castañeda-Zárate Miguel[1] and Johnson Steven D.[1], [1]Centre for Functional Biodiversity, University of KwaZulu-Natal

Abstract: Honeybees dominate the flower-visitor assemblages of many crops and natural plant communities, yet their efficiency in terms of quality of pollen delivered is largely unknown. Honeybees are very frequent visitors to flowers of this species and cumulatively deposit as much pollen on stigmas as do birds. Yet, flowers from which birds but not bees were excluded seldom set seed. We captured honeybees and used half of them to pollinate virgin flowers on the plant on which bees were caught and the other half to pollinate virgin flowers on different plants. This “split-pollinator” method revealed that the pollen deposited on Aloe ferox flowers by honeybees is mostly low quality self pollen that that leads to substantial ovule discounting and depressed seed set. Lack of movement among A. ferox plants during individual honeybee foraging bouts is the most likely explanation for their deposition of low quality self pollen on stigmas. This study sheds light on why honeybees are often poor pollinators of mass flowering self-incompatible shrubs and trees, and introduces a simple new method to evaluate the quality of pollen delivered by pollinators in both natural and agricultural systems.

Bumble bee queens exploit microrefuges to survive a late summer cold-snap

Authors: Dillon Megan[1] and Dillon Michael[1], [1]University of Wyoming, United States

Abstract: With climate change, frequency and intensity of extreme weather events are expected to increase. Extreme temperatures associated with these weather events may significantly harm some insect populations, particularly during lifecycle milestones. Fall and spring are key milestones for bumble bees; new queens emerge and leave the natal colony in the late summer, mate, and then overwinter underground before starting new spring colonies. Queens may be especially vulnerable to extreme weather events during these milestones as they lack colony or hibernaculum refuges. However, behavior and microhabitat selection of queens are not well documented for these unprotected, solitary periods. Further, whether queens seek environments that would allow them to survive extreme weather is unknown. To assess queen microhabitat selection and survival during an unusual cold weather event, we measure the responses of wild Bombus huntii queens to a late summer snowstorm, during which temperatures fell 16°C in six hours and stayed below 5°C for three days. Only one of 26 queens did not survive the storm. The remaining queens retreated underground or found other cover, often clustering together. These findings show that bumble bee queens behaviorally adapt to sudden temperature drops and have remarkable cold tolerance during an active life stage.

Body condition predicts timing of spring emergence for queen bumble bees

Authors: Dillon Michael E.[1], Keaveny Ellen[1], [1]University of Wyoming, United States

Abstract: For insects, the timing of life history events (phenology) often depends on temperature cues. Body size often mediates insect responses to temperature, so body size may also play an important role in phenology. The determinants of spring emergence of bumble bee queens are not well understood, but body size is likely important for several reasons. In fall, queens accumulate energy stores to fuel overwinter survival. Accumulation of fat stores prior to and depletion of fat stores during overwintering are size-dependent: larger queens accumulate relatively more lipids and have lower mass-specific metabolic rates, suggesting delayed depletion of energy stores and potentially leading to later spring emergence. To address whether timing of spring emergence correlates with body size, we captured 237 Bombus huntii queens in Laramie, WY, during the 2020 and 2021 growing seasons, weighed them, and measured intertegular width (a size metric less affected by variation in feeding and hydration state). Early emerging queens were smaller than later emerging queens across years. Mass relative to intertegular width increased as the season progressed, suggesting, as predicted, that body condition influences the timing of spring emergence for these crucial pollinators.

Shifts in the thermal sensitivity of metabolism for overwintering bumble bee queens

Authors: Dillon Michael E.[1], Dodge D. M. Shayne[1] and Dillon Megan[1], [1]University of Wyoming, United States

Abstract: Insects display various strategies for dealing with temperature, especially cold. Two common metabolic methods are compensation and depression. Diapausing animals exhibit metabolic depression as a means of overwintering. While during the cooler temperatures of the active season, they may show higher metabolic rates to compensate for their environment. Metabolic rates of diapause and post-diapause Bombus impatiens queens were measured between approximately 1 and 11°C. We found metabolism shifts for diapausing queens relative to the same individuals 1 week after diapause termination. However, contrary to the expectation of metabolic suppression, diapausing queens tended to have higher and more variable metabolic rates, at least at the intermediate temperatures at which we measured them. These queens showed significant metabolic elevation at temperatures 4, 6, and 8°C (paired t-test, $P = 0.006$, $P = 0.047$, and $P = 0.002$, respectively), but not at 2 and 10°C (paired t-test, $P = 0.884$ and $P = 0.139$, respectively). This may suggest that active post-diapause queens more tightly regulate CO2 emission, particularly at temperatures 8°C and below.

Transgenic dissection of the Aedes siRNAi pathway in antiviral defense and cross-talk with antibacterial immune pathways

Authors: Dimopoulos George, Johns Hopkins University, United States

Abstract: Arboviruses remain an immense public health threat despite vector control efforts, causing yearly large epidemics. The major arbovirus vector Aedeses aegypti utilizes its innate immune system to defend against microorganisms including human pathogens. The RNA interference pathway-mediated antiviral defense system is known to act against a broad range of viruses. However, despite the RNAi pathway's emergence as the major pan-antiviral defense system it remains understudied in mosquitoes, and its utility for vector-borne disease control has not been extensively explored. We have developed the first RNAi pathway engineered mosquitoes that show resistance against multiple human pathogens including dengue and Zika virus. Transgenic over-expression of Dicer-2 (Dcr-2) and R2D2 poses only mild fitness costs and, interestingly, also renders the mosquito more resistant to bacterial infections. The influence of the RNAi pathway on antibacterial defense appears to involve the induction of several antimicrobial peptide genes and other effectors, suggesting a cross-talk with antibacterial immune pathways such as the Toll and Immune deficiency (IMD) pathways. We are also investigating tissue-specific action of the RNAi pathway in antiviral defenses, as well as inter-tissue signaling using state-of-the-art genetic and molecular tools.

Invasive gall-forming wasps threatening non-native plantation-grown Eucalyptus: diversity and invasion patterns

Authors: Dittrich-Schroder Gudrun[4], Hurley Brett P[3], Wingfield Michael J[3], Nahrung Helen F[2], Slippers Bernard[1], [1]FABI, University of Pretoria, South Africa, [2]The University of the Sunshine Coast, [3]University of Pretoria, [4]University of Pretoria, FABI & Department of Zoology and Entomology, South Africa

Abstract: Gall-forming hymenopterans on Eucalyptus species are highly successful invaders causing significant damage to non-native plantation forests. About 80% of the invasive species have emerged over the past two decades and fewer than 10% of these were known from Australia beforehand. Two species, Leptocybe invasa and Ophelimus maskelli, are global invaders that have become established since 2000 in 45 and 25 countries, respectively. There are a number of Hymenopteran groups that cause similar damage and that could become invasive in the future, most of which very poorly studied. The small number of taxonomists able to identify these insects slows accurate and effective diagnoses. Even when initial identifications have been made, these are frustrated by the existence of morphologically similar, but distinct cryptic species, which may differ in their ecology, including host and climatic range, and natural enemy interactions. This lack of information impacts management because breeding for resistance and biological control require accurate identification of the target pest. Given the global nature of invasions by these insects an international and collaborative research approach is required, to inform pre-emptive quarantine, monitoring and potential management options

Molecular tools fast track identification of insect pests in plantation forestry

Authors: Dittrich-Schroder Gudrun[3], Hurley Brett P[2], Wingfield Michael J[2], Slippers Bernard[1], [1]FABI, University of Pretoria, South Africa, [2]University of Pretoria, [3]University of Pretoria, FABI & Department of Zoology and Entomology, South Africa

Abstract: Accurate identification of invasive insect pests is a crucially important first step towards effective management. The rapid increase in invasive insects pests in plantation forestry require rapid and accurate tools for specimen identification. This is complicated by the growing shortage of specialist taxonomists and the shortcomings of morphological comparisons for to identify cryptic insect lineages. Sequence databases can be used to help address these challenges, but these are often poorly curated and incomplete. To address this challenge with reference to the identification of invasive insects pests of Eucalyptus plantation forestry, a forest insect mitochondrial (FIMT) online barcode tool was developed. This database and its associated tools facilitate the identification of unknown specimens through sequence comparisons with a curated database of identified insects pests. It also provides a platform for researchers and practitioners to share information before it is published in public databases, which often take years after the work is started. The information that FMIT can provide is essential in the management of these invasive species using tree breeding or biological control, where the accuracy of identification of the pests and their natural enemies are fundamentally important.

Vicia sativa contains A1b like entomotoxin; biopesticide of plant origin

Authors: Diya Fatima, INSA Lyon, Lebanon

Abstract: To date, crop protection relies almost exclusively on chemical treatments, which cause environmental pollution and lead to the emergence of pest resistance. Societal and public policy considerations create the need for ecologically friendly new solutions. In this perspective, biopesticides are effective alternatives to chemical insecticides for the control of various insect pests. Legume seeds contain numerous insecticidal proteins aimed at protecting their high nitrogen content from animal/insect predation. PA1b (Pea Albumin 1, subunit b), a 37 amino acid is an entomotoxin extracted from pea seeds and is of great interest for the control of cereal weevils (sitophilus spp.), a major pest of stored cereals. Investigating on such a protein family in seed of legumes of the Middle East origin, we discovered insecticidal activity of seed extracts, from different species belonging to the papilionoideae subfamily. We uncovered 12 sequences of amino acids that are homologues to PA1b. Our discovery shows that PA1b-like peptide found in Vicia sativa displays an outstanding insecticidal activity against Sitophilus oryzae WAA42. Besides, it shows cytotoxic effect against insect Sf9 cells (Spodoptera frugiperda). Mass spectrometry is in progress to determine the amino acid sequence of this interesting peptide through a biochemical approach. Moreover, binding assays of the newly discovered homologue to the receptor found in the sitophilus oryzae's proteinaceous tissue will be carried out to determine its affinity. Such observations pave the way for the development of bioinsecticides, with PA1b like peptides as lead compounds.

TaxonWorks: World Auchenorrhyncha Database (Hemiptera)

Authors: Dmitriev Dmitry, Illinois Natural History Survey, United States

Abstract: Suborder Auchenorrhyncha is abundant group of plant-feeding insects. This group consists of leafhoppters, planthoppers, treehoppers, cicadas, and spittlebugs and together with other suborders, Heteroptera, Sternorrhyncha, and Coleorrhyncha, it forms one of the largest insect order Hemiptera. World Auchenorrhyncha database provides information on the nomenclature of the group. At the present time the groups includes 70 valid families, 6,851 valid genera, 47,695 valid species, and >50,000 synonyms and subsequent combinations. The original version of the database could be accessed from http://dmitriev.speciesfile.org. Recently, the database was migrated into TaxonWorks (http://taxonworks.org). Besides nomenclature, the website provides information on species distribution, type material, biological associations, bibliography as well as tools for species identification (dichotomous keys, interactive matrix based keys, and pictorial keys). The data from the database are shared with global aggregates like Catalogue of Life and GBIF.

Higher-Level Phylogeny of the family Cicadellidae and related groups (Hemiptera: Cicadomorpha) based on DNA evidence

Authors: Dmitriev Dmitry[2], Lu Lin[3], Dietrich Christopher[1] and Zhang Yalin[3], [1]Illinois Natural History Survey, Prairie Research Institute, University of Illinois at Urbana-Champaign, United States, [2]Illinois Natural History Survey, United States, [3]Northwest A&F University, China

Abstract: The family Cicadellidae belongs to the most diverse superfamily Membracoidea (Insecta: Hemiptera: Cicadomorpha). It is spread worldwide consisting of about 25,000 described species of 40 subfamilies in the world, including 24 in China (sensu Oman et al., 1990). All being plant-feeders, these leafhoppers include many species that are very harmful pests on trees, fruits, vegetables and other economic crops. Because of their species diversity and morphological differences, and higher-level classification system has been a controversy among leafhopper taxonomic workers and is an urgent issue to resolve. Taxonomy and phylogeny have certain limitations because previous analyse of phylogeny have not consistently parse the relationships of leafhopper based on the morphological characters.
We reconstruct the higher-level phylogeny of the family Cicadellidae and related groups based on five molecular marker genes to test the monophyly of this family and further clarify the relationships among the genera, tribes and subfamilies, using the phylogenetic ML analysis with 237 representative taxa of all major lineages, including 218 cicadellid representatives out of 86 tribes among 34 leafhopper subfamilies (sensu Oman et al., 1990) and 18 species among four superfamilies of related groups. We gained the relationship of Cicadomorpha with bootstrap support at least 90% which is in agreement with previous research (Cryan & Urban, 2012; Dietrich, et al., 2017; Johnson et al., 2018; Skinner et al., 2019) on the phylogenetic relationship of Cicadomorpha and outgroup taxa. The family Cicadellidae is paraphyletic with the two families Membracidae and Aetalionidae, which is consistent with Dietrich et al. (2001, 2017). The largest subfamily Deltocephalinae is also evidenced to monophyly, and 10 related subfamilies are merged into Deltocephalinae,corroborating Zahniser & Dietrich (2010, 2013). Meanwhile, it is worth mentioning that the subfamily Typhlocybinae, the monophyletic group of the second largest group of Cicadellidae is first verified with 27 species of six tribes based on the above genes.

Aposematism and chemical defense in chrysomelid beetles and the physiology behind it

Authors: Dobler Susanne, Molecular Evolutionary Biology, Universitaet Hamburg, Germany

Abstract: Chrysomelid beetles are often shiny and display striking colors, that are usually assumed to represent aposematic warning colorations. Many of these beetles are actually reknown for their chemical defenses which may either be autogenously produced or sequestered from their host plants. Using Chrysolina, Oreina and Chrysochus species as model system I here review evidence for colors as defensive signals and discuss the value of cardiac glycosides and pyrrolizidine alkaloids as defense compounds. Both types of defenses necessitate intricate physiological adaptations to avoid autotoxicity and to transport defensive compounds into specific storage compartments while on the other hand excluding them from sensitive organs. These physiological adaptations are the current focus of my group and our recent results on the role of target site insensitivity and ABCB transporters will be presented.

The making of the monarch: A constrained adaptive path to toxin resistance

Authors: Dobler Susanne[6], Matsunaga Teruyuki[3], Karageorgi Marianthi[3], P. Hastings Amy[2], Agrawal Anurag[2], Rico Felix[5], Sumbul Fidan[5], Guerra Geno[5], M. Aguilar Jessica[3], N. Pelaez Julianne[3], I. Verster Kirsten[3], Astourian Michael[3], Whiteman Noah[3], C. Groen Simon[1] and L. Bernstein Susan[3], [1]Department of Biology, Center for Genomics and Systems Biology, New York University, New York, United States, [2]Department of Ecology and Evolutionary Biology, Cornell University, Ithaca, United States, [3]Department of Integrative Biology, University of California, Berkeley, United States, [4]Department of Integrative Biology, University of California, Berkeley, United States, [5]LAI, U1067 Aix-Marseille Université, Inserm, CNRS, Marseille, France, [6]Molecular Evolutionary Biology, Universitaet Hamburg, Germany

Abstract: Identifying the genetic mechanisms of adaptation requires the elucidation of links between the evolution of DNA sequence, phenotype, and fitness. Convergent evolution can be used as a guide to identify candidate mutations that underlie adaptive traits, and new genome editing technology is facilitating functional validation of these mutations in whole organisms. We combined these approaches to study a classic case of convergence in insects from six orders, including the monarch butterfly (Danaus plexippus), that have independently evolved to colonize plants that produce cardiac glycoside toxins. Many of these insects have evolved parallel amino acid substitutions in the a subunit (ATPa) of the Na+/K+ ATPase, the physiological target of cardiac glycosides. We found substitutional paths involving three ATPa amino acids (111, 119 and 122) that are associated with cardiac glycoside specialization. Using CRISPR/Cas9 genome engineering, we edited the native ATPa gene in Drosophila melanogaster and retraced the substitutional path taken across the monarch butterfly lineage. We could show in vivo, in vitro and in silico that the path confers resistance and target site insensitivity to cardiac glycosides, culminating in triple mutant “monarch flies” as resistant as the monarch butterflies. We also demonstrated that the order in which the substitutions evolved ameliorated, but did not eliminate, antagonistic pleiotropy through epistasis. In our current work, studying natural populations of Drosophila carrying the “monarch” genotype in the three ATPa amino acids (111,119 and 122), we aim to elucidate whether convergent compensatory substitutions have evolved in the monarch and other insect specialists to eliminate the fitness costs of the resistance substitutions. Overall, our work illuminates how the monarch butterfly evolved resistance to cardiac glycoside toxins and reveals rules that govern the evolution of novel adaptive traits.

Large-scale population suppression of wild Aedes Aegypti by release of Wolbachia-infected males

Authors: Dobson Stephen[2], White Bradley[3], Crawford Jacob[3], Holeman Jodi[1] and Mulligan Steve[1], [1]Consolidated Mosquito Abatement District, United States, [2]MosquitoMate, United States, [3]Verily, United States

Abstract: The range of the mosquito Aedes aegypti continues to expand, putting over 2 billion people at risk of arboviral infection. Novel, scalable mosquito abatement tools are needed as chemical insecticides and source-reduction have failed to prevent the proliferation of this species. The sterile insect technique (SIT) has been used to successfully combat agricultural pests at large scale, but not mosquitoes - largely due to challenges with consistent production and distribution of high-quality male mosquitoes. We developed automated processes to rear and release millions of competitive, male-only, sterile (Wolbachia) mosquitoes and conducted a large-scale suppression trial in Fresno County, California. In 2018, we released 14.4 million males across three replicate neighborhoods encompassing 293 hectares. At peak mosquito season, the number of female mosquitoes was 95.5% lower (95% CI: 93.6 - 96.9) in release areas compared to non-release areas, with the most geographically isolated neighborhood reaching a 99% reduction. We speculate that immigration of mosquitoes from neighboring untreated areas prevented higher suppression in release sites. Collectively, our work demonstrates a viable path to effective, large-scale mosquito SIT, re-energizing the prospects for area-wide control of Ae. aegypti.

Exhibition of ant-lepidopteran commensalism is not only for honeydew tending but the similarities of cuticular hydrocarbons also power the attraction

Authors: Dolai Avishek[1], Das Amlan[1], [1]Entomology Laboratory Department of Zoology University of Calcutta Kolkata, West Bengal, India

Abstract: In ant-lepidopteran commensalism, the myrmecophilous grass moth, Parotis marginata, Hampson, 1893 (Lepidoptera: Crambidae) exhibits commensals with Asian weaver ant, Oecophylla smargdina (Hymenoptera: Formicidae). Several weaver ant nests (n=340) of variable sizes were examined from different fruit (n=310) and non-fruit trees (n=30) from West Bengal, India for one year. The lepidopteran caterpillars (n=246) and/or its pupae (n=152) were noticed in almost 24% (n=80) of the studied nests. In understanding of 'cuckoo strategy' behind the commensal association between the moth and the ant, we performed cuticular hydrocarbon (CHC) profiling of the associated commensals. It was found that nearly 33 different CHCs were present in attendant worker ants from decane (C10) to tritetracontane (C43), where the mature ant larvae had only two and half of it (CHC, n=13). In compare to ant's CHC diversities, the hydrocarbons were noticed very limited to the matured caterpillar (CHC, n=7) or absent in its pupae (CHC, n=0). The CHC profiles of caterpillars were fully shared by either the adult workers or the ant larvae. It was well hypothecated that the ants were likely to tend the caterpillars by the attraction of honeydews secreted from the myrmecophilous organs of the caterpillars, but our study indicates that, in addition to attraction of honeydews, CHC alikeness of lepidopteran larvae also excites the ants to attract the caterpillars as a case of exhibiting chemical mimicry.

Evolution of circadian clock genes in insects

Authors: Dolezel David[4], Smykal Vlastimil[4], Chen Ping[3], Thakkar Nirav[2] and Chodakova Lenka[1], [1]Faculty of Science, University of South Bohemia, Ceske Budejovice, Czech Republic, [2]Biology Centre AS CR, v.v.i., Institute of Entomology, Ceske Budejovice, Czech Republic, [3]Biology Centre AS CR, v.v.i., Institute of Entomology, Ceske Budejovice, Czech Rollege of Plant Protection, Fuzhou, China, Institute of Applied Ecology, [4]Biology Centre CAS, Institute of Entomology, Ceske Budejovice, Czech Republic

Abstract: Circadian clocks are time-measuring devices that were identified in almost all organisms. The molecular mechanism of clocks in animals relies on several interlocked transcription-translation feedback loops, the majority of which conserved between vertebrates and Drosophila. However, several important differences in the clock setup exist. Here, we will present our systematic analyses of clock setup in all major insect lineages, point to important Drosophila-specific idiosyncrasies, and highlight the conserved and variable components. Furthermore, we will present our functional reverse genetic data on the linden bug Pyrrhocoris apterus, a hemipteran insect in which we have tested the function of the majority of clock components. In addition to recently published data, we will present new phylogenetic analyses and a functional description of novel genetic components identified by RNA-mediated interference.

Photoperiodic timers, diapause and circadian clock genes in the linden bug, Pyrrhocoris apterus (Heteroptera)

Authors: Dolezel David[1], Kotwica-Rolinska Joanna[2], [1]Biology Centre CAS, Institute of Entomology, Ceske Budejovice, Czech Republic, [2]Branisovska 31 Institute of Entomology Biology Center Czech Acad Sci Branisovska, Czech Republic

Abstract: Organisms synchronize their behavior to daily changes of environmental conditions and restrict activity to certain periods of the daily cycle. Exogenous cues inform about the time of a day, but mechanisms which control activity rhythms are controlled by endogenous circadian clock. In addition to daily changes of environment we observe also seasonal differences. Many organisms evolved time measuring device which counts the ratio of light to dark (photoperiod) which enables surviving adverse conditions arising from seasonal changes.

The understanding of how photoperiodic calendar works on a molecular level is still not clear, several authors proposed connections between circadian and photoperiodic clock since both rely on similar architecture, but this hypothesis is dismissed by others. The major complication in interpreting functional involvement of circadian gene in photoperiodism is pleiotropy of many factors.

In Drosophila melanogaster cytoplasmic acumulation of PER is delayed by the activity of a DBT kinase which promotes phosphorylation and turnover of PER. dbt mutants of Drosophila melanogaster have altered period of the rhythm. In the linden bug, Pyrrhocoris apterus, RNAi works systemic. After the dbt knock-down we observe lengthened circadian periods but also altered photoperiodic response curves. In the same time, the animals are still able to be reproductive or undergo diapause under specific conditions. We propose dbt involvement in photoperiodic time measurement. The influence of long or short photoperiods on Pyrrhocoris behavior is in consistency with our results from geographic field lines, where animals from different latitudes show great variability in circadian behavior.

Sex determination in the linden bug Pyrrhocoris apterus: identification and functional analysis of doublesex and transformer genes

Authors: Dolezel David, Kaniewska Magdalena, Verhulst Eveline, Kotwica-Rolinska Joanna, Smykal Vlastimil, Vaneckova Hana and Wu Bulah Chia-Hsiang

Abstract: A variety of sex-determining mechanisms have been described and are fairly well understood in some insect groups. However, data on sex determination in basal insects are mostly lacking. The cascade of genes regulating the sex determination involves two transcription factors – doublesex (dsx) and transformer (tra). The latter is known for its conserved function, playing a role of the dsx's splicing regulator, and has been found in all studied insects. Here we describe the discovery of dsx and tra genes in the linden bug Pyrrhocoris apterus (Heteroptera). We created detailed gene models, identified multiple isoforms in silico, and confirmed them using PCR and Sanger sequencing. Our results show that the observed tra splicing pattern seems to differ from other insect species. We also discovered a clear, sex-specific alternative splicing pattern for dsx, as there are three unique exons present in both female and male transcripts. Further, we analyzed the predicted gene function using maternal RNAi-mediated knockdown. All the progeny of tra dsRNA injected mothers developed into males with clear male-specific morphological structures, while dsx knockdown seemed to have no effect on the offspring's sex determination.

Enhancing khapra beetle detection technology

Authors: Domingue Michael[1], Morrison William[5], Scheff Deanna[4], and Athanassiou Christos[2], [1]Kansas State University, United States, [2]University of Thessaly, [3]USDA-APHIS, [4]USDA-ARS, [5]USDA-ARS Center for Grain and Animal Health Research, United States

Abstract: The khapra beetle is the only stored product insect quarantine pest in the US, feeds on variety of grains. There has been increasing frequency of interceptions at US ports of KB making improved detection crucial for food security. To improve trapping we have examined the surfaces the insects can most easily move upon and made improvements to traps where appropriate. We have also examined how insecticide coated surfaces affect behavior in relation to trapping. Trapping might be improved by design improvements that consider the ability to move on substrates. Insecticide-impregnated materials in traps are likely to affect behavior by disrupting semiochemical responses, but not movement.

Sugar Beet De-Icing Liquid Exposure Perturbs Salt and Water Balance in Mayfly Nymphs

Authors: Donini Andrew[1], Nowghani Fargol[2], Ana Cuciureanu Laura[2] and P. Kelly Scott[2], [1]Department of Biology, Faculty of Science, York University, Canada, [2]Department of Biology, York University, Canada

Abstract: Mayfly nymphs are established bio indicators of freshwater (FW) quality. This study examined the ion/osmoregulatory physiology of Hexagenia limbata nymphs following exposure to beet juice de-icing (BJD) liquid, an alternative to rock salt. The LC50 of BJD liquid was determined to be 4%, therefore a sub-lethal dose of 3.2% was selected for a 7 day exposure and following this ion (K+, Na+, Cl-, NH4+ and H+) concentrations in nymph hemolymph were examined as well as ion fluxes across tracheal gills and rectum. The presence of 3.2% BJD liquid in FW distinctly elevated environmental Na+, Cl-, K+, and NH4+ levels as well as pH, but all remained well below their individual LC50. In the hemolymph, Na+, Cl- and pH were higher in 3.2% BJD-exposed nymphs compared to FW nymphs, but other ions did not significantly differ. Na+ was absorbed at the rectum regardless of treatment, while the gills in nymphs exposed to 3.2% BJD excreted Na+, which was in contrast to the Na+ uptake observed across FW nymph gills. Observations of systemic perturbations in Na+, Cl- and pH balance indicate that these mayfly nymphs attempt to deal with 3.2% BJD liquid exposure, in part, by excreting sodium via the gills.

Genome-wide gene birth-death dynamics are associated with diet breadth variation in Lepidoptera

Authors: Dort Hanna[3], van der Bijl Wouter[4], Wahlberg Niklas[2], Wheat Christopher[3] and Nylin Sören[1], [1]Department of Zoology, Stockholm University, Sweden, [2]Lund University, Sweden, [3]Stockholm University, Department of Zoology, Sweden, [4]University of British Columbia

Abstract: Both the duplication and loss of genes have been shown to facilitate the evolution of novel and adaptive traits. Thus, quantifying gene duplication and death across a lineage can potentially reveal gene families that have critically shaped morphological, behavioral, or physiological variation. In this study, we explored patterns of gene duplications and deaths among the Lepidoptera and linked gene family sizes with host plant repertoire sizes. We first generated de novo annotations for 30 publicly available reference genomes and then used the complete predicted protein sets to estimate instances of gene family expansions and contractions across Ditrysia. These results were correlated with host plant repertoire data in a multilevel Bayesian model that enabled us to detect significant differences in gene family size along a specialist-generalist feeding axis. We discovered that the sizes of several important gene families (e.g., those linked with detoxification and digestion) are significantly correlated with diet breadth. Our findings highlight significant genomic differences between generalist and specialist Lepidoptera species and demonstrate the value of pairing gene birth-death analyses with life history data to identify repeated patterns of evolution in distantly related clades.

Novel bee viruses - insights into pathogen evolution and conservation impacts

Authors: Doublet Vincent[4], Wilfert Lena[2], Pascall David[1] and Manley Robyn[3], [1]David Pascall University of Glasgow, United Kingdom, [2]Ulm Universität, [3]University of Exeter, United Kingdom, [4]University of Ulm, Germany

Abstract: Many viruses infect multiple host species. Such multi-host pathogens can show considerable variation not only in their degree of virulence in different host species, but also in their degree of infection and transmission specificity, which has important implications for potential disease emergence. Using multi-host viruses that infect wild and managed bee species but vary in their degree of specificity, we investigate how ecological changes such as the acquisition of a novel vector affects pathogen prevalence and infection strength in contrasting viruses. We discuss the potential relevance of host-species specific variation in pathogenicity for control and conservation measures. As horizontal transmission of infectious diseases is determined by the hosts' contact networks, these measures in turn need to be informed by the host's contact networks. We combine ecological network data with virome sequencing approaches to study the impact of plant-pollinator interactions on virus dynamics. Together, this evidence on pathogenicity, specificity and interactions can inform how best to control pollinator diseases and improve pollinator population health.

Relationship between entomological indices, climate variables and dengue seroconversion rates in northeastern Thailand and southern Laos

Authors: Doum Dyna, Khon Kaen University, Thailand, Cambodia

Abstract: Dengue is the most rapidly spreading mosquito-borne viral disease in the world. About 390 million people are infected per year, and 96 million are clinically apparent. Asia records 70% of the global dengue disease burden. Currently, there are no effective drugs for treating dengue and a recent licenced vaccine confers only partial protection. Although dengue virus infection induces a long-lasting protective immunity to the same homologous serotype, subsequent infection with a heterologous serotype is associated with increased risk of developing severe disease. The detection of clinical cases enables us to measure the incidence of dengue infection, whereas serological surveys gives insights into the prevalence of infection, including those infections that are asymptomatic. In addition, determining factors associated with mosquito abundance is central to predicting the risk of dengue virus transmission. However, it remains unclear whether any consistent association exists among dengue incidence or prevalence and the various entomological indices. This study is, therefore, designed to investigate the relationship among dengue seroconversion and entomological indices, climate variables and socioeconomic factors. Study areas were selected for urban and rural areas of 4 provinces in northeastern Thailand and southern Laos along the Mekong River where dengue is highly endemic. The study regions have a tropical climate with a dry season from October to April and a rainy season from May to September, and dengue transmission occurs mainly in a rainy season. A total of 720 households (HH), 90 households per site, were randomly selected. Baseline socioeconomic and demographic data were collected from all selected HH at the beginning of the study. Two cross-sectional seroprevalence surveys were carried out in May and November 2019. Blood samples were collected from all participants in the selected HH to assess previous exposure to dengue. Monthly entomological collections have been conducted for the whole year of 2019 from the all randomly selected HH. The entomological data include; the number of total containers, number of dry and wet containers, the number of mosquitoes-positive containers and their types and location (indoors/outdoors) and the identification/speciation of all mosquitoes. At the beginning of the study, weather stations were set up in all 4 study sites. Daily max. and min. and total rainfall, max. and min. temperatures, diurnal temperature range, and humidity data were collected. All these variables will be used for the logistic regression univariate and multivariate analyses to examine the relationship among seroconversion rates, socioeconomic characteristics, and entomology indices. The significance of individual coefficients in the logistic regression models will be determined. The results of this study aim to help to establish improved guidance for disease surveillance and vector control strategies.

Pest status and life history of the Afrotropical subterranean scale insect Stictococcus vayssierei (Hemiptera: Stictococcidae) in the Congo Basin

Authors: Doumtsop Armand R. P. F.[5], Normark Benjamin B.[6], Fomena Abraham[7], Fotso Apollin K.[2], Fiaboe Komi K. M.[2], Tindo Maurice[4], Hanna Rachid[1] and Tata-Hangy Willy K.[3], [1]Institute of the Environment and sustainability, Center for Tropical Research, Congo Basin Institute (present address) International Institute of Tropical Agric, [2]International Institute of Tropical Agriculture, Cameroon, [3]International institute of Tropical Agriculture, Democratic Republic of the Congo, [4]University of Douala, Cameroon, [5]University of Maroua, Cameroon (present address) International Institute of Tropical Agriculture University of Yaounde 1, Cameroon, [6]University of Massachusetts Amherst, United States, [7]University of Yaounde 1, Cameroon

Abstract: Stictococcus vayssierei is a major pest of root and tuber crops in central Africa. However, data on its biology and ecology are lacking. Here we provide an updated estimate of its distribution and and abundance, and we evaluate its life history in response to a range of temperatures on two common host plants, with the aim of facilitating the sustainable control of its populations. Surveys conducted in nine countries encompassing thirteen ecological regions around the Congo basin showed that ARTS was present in Cameroon, Central African Republic, Congo, Democratic Republic of Congo, Equatorial Guinea, Gabon and Uganda. The scale was not observed below 277 m asl. The pest occurred in the forest and the forest-savannah mosaic as well as in the savannah where it was never recorded before. However, percentage occurrence was higher in the forest (43.1%) where cassava was the most infested crop, compared to the savannah (9.2%) where aroids (cocoyam and taro) were the most infested crops. Scale cohorts reared on cassava cuttings and cocoyam cormels (females) and in plastic tubes (males) in environment chambers at six constant temperatures showed a significant decrease of development time with an increase in temperature in both sexes. The pest can tolerate a broad range of temperature (13-29°C). Females survived better and developed faster on cassava than on cocoyam. At 21°C – the highest survival rate observed – females developed in 15-17 days regarding the host plant and males developed in 12 days. The lower threshold temperatures were estimated to be 7.4°C and 9.8°C for female development on cassava and cocoyam respectively, and 7.6°C for male development. While good regulatory measures within and between countries are required to control the exchange of plant materials and limit the spread of the pest, the study provides information for niche modeling and risk mapping.

The starry sky provides compass information during long-distance nocturnal navigation in the Australian Bogong moth

Authors: Dreyer David[6], Warrant Eric[3], Adden Andrea[5], Frost Barrie[4], Mouritsen Henrik[7], Chahl Javaan[8], Xu Jingjing[7], Green Ken[1] and Whitehouse Mary[2], [1]ANU Canberra, Australia, [2]CSIRO, Australian Cotton Research Institute, Australia, [3]Department of Biology, Lund University, Lund, Sweden, [4]Queen's University, Kingston, Canada, [5]University of Lund, Sweden, [6]University of Lund, Sweden, [7]University of Oldenburg, Germany, [8]University of South Australia, Australia

Abstract: The Australian Bogong moth Agrotis infusa is a remarkable nocturnal navigator. Following its emergence in early spring, millions of moths migrate over enormous distances (~1000 km) from various regions of southeast Australia to a geographically restricted assemblage of high alpine caves in New South Wales and Victoria. Once in these caves, moths enter a dormant state over the summer ("aestivation"). Towards the end of the summer, the same individuals that arrived months earlier emerge from the caves and begin the long return trip to their place of birth. Once there, these moths mate, lay their eggs and die. The next generation of moths – hatching in the following spring – then repeat the migratory cycle afresh. How do these moths find their way to the mountains? Upon which external compass cues do they rely for navigation while migrating through previously uncharted territories or environments?

In our earlier studies, we found that moths turned predictably when visual landmarks and a correlated natural Earth-strength magnetic field were turned together, but that they became disoriented when these cues were set in conflict. To test whether celestial (stellar) cues might be important as visual cues for migrating Bogong moths, we tethered moths in a flight simulator housed within a 3D array of Helmholtz coils to annul the magnetic field and occlude the magnetic sense. We also projected an image of the starry sky onto a circular screen above the moths in an otherwise visually featureless arena. We found that spring and autumn migratory moths, viewing a seasonally natural starry sky, flew in their seasonally appropriate migratory directions. Moreover, moths turned predictably in the opposite direction when the projection of the sky was rotated by 180°. When stars were randomly and evenly scrambled in the projected night sky stimulus, moths became totally disoriented. Our results suggest that Bogong moths (1) use a stellar compass for long-distance navigation, and (2) can rely on a navigational strategy whereby visual cues in conjunction with a magnetic compass create a robust system for holding a migratory bearing.

In addition to our behavioural experiments we conducted electrophysiological recordings from orientation related brain regions of intact animals while we exposed the animals to the same stimulus configuration as described above (projection of the natural starry sky and a nulled magnetic field). We were able to record directional neuronal responses to the rotation of the projection of the starry sky, but not to the rotation of a control. After the recordings, a neural tracer was injected in these neurons, allowing a subsequent morphological classification of several types of neurons encoding star compass information.

Estimates of real arthropod density in bryophytes

Authors: Drgová Michaela[2], Pyszko Petr[2] and Drozd Pavel[1], [1]University of Ostrava - Faculty of Science, Czech Republic, [2]University of Ostrava, Czech Republic

Abstract: Bryophytes provide an ideal environment for a range of bryobionts and a food source for bryophages. As climate change alters the cover of bryophytes in the environment, these changes have an impact on invertebrate communities. Density of arthropods in mosses can be difficult to evaluate, since unbiased estimates cannot be made by any standard sampling method, including the sieving. Manual inspection is the only way to do it, although it is referred to as “dirty hard work”. Our aim was to quantify the attractiveness of individual bryophytes species for bryophages and bryobionts. At 42 localities, we collected 633 quadrates of moss layer with a size of 0.25 m^2. We gathered data for > 60 species of bryophytes and obtained > 7,500 invertebrates, including > 800 bryophages. We analyzed data for the 20 most common bryophytes (area > 1 m^2, occurrence in ≥ 10 quadrates) using GLMMs. Campylopus introflexus was the most preferred bryophyte for bryobionts but hosted low densities of bryophages. Bryophages and bryobionts densities did not correlate. The exception was Pohlia nutans preferred within both groups. Our results provide the first quantified comparison of the attractiveness of individual bryophyte species for arthropods.

Transcriptome response to early EHDV-2 infection in Culicoides sonorensis: insight into viral dissemination and potential modification of midge sensory function

Authors: Drolet Barbara[2], Nayduch Dana[4], Saski Christopher[1] and K. Mills Mary[3], [1]Clemson University, United States, [2]United States Department of Agriculture, Agricultural Research Service, Arthropod-Borne Animal Diseases Research Unit, Manhattan, KS, United States, [3]University of South Carolina - Aiken, United States, [4]USDA-ARS, United States

Abstract: Female Culicoides sonorensis midges are vectors of epizootic hemorrhagic disease virus (EHDV), an orbivirus which causes morbidity and mortality in wild and domesticated ruminants. We used a comparative transcriptomics approach to identify key gene expression changes in female midges 36 h after ingesting a meal containing EHDV serotype-2 (EHDV-2). The transcriptomes from EHDV-fed and control (blood fed) midges were comprised of 18,754 unigenes. A total of 2401 unigenes were differentially expressed and ~60% were downregulated in response to the virus (953 up; 1448 down). Differentially expressed genes were analyzed by Gene Ontology (GO) enrichment, KEGG pathway mapping, and additional manual inspections in order to pinpoint the effect of virus ingestion at both the gene and pathway levels. A large number of downregulated unigenes were assigned to pathways related to cell/tissue structure and integrity, such as actin cytoskeleton, adherens junction, focal adhesion, and hippo signaling, which taken together may give insight into the process of early virus dissemination. Surprisingly, many downregulated unigenes also were associated with GO terms and KEGG pathways for eye morphogenesis and axon guidance. Manual inspection assigned these unigenes to a variety of sensory functions, especially vision, behavior, learning and memory, indicating that EHDV-2 may have a significant phenotypic effect on sensory and neural tissues, and presumably their function. Upregulated unigenes included those coding for innate immune processes, which may be involved in midge antiviral defenses, as well as photoreceptor pigments and odorant binding proteins, which presumably were upregulated in response to alterations of the other sensory systems. Our study presents the first insight into an orbivirus-induced phenotype in its primary vector and further suggests that EHDV-2 may significantly modify midge sensory function and, consequently, host seeking. EHDV-induced behavioral modification in midges is being explored further in order to better understand how virus infection impacts host seeking and feeding, which could have wide-reaching impacts on the design of collection and control methods.

Transcriptome responses of virus-transmitting aphid vectors are shaped by the host plant and the virus mode of transmission

Authors: Drucker Martin[1], Chesnais Quentin[2], Verdier Maxime[1], Velt Amandine[1], Brault Véronique[1], Pooggin Mikhail[1], Golyaev Victor[1], [1]INRAE, [2]Université de Strasbourg, INRAE, SVQV UMR-A1131, Colmar, France

Abstract: Viral infection often modifies plant phenotypical traits with consequences on insect-host interactions. There is evidence that these changes can improve virus transmission, in which case one may speak of ‘pathogen manipulation’. How viral plant manipulation translates into changes in vector behavior and performance is largely unknown. It is assumed that most of the modifications are indirect, i.e. aphids and other vectors respond to virus-induced changes in the plant. But recent reports are indicating that not only host plant-mediated changes but also direct virus-mediated changes in aphids are to be considered. While virus-mediated effects on aphids and other hemipteran vectors are well documented, we have only a nascent understanding of how viruses are controlling vectors and which genes are involved. In this study, we were interested to see whether the virus mode of transmission (circulative vs. non-circulative viruses) influences the aphid transcriptome changes. Another objective was to highlight common and virus- as well as plant-specific effects on a vector. We first show a strong plant-specific response of aphid transcriptome, likely related to the hosts’ different susceptibilities to the viruses studied. We also found that stress-related aphid genes were downregulated on both infected plants (regardless of the virus). This suggests that viral infections facilitate the colonization of vectors on the plants. Our results also indicate virus-specific gene expression changes, which might be related to the virus mode of transmission. Overall, the circulative virus tended to affect genes involved in the development, whereas the non-circulative virus had a stronger impact on feeding-related genes.

The charismatic praying mantis: A gateway for insect conservation.

Authors: du Plessis Hannalene[1], Greyvenstein Bianca[2] and Van den Berg Johnnie[1], [1]North-West University, South Africa, [2]Unit for Environmental Sciences and Management, North-West University, Potchefstroom, South Africa

Abstract: Praying mantids (Mantodea) are not only apex predators with a “mystical‘’ status but are also regarded as a kind of oracle and in some cultures as omens associated with bad or good. The cultural, mystical and religious values allocated to mantids over millennia can in future contribute not only to their own conservation but also to conservation of arthropods in general. Historically, Mantodea influenced African, Greek, Egyptian, Japanese and Chinese cultures and they impacted human culture in a variety of ways, for example, coin designs, hairstyles, swords, death rituals, war strategies and even modern music, advertisements and children’s books. Despite human fascination with mantids, this group of arthropods is unfortunately overlooked in terms of conservation and research. Conservation as a mitigation strategy to protect threatened and endangered species is influenced by philosophical and psychological aspects more than a pure scientific approach. This paper highlights the role of praying mantids in human culture and the historical relationships between humans and other arthropods. Acknowledgement of these cultural aspects of the Mantodea may contribute to a positive change in people’s perceptions of arthropods and eventually insect conservation. It is suggested that Mantodea could be used as a flagship or gateway species to further awareness of insect conservation. By building on the existing “global” cultural values, fascination and intrigue of the charismatic mantis, this can be used to generate much needed insect appreciation and wonderment of the small things that run the world we live in.

Resistance of Busseola fusca and Spodoptera frugiperda and other lepidopteran species to Bt maize: implications for IRM in Africa

Authors: du Plessis Hannalene[2], Van den Berg Johnnie[2], Erasmus Annemie[1], Strydom Elrine[1] and Botha Luan[2], [1]Agricultural Research Council, South Africa, [2]North-West University, South Africa

Abstract: Many lepidopteran species attack maize in Africa. Spodoptera frugiperda, the fall armyworm (FAW), invaded Africa during 2016 and is now considered the number one maize pest on the continent. The destructive feeding habits of FAW and a wide range of indigenous lepidopteran pests threaten maize production in Africa. Since stem borers and FAW larvae occupy virtually the same ecological niche, and Bt maize is effective against both these and several other lepidopteran pests, this technology provides a tool for their management. Bt maize that express Cry proteins have been used effectively for control of this pest in the United States, Canada, and several countries in South America. Although most Cry proteins provide effective control of the FAW, this pest evolved resistance to Cry1F Bt maize in Puerto Rico, Brazil and United States, and Cry1Ab Bt maize in Brazil. The African maize stem borer, Busseola fusca, also evolved resistance to single- and pyramid events in South Africa. Monitoring of resistant and proactive management of resistance evolution is therefore required. This study reports on the efficacy of single- and pyramid-gene Bt maize against the lepidopteran pest complex of maize in Africa. The efficacy of Bt maize for the control of S. frugiperda, Spodoptera exempta, B. fusca, Eldana saccharina, Leucania loreyi, Helicoverpa armigera and Chilo partellus was determined by means of larval feeding bioassays in which plant tissue of maize expressing Cry1Ab (single-toxin event) or Cry1A.105 + Cry2Ab2 (pyramid-toxin event), were fed to larvae. Results indicated moderate levels of survival of FAW (4-35%) on Cry1Ab maize and very high levels of mortality on the pyramid event. All the other lepidopteran species were highly susceptible to both Bt maize events. This study provides information on the efficacy of Bt maize against most of the lepidopteran species that damage maize in Africa.

The effect of temperature on the development of Spodoptera frugiperda (Lepidoptera: Noctuidae) in South Africa

Authors: du Plessis Hannalene[2], Van den Berg Johnnie[2] and Schlemmer Marie-Louise[1], [1]Insect Science (Pty) Ltd, Tzaneen, South Africa, [2]North-West University, South Africa

Abstract: The fall armyworm, Spodoptera frugiperda, is native to the tropical and sub-tropical regions of the Americas, but also spread to Africa, Asia and Australia. The effect of temperature on the development of S. frugiperda was studied at five different temperature regimes, namely 18, 22, 26, 30 and 32 ± 1 °C. Fertility was found to be high with all eggs that hatched at temperatures ranging between 18 to 32 °C. Development of eggs at a constant temperature of 18 °C was, however, slow and the percentage of eggs that hatched, very low. Continuous low temperature, although above the lower thermal limit, will therefore delay development and reduce population numbers as a result of high mortality. The optimal range for egg, larval and egg-to-adult development of S. frugiperda was between 26 and 30 °C. Development rate of S. frugiperda increased linearly with increasing temperatures between 18 and 30 °C and larval survival was also the highest between 26 and 30 °C. The optimum temperature with the fastest development rate and lowest mortality for larvae was at 30 °C. Pupal development period ranged between 7.82 to 30.68 days (32 – 18 °C) with a mean pupal development time of 17.06 days at 22 °C. Larvae took only 11.43 days to complete their cycle at 26 °C. Development period from eggs to the adult stage decreased from 71.44 at 18 °C to 20.27 days at 32 °C. Based on linear regression analyses of development rate at all temperatures, a minimum temperature threshold of 13.01 °C was calculated for egg development and 12.12 °C for larvae, 13.06 °C for pupae and 12.57 °C for egg-to-adult development. Degree-day requirements for S. frugiperda egg and larval development was 35.68 ± 0.22 and 204.60 ± 1.23 °D respectively. Pupae needed 150.54 ± 0.93 °D for development while for egg-to-adult development (life cycle) 391.61 ± 1.42 °D were required.

Tuta absoluta base line susceptibility and resistance to insecticides in South Africa

Authors: du Plessis Hannalene[1], Kleynhans Gerhard [2] and van den Berg Johnnie[2], [1]North-West University, South Africa, [2]Unit for Environmental Sciences and Management, North-West University, SA

Abstract: Insecticide resistance by Tuta absoluta threatens tomato production worldwide. Heavy reliance on chemical control resulted in resistance evolution to the main insecticides used in South America, Europe and Asia. It was not known if the pest population that invaded South Africa in 2017 carried insecticide-resistance alleles. The aim of this study was to estimate baseline insecticide susceptibility of T. absoluta and to monitor if shifts in susceptibility occurred over the first five years after invasion. Populations were collected from three localities in South Africa in 2019, 2021 and 2022. Susceptibility testing with commercial formulations of insecticides was done according to the IRAC method 022. Data from populations collected in 2019 and 2021 serve as baseline data and are used in resistance monitoring. Two populations sampled in 2022 exhibited high levels of resistance to the diamides, chlorantraniliprole and flubendiamide, and indoxacarb. This rapid evolution of resistance to chlorantraniliprole and indoxacarb and cross resistance to flubendiamide is ascribed to off-label misuse of chlorantraniliprole and indoxacarb.

Biological control in the aftermath of invasion: a case study with an invasive forest pest

Authors: Duan Jian, USDA ARS Beneficial Insects Introduction Research Unit 501 South Chapel Street Newark, DE, United States

Abstract: The emerald ash borer (EAB) (Agrilus planipennis) was accidentally introduced to North America from Asia during the 1990s. Despite early efforts by U.S. and Canadian regulatory agencies to eradicate and contain EAB, it has continued to spread and cause economic damage to ash nursery stock and the lumber industry, degradation of ash forests, and reduction in ecosystem functions in ash forests in North America. The classical biocontrol program against EAB, which started over a decade ago with the introduction and establishment of co-evolved natural enemies from the pest's native range, has shown the ability to suppress EAB to lower densities, which may allow North American ash species in hardwood forests to recover and regenerate in the aftermath of the EAB invasion. This program has now documented successful establishment of the egg parasitoid O. agrili and the two larval parasitoid T. planipennisi and S. galinae in EAB-infested forests at most release sites in the northern United States, in areas where surveys to document parasitoid establishment have been conducted. While the role of O. agrili in suppressing EAB population growth requires continued evaluation, the larval parasitoids T. planipennisi (from China) and S. galinae (from the Russian Far East) have become the dominant biotic factors suppressing EAB population growth rates and significantly reducing EAB densities in the aftermath forests in Michigan and several northeastern states, where these parasitoids were released between 2007 and 2017. EAB densities at these biocontrol study sites are now sufficiently low (<10 larvae per m2 phloem area) to allow the surviving trees and saplings to recover and grow to canopy trees, reaching the overstory (Duan et al. 2015b, 2017a, 2021b). Here, we examine the ecological premise of EAB natural enemy introductions, and review the development, implementation, impacts, and challenges in conserving native Fraxinus using biocontrol in the aftermath of the EAB invasion throughout North America. We conclude that successful establishment, spread, and impact of three of the EAB biocontrol agents, T. planipennisi, S. galinae, and O. agrili in Michigan and several Northeastern states (Connecticut, Massachusetts, and New York) in the aftermath forests following EAB invasion, have resulted in low EAB densities, which may allow surviving ash trees to gradually recover, regenerate, and grow into the forest canopy.

Colorado potato beetle semiochemistry: new complexity and potential for field application

Authors: Duan Jian[3], Haber Ariela[2] and Weber Donald C.[1], [1]U.S. Dept. of Agriculture, Agricultural Research Service, Invasive Insect Biocontrol and Behavior Laboratory, Beltsville, Maryland, United States, [2]USDA Agricultural Research Service, Invasive Insect Biocontrol and Behavior Laboratory, United States, [3]USDA ARS Beneficial Insects Introduction Research Unit 501 South Chapel Street Newark, DE, United States

Abstract: Demand for intensive production of potato, the world's fifth most important staple food outside the lowland tropics, has led to unsustainable pest management practices (i.e., frequent applications of many insecticides), provoking evolution of spectacular pesticide resistance by the key potato pest, Colorado potato beetle, in many growing regions. The result of such resistance is the near-permanent loss of once-effective insecticides and more expensive and in many cases excessive pesticide use. These impose risks to human health, non-target beneficial organisms, and the non-crop environment.

Sustainable potato culture where the beetle is present should rely on integration of multiple control tactics to reduce pesticide applications to a necessary minimum. Cultural and biological methods have been underutilized, provoking quick adaptation or evolution of resistance by beetle populations to pesticides with new modes of action. This situation has been likened to the pursuit of the “Red Queen” by Alyokhin et al. in a recent review. Moreover, insights by Jermy, Visser, Dickens, and other researchers have elucidated the beetle's behavioral response to plant and insect semiochemicals, offering opportunities for management that have until now gone largely untapped.

Here we investigated whether male mate-finding behavior was altered based on previous exposure of potato plants to female, male, or no adults. We found that in no-choice tests, virgin males walked for a longer time, undertook more transitions between walking and stopping with antennae up, visited more leaves, and departed more slowly from female-exposed plants than from male-exposed or unexposed plants. When presented leaves from female-exposed, male-exposed, and unexposed plants simultaneously in a three-way choice test, virgin males exhibited behavior consistent with that in no-choice tests. In particular, virgin males spent more time overall, and undertook more transitions between walking and stopping with antennae up, on the female-exposed plants than on male-exposed or unexposed plants. These results indicate a preference for plants containing female-specific residues, which can increase the probability of mate-finding by male beetles. These findings therefore provide insight into which chemical cues mediate attraction and retention of male beetles on potato plants.

With prior knowledge of the male-produced aggregation pheromone, as well as new discoveries by our laboratory concerning female-produced pheromone altering male beetle searching behavior, we propose to develop a new sustainable Colorado potato beetle management strategy that integrates cultural and behavioral controls with infrequent applications of selective chemical or microbial controls. This strategy would control this key potato pest while minimizing resistance selection and conserving natural enemies.

Effects of landscape vegetation productivity and managed pollinators on avocado (Persea Americana Mill.) fruit set in Muranga, Kenya

Authors: Dubois Thomas[2], Toukem Nadia Karelle[3], Yusuf Abdullahi[5], Lattorff Michael[4] and Mohamed Samira[1], [1]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [3]International Centre of Insect Physiology and Ecology, Nairobi, Kenya; The University of Pretoria, South Africa, [4]University of Nairobi; Martin-Luther-University Halle-Wittenberg, [5]University of Pretoria, South Africa

Abstract: Insect pollinators provide a critical ecosystem service, yet there is mounting evidence of a global pollinator decline. The effect of interactions between managed and wild pollinators on crop production is inadequately investigated. Avocado, Persea Americana, is an important pollinator-dependent crop grown mainly by smallholders in East Africa. Managed avocado pollination could contribute to closing yield gaps present in African smallholder agriculture. We conducted a study in smallholder avocado farms in Muranga, Kenya to assess effects of managed honeybees on local wild pollinators and fruit set across the three classes of vegetation productivity, viz., low, medium at a landscape scale. The normalized difference vegetation index (NDVI) which is the greenness indicator was used as a proxy for the vegetation productivity. Multi-date Sentinel-2 satellite data were used to estimate the index. Two types of treatments (presence and absence of honeybee (Apis mellifera) hives) were implemented each in distinct avocado farms at the beginning of the blooming period in August 2019 and repeated six-fold within each vegetation productivity class. Flower visitors were sampled during the peak bloom (September 2019). The number of fruits was recorded three weeks after flower marking and counting.

Flower visitors distributed into 21 families, one superfamily and 54 species were captured during the peak bloom period. The most abundant visitors were represented in Apidae (55%), Syrphidae (13%), Muscoidea (10%), Calliphoridae (8%) and Halictidae (1%). The abundance of wild visitors (i.e. excluding honeybees), honeybees, and species richness were compared between vegetation productivity classes and treatments. There was a significant interaction ($P = 0.023$) between vegetation productivity class and treatment on the abundance of wild visitors. Wild visitors were relatively more abundant in medium and high vegetation productivity classes supplemented with hives than in the low class with hives. Landscape vegetation productivity significantly influenced ($P = 0.0099$) species richness of flower visitors. The abundance of honeybees did not vary significantly across vegetation productivity classes and treatments ($P = 0.14$). Species richness was higher in high and medium NDVI than low NDVI. A mixed beta regression showed that only vegetation productivity significantly influenced fruit set ($P = 0.0019$). Fruit set was higher in high vegetation productivity (13%), followed by that in medium (10%) and low (9%) classes. Wild visitors seem to play a role in avocado pollination and seem not affected by managed honeybees. An increase in landscape vegetation cover should be adopted to support wild pollinators and optimize avocado pollination.

Bacillus thuringiensis Spores and Cry3A Toxins Act Synergistically to Expedite Colorado Potato Beetle Mortality

Authors: Dubovskiy Ivan[2], Tereshenko Dasha[3], Grizanova Ekaterina[3], Kabilov Marsel[1] and Krytsyna Tania[3], [1]Institute of Chemical Biology and Fundamental Medicine, Siberian Branch of Russian Academy of Science, Novosibirsk, Russia, [2]Novosibirsk State Agrarian University, Siberian Federal Scientific Centre of Agro-Bio Technologies of the Russian Academy of Sciences, Russia, [3]Novosibirsk State Agrarian University, Russia

Abstract: Bacillus thuringiensis (BT) is a widespread bacterium that has been developed as a biopesticide to control insect pests attacking crops as well as disease vectors such as mosquitoes. The insecticidal activity of Bt is primarily due to proteinaceous crystal endotoxins (Cry), which are produced during sporulation and activated by the host's gut fluids. BT virulence factors also include enterotoxins, hemolysins, phospholipases and metalloproteases, which are transcribed in the vegetative cells and play an important role in the infection process. At the same time, the midgut microbiota may be an additional factor enhancing the virulence of the bacteria BT. The Colorado potato beetle Leptinotarsa decemlineata (CPB) is an important pest that can be control with biological preparations based on BT bacteria. Uncovering of BT virulence factors activity in midgut, as well as the participation of host defense systems is necessary for further improvement of biological preparations and their field application strategies. The BT enters the insect host via the mouth and must thwart the gut-based defences to make its way into the body cavity (haemocoel) and establish infection. We sought to uncover the main antibacterial defences of the midgut and the pathophysiological features of Bt in a notable insect pest, the Colorado potato beetle. Exposing the beetles to both Bt spores and their Cry3A toxins (crystalline δ-endotoxins) via oral inoculation led to higher mortality levels when compared to either spores or Cry3A toxins alone. Within 12 hours post-exposure, Cry3A toxins caused a 1.5-fold increase in the levels of reactive oxygen species (ROS) and malondialdehyde (lipid peroxidation) within the midgut – key indicators of tissue damage. When Cry3A toxins were combined with spores, gross redox imbalance and 'oxidation stress' were apparent in beetle larvae. The insect detoxification system was activated when Bt spores and Cry3A toxins were administered alone or in combination to mitigate toxicosis, in addition to elevated mRNA levels of candidate defence genes (pat-tern-recognition receptor, stress-regulation, serine proteases, and prosaposin-like protein). The presence of bacterial spores and/or Cry3A toxins coincided with subtle changes in microbial community composition of the midgut, such as, decreased Pseudomonas abundance at 48 hours post inoculation. Both Bt spores and Cry3A toxins had negative impacts on larval health, and when combined, likely cause metabolic derangement due to multiple tissue targets being com-promised. This work was supported by the Russian Science Foundation grant No. 22-16-20031.

Moving like a model: high-speed videography reveals locomotor mimicry of hymenopterans by clearwing moths- novel morphological mimicry features

Authors: Dudley Robert[4], Skowron Volponi Marta[3], McLean Donald[2] and Volponi Paolo[1], [1]ClearWing Foundation for Biodiversity, Poland, [2]Department of Biological Sciences, Macquarie University, Sydney, Australia, [3]Laboratory of Insect Evolutionary Biology and Ecology, Faculty of Biology, University of Bialystok, Poland, [4]University of California, Berkeley, United States

Abstract: Clearwing moths (Lepidoptera: Sesiidae) have long been known for their physical resemblance to hymenopterans, which was, due to their elusive nature, described mainly from pinned specimens. We studied new species of clearwing moths in their habitat – lowland dipterocarp rainforests of Southeast Asia – using high-speed videography in the field to reveal novel behavioural and morphological features. After having observed that clearwing moths in flight are nearly indistinguishable from their hymenopteran mimicry models, we filmed flight trajectories of both bee and wasp mimics, as well as those of sympatric species of bees and wasps. Trajectories' digitization and comparisons revealed that bee mimics have slower, more zigzaggy and irregular flight paths, whereas wasp mimics fly faster, less erratically and in a straighter trajectory, as do wasps. These findings represent the first experimental evidence for behavioural mimicry in clearwing moths. Additionally, slow motion filming allowed us to determine the body posture of insects in flight: bees and bee mimics hold their hind legs hanging downwards in flight, whereas the studied wasps and wasp mimics kept their legs folded against their body. Some bee-mimicking Melittia Hübner species use their strongly tufted, long hind legs to maneuver in flight and to stabilize their body when perching on a surface with their front legs to reach liquids with their proboscis. Finally, high-speed videography shows that a newly described spider wasp mimic, Melanosphecia paolo Skowron Volponi, has an illusion of a narrow wasp waist formed by matching white colouration on the abdomen, inner side of hind legs and inner margin of the hindwing, on the otherwise metallic blue sesiid. Modern filming techniques can thus reveal a number of remarkable adaptations in insects, serving e.g. as a tool to broaden our understanding of the complex mimicry systems in the family Sesiidae.

Mechanistic insights for prostate disease: Lepidoptera sp' actives targeting human cells' inflammation and oxidative balance impairment

Authors: Dumitriu Brindusa[2], Olariu Laura[2], Ene Manuela Diana[1], Papacocea Raluca Ioana[1], Tanase Mariana Luiza[1], [1]BIOTEHNOS, [2]SC BIOTEHNOS SA, Romania,

Abstract: The concept of natural drug design has valuable, but less capitalized resources in entomological compounds, based on the structural similarity between insects' active substances interacting with human receptors. Our studies have pointed out therapeutic solutions in an interrelated „in vitro" screening encompassing vascular and prostate inflammation and oxidative processes. Human standardized cell line (PWR-1E - ATCC® CRL-11611™ from prostate dysplasia and vascular endothelial cells HUVEC-C- ATCC® CRL-1730™) and positive controls (Dutasteride 10mM, Dexamethasone 200ng/ml, N-Acetyl-Cysteine 0.5mM) were used, in order to confirm the mechanisms of action for two types of entomological compounds extracted from Lepidoptera sp.: polypeptides and hormone-like compounds. The pro-inflammatory status was induced by a cocktail of TNFa, a powerful, systemic stimulus, and PMA, a pro-inflammatory and pro-oxidative inducer, creating the premises of simultaneous oxidative stress induction. On prostate cells were investigated processes directed by IL6, IL8 cytokines release, concurrent with changes in intrinsic and extrinsic oxidative status: reactive oxygen species and the first defense enzymes catalase / superoxide-dismutase balance, as well as glutathione, the key – molecule for the cellular self- antioxidant protection. Considering the role of the vascular network in the appropriate functionality of prostate, our studies applied on HUVEC cell line focused on effects of entomological compounds on cellular oxidative homeostasis (H2O2 / O2- and intracellular glutathione) and inhibition of inflammation trigger (expression of ICAM-1 and VCAM-1, monocytes – endothelium adhesion molecules and IL6 / IL8 signaling). The accuracy of results was assured by the convergent mechanisms investigated, as well as the specificity and reliability of antigen – antibody binding combined with flow cytometry. Studies have led to the identification of new therapeutic targets for prostate dysfunctions, modulated by entomological water-soluble complex: catalase and H2O2 re-balance (106-240% catalase; 30-83% H2O2); and hormone-like liposoluble compounds: intracellular glutathione recovery (34-64%); superoxide-dismutase activation and O2- decrease (66-80% for SOD and 10-46% for O2-); IL8 inhibition (6-27%). The therapeutically impact is augmented by their vascular action: intrinsic antioxidant system stimulation (increase of glutathione) and inflammatory processes inhibition through reduced release of IL6 (21-56%) and expression of both soluble and membrane forms of ICAM-1 (10-17%). Research project SMIS 122180 - contract no. 256/2020

Genetic diet specialisation in phytozoophagous and zoophytophagous mirids

Authors: Dumont François, Centre de recherche agroalimentaire de Mirabel, Canada

Abstract: The Miridae have a true omnivorous diet that includes varying proportions of animal and plant resources. Species belonging to this family can therefore be classified on a spectrum varying from phytozoophagy to zoophytophagy according to the relative proportion of plant and animal resources in their diet. The differences in diet composition can be as important within the species, than between species. Genetic variability in omnivorous populations generate diet specialization (individuals of the same population may consume different proportion of available resources). Here, we compare genetic diet specialisation among two North American species of Miridae, namely the tarnished plang bug Lygus lineolaris and Dicyphus hesperus. These species form a spectrum from phytozoophagous to zoophytophagous. The consequences of genetic diet specialisation in these economically important species in agricultural environments is discussed.

Efficiency of indigenous Nabis americoferus against tarnished plant bugs and aphids in greenhouse

Authors: Dumont François[1], Labrie Genevieve[1], Solà Mireia[2] and Provost Caroline[1], [1]Centre de recherche agroalimentaire de Mirabel, Québec, Canada, [2]Laboratoire de Lutte Biologique, Biological sciences department, Université du Québec à Montréal (UQAM), Canada

Abstract: The damsel bug, Nabis americoferus (Carayon) (Hemiptera: Nabidae) is a polyphagous predator indigenous to North America and commonly found in many crops. Nabis species can feed on several important agricultural pests such as the tarnished plant bug (TPB), Lygus lineolaris (Palisot de Beauvois) (Hemiptera: Miridae) or aphids such as Myzus persicae (Sulzer) and Aphis gossypii (Glover) (Hemiptera: Aphididae). Both insect groups are pests of greenhouse crops and can impede high economic damage. The objective of this study was to evaluate the efficiency of this indigenous predator against TPB and A. gossypii in cucumber in greenhouse. This species is one that have been targeted for the development of new biological agent for Canada greenhouses. Experiments have been done in cages in greenhouse. Five cucumbers have been grown in cages, and 3 adults N. americoferus were introduced in cages with cucumber plants initially infested with: 1) 5 TPB/plants, 2) 25 A. gossypii/plants or 3) a mixture of both. A control with the mixture of preys but without the predator was also prepared. After six weeks, the three populations were evaluated. First results showed that at an introduction rate of 3 Nabis per 5 plants failed to control TPB or aphids. Nabis population was highest in presence of both type of preys, suggesting that this predator benefits from a mixture of preys. This predator could be a good biological control agent, but further experiments are needed to evaluate properly the introduction rate and the timing of introduction in greenhouse.

Evaluation of Tarnished plant bug responses to the risk of predation in the presence of Nabis americoferus

Authors: Dumont François[1], Labrie Genevieve[1], Solà Mireia[2], Lucas Eric[3] and Provost Caroline[1], [1]Centre de recherche agroalimentaire de Mirabel, Québec, Canada, [2]Laboratoire de Lutte Biologique, Biological sciences department, Université du Québec à Montréal (UQAM), Canada, [3]Université du Québec à Montréal, Canada

Abstract: The Tarnished plant bug (TPB), Lygus lineolaris (Palisot de Beauvois) (Hemiptera: Miridae) is a major pest in North America. This species threats more than 120 economically important plants, possesses a high reproduction rate and shifts from phytophagy to zoophagy according to the situation. Overall, the presence and high complexity of this species prevents growers to convert to organic agriculture. Currently, to control this pest, the potential of the polyphagous predator naturally present in TPB host crops, Nabis americoferus (Carayon) (Hemiptera: Nabidae), is being evaluated. The effectiveness of predation can be affected by several factors such as handling time, presence of alternative preys or pest response to the risk of predation that needs to be also considered for an optimal biological control strategy. Pest responses to the risk of predation can imply changes in diet preferences, location or resource investment. Then, the objective here is to assess TPB responses to the risk of predation in the presence of N. americoferus.

First results on the effectiveness of the predator have shown that N. americoferus is able to predate on every stage of TPB, is highly voracious and follows a functional response type III that saturates with the ingestion of 13 preys when 20 TPB are offered for 24h. This saturation is much lower when feeding on aphids. On the other side, a greenhouse experiment on cucumber plants has revealed, that after 6 weeks, TPB may invest producing high offspring in the presence of the predator, especially when other preys are not available. Experiments to assess TPB trophic choices, location and number of offspring in the presence of the predator and alternative preys are currently being conducted in controlled arenas. It is expected that in the presence of Nabis, TPB will adapt his choices to evade the risk of predation. Fresh results will be presented during the conference.

Aedes aegytpi and the use of natural molecules for its control

Authors: Duque Jonny[2] and Méndez Stelia[1], [1]Industrial University of Santander “Centro de Investigaciones en Enfermedades Tropicales (Cintrop). Departamento de Ciencias Básicas. Escuela de Medicina Parque Tecnológico y de Investigaciones”, [2]Professor, Colombia

Abstract: To impact on the suppression of diseases like the Chagas, Zika, dengue, and chikungunya are necessary that all activities of vector control converge in a system smart and exclusive for this goal. That means that many people, like scientific, politics, sociologists, environmentalists, and ordinary people, must be contributing to joining forces to get the goal of mosquito suppression. According to this philosophy, here are we wish to present information focused on our understanding of the discovery of natural molecules to be used by many people implicated in the world of mosquito control. In this sense, this presentation will have information not only understandable to the specialist in the topic, but also for the regular people who suffer from the problem and have no knowledge of how to protect themselves against mosquitoes in their homes.

Product development with entomological application in collaboration with industrial designers

Authors: Duque Jonny[2], Parra Hector[2], Peña Jessica[1], Vidal Maria[1] and Aranda Monica[1], [1]Industrial Designer, Colombia, [2]Professor, Colombia

Abstract: Objective.Show the Importance of transdisciplinary work to create new technologies of scientific interest in entomology. Case: Devices for pest control in public health with input from entomologists and industrial designers. Materials and Methods.We use the scientific method as a line of thinking with students of biology, chemistry and industrial design, as well as PhD in entomology, chemistry and Ms.C in industrial design. In “Trap for capture and monitoring of Aedes aegypti 2011 (WO / 2014/167553) hypotheses were tested with functional models made by industrial designers to determine the mosquito’s preference for oviposition. Trap models with circular, square and triangular section shapes, materials, input characteristics, color, size, capture system and leakage reduction were tested. Following the scientific method treatments and replicas were located, periodic readings, review of results and statistical analysis were made, to make incremental changes until traps with product attributes were reached. Results. For the oviposition of Aedes aegypti it was observed that the shape and size of the trap is not important. The mosquito prefers the red color for the body of the trap. The entrance has color contrast between red and black. The trap allows live mosquitoes to be taken to the laboratory. In the field the trap has a red color and in the laboratory it is translucent. In “Household trap for insects” (2013) WO / 2016/075624, the mosquito has a 78% preference for red traps. Translucent windows with holes allow mosquito to remain in it. In the “Trap for capture and death of culicides” (2016) (patient pendin), it was discovered that a large funnel-shaped entrance facilitates entry and prevents the escape of mosquitoes. Discussion.The publication Desing and Testing of Novel Lethal Ovitrap to reduce Populations of Aedes Mosquitoes. https://doi.org/10.1371/journal.pone.0160386.g001, helps to know the design of the trap. They do research involving entomologists, epidemiologists, social scientists and design engineers. They Built prototypes and experimented in the laboratory. Is a process similar to ours, however, in the design of the trap the aesthetic factors, size and shape, determined them according to community opinions. In our case, the characteristics of the traps are subject to experimental verification, to avoid subjectivity in decision making. In this process is no participation of Industrial Designers. The publication Exacta –EP, São Paulo, v. 15, n. 3, p. 515-526, 2017. ISSN: 1678-5428 of Brazil, identifies the articles published on the Web of Scienci since 1980 to 2014, there is no evidence of collaborative work between Entomology and Industrial Design. Conclusions. Works of devices for pest control in public health with a collaborative approach to Entomology and Industrial Design is little known. The Industrial Design contribution determine in the products the functions practices, aesthetics and symbolic.

Enzymatic defense responses of aphids and their host plants to stress caused by an increase in air temperature

Authors: Durak Roma[1], Dampc Jagoda[3], Dampc Jan[2] and Durak Tomasz[3], [1]Department of Biology, University of Rzeszów, Poland, [2]Department of Experimental Biology and Chemistry, University of Rzeszów, Poland, [3]Department of Plant Physiology and Ecology, University of Rzeszów, Poland

Abstract: It has been observed in recent years that climate change can affect plants and herbivorous insects. An increase in temperature can indirectly affect insects by changing quality of host plant tissues or directly affecting their biology. So far, little research has addressed the problem of the interactive impact of abiotic and biotic stress on the defense mechanisms and effectivity of a plant, and the direct effect of a rise in temperature on herbivorous insects. The work is aimed at explaining how the plant reacts to abiotic stress caused by elevated temperature and additional biotic stress caused by feeding aphids and also explains how the aphid responds to abiotic stress caused by temperature rise.

Experiments in climatic chambers at three temperatures: 20, 25 and 28 °C were carried out to detect changes in developmental stages, demographic parameters and insect fertility. The activity of enzymatic markers (SOD, CAT, GST, ß-glucosidase, PPO, POD) in the tissues of the host plant and tissues of aphids Aphis pomi were determined.

An increase in air temperature to 28 °C significantly negatively affects the biology of A. pomi, with a shortening of the reproduction period, total lifespan; reducing population demographic parameters and fertility by half. The increase in temperature and foraging of sucking insects, act additively, causing a synergistic defense effect on the plant. Both the plant defense responses and the aphid’s defense responses differed significantly depending on the temperature.

Novel Functions of Ammonia Transporters During Mating and Reproduction in the Adult Aedes Aegypti Mosquito

Authors: Durant Andrea[1], Donini Andrew[1], [1]Department of Biology, Faculty of Science, York University, Canada

Abstract: In the present study, we explored the function of ammonia ($NH3$ and $NH4+$) transporters during blood meal digestion, reproduction, and egg laying in mosquitoes. Shortly after emergence of adults of the disease vector mosquito, Aedes aegypti, a female will pair with a male in flight for copulation whereby the male inseminates the female with sperm and seminal fluid. The female will then imbibe a large protein-rich blood meal for egg development and will excrete unutilized digested protein as nitrogenous wastes. Whilst terrestrial animals typically excrete nitrogenous wastes as uric acid and/or urea because ammonia is toxic at low concentrations, A. aegypti excrete ammonia as their primary nitrogenous waste. The organs and molecular mechanisms involved in ammonia transport and excretion during blood meal digestion and egg development in the adult mosquito are not fully understood. A. aegypti possess at least four specific ammonia transporters; two Rhesus glycoproteins (Rh proteins), AeRh50-1 and AeRh50-2, which are vertebrate homologs and two ammonium transporters (Amts), AeAmt1 and AeAmt2 which are plant, fungal, and bacterial homologs. In blood-fed females, we show that hemolymph $NH4+$ levels and $NH4+$ transport rates by the renal Malpighian tubules (MT) are significantly elevated up to 48 hr post blood meal (PBM), measured using ion-selective micro-electrodes and the Ramsay assay for analysis of MT secretions. We also show that the MTs, hindgut, and fat body most abundantly express Rh and Amt in non-blood fed adult females determined using immunolocalization and qPCR. AeAmt1 is almost exclusively localized in the flagella of the sperm during all stages of spermatogenesis, including mature sperm stored in the spermathecal organs of the inseminated female. Using immunohistology and RNA in-situ hybridization, we demonstrate that AeRh50-1 mRNA and protein is expressed within the nurse cells and follicular epithelium surrounding the developing oocyte during egg development, as well as having high expression in the hindgut epithelium. RNAi studies employing dsRNA injections of adult mosquitoes targeting Amt and Rh protein knockdown suggest integral roles of ammonia transporters in sperm viability and fecundity demonstrated by significant decreases in egg laying and larval hatching, with no effect on blood-fed adult female survival, as a result of Amt and Rh protein knockdown.

Nature conservation considering vector ecological burdens – an interdisciplinary view on cases studies from Germany

Authors: Dworrak Tarja Viviane[1] and Kiel Ellen[2], [1]University of Oldenburg, Germany, [2]University of Oldenburg Institute for Biology and Environmental Sciences Research Group Aquatic Ecology and Nature Conservation, Germany

Abstract: This research project focuses on one of the conflicts in wetland management. On the one hand conservation measures can benefit biodiversity. On the other hand, these measures may create stagnant water pools, which can offer suitable habitats for mosquito immatures. Mosquitoes are well known as nuisance species and carriers of infectious diseases. If nuisance mosquito species disperse numerously from wetlands to residential areas and health concerns arise, the public could then demand systematic mosquito control. Systematic mosquito control, principally control with insecticides, can affect non-target organisms and interfere with conservation goals. Knowledge about present mosquito species, their nuisance potential and the effects of wetland conservation on mosquitoes is important. However, particularly in Central Europe, this knowledge is still missing. Therefore, we studied mosquitoes before and after the implementation of conservation measures in selected wetlands in Germany from 2019 to 2021. We evaluated if and to what extent mosquito abundance, development and composition change after wetland conservation measures in wetlands along the river Danube in southern Germany and the Müritz national park in eastern Germany. In one of the four study areas at the river Danube, we noticed a marginal increase in mosquito numbers. While in other areas at the Danube and the Müritz, numbers maintained the same as before the measures. Derived from our observations, we cannot entirely exclude that conservation measures in wetlands benefit mosquitoes. Mosquito control, especially in Central Europe, usually means applying Bacillus thuringiensis var. israelensis (Bti). Bti has lethal effects on the mosquito immatures and is regarded to be the most specific agent. The impacts of Bti on non-target organisms such as chironomids and the ecosystem itself are still discussed in science. Establishing an expertise on mosquito species-specific reactions to conservation measures, can support targeted mosquito control. Additionally, the wetland type and local conditions might play an eminent role for this species-specific control and help future wetland conservation projects.

Latitudinal gradients in tritrophic interaction diversity.

Authors: Dyer Lee[1], Salcido Danielle[1], [1]Biology Department EECB Program University of Nevada Reno, United States

Abstract: Latitudinal gradients in diversity and specialization have revealed strong patterns of increased diversity and specialization towards the equator. Depending on the strength of these two gradients, interaction diversity and associated ecosystem function may exhibit nonlinear changes along latitudinal gradients. For example, interaction diversity may decrease as specialization increases towards the tropics, but then as diversity increases more rapidly around the tropics, interaction diversity may increase. We present analyses from our long-term plant-caterpillar-parasitoid networks collected using the same methods at sites across the Americas. Our data suggest complex but predictable relationships between diversity, specialization, and interaction complexity for plant-consumer interactions, and these relationships are changing rapidly with global change parameters, particularly increases in extreme weather events. Understanding these relationships provides unique insights into the origin and maintenance of tritrophic diversity as well as a deeper understanding of the consequences of potential global insect declines.

The invasion history of the ambrosia beetle Xylosandrus germanus, an important pest in Europe and North America

Authors: Dzurenko Marek, Technical University in Zvolen, Slovakia

Abstract: Xylosandrus germanus is an economically significant invasive pest in various artificial and natural ecosystems in North America and Europe. Originally from Eastern Asia, X. germanus has managed to successfully colonize novel areas thanks to its peculiar biology, specifically haplodiploidy, inbreeding and fungal mutualism typical of all ambrosia beetles in the tribe Xyleborini. In Europe, it was recorded for the first time in 1951 in Germany, and throughout the rest of the 20th century, its spread to neighboring countries was a relatively gradual process. Its spread seems to have accelerated post-2000 and presently, it is found in most European countries. The expansion of X. germanus also occurs altitudinally, with numerous recent reports from much higher elevations than previously recorded. Genetic data reveal that non-native populations are highly uniform and point to their origin in Japan. However, different haplotypes occurring in Europe and North America indicate that these continents were colonized separately, with a single introduction in Europe and multiple introductions in North America. These findings are in contrast with the inferred invasion histories of some other closely related species, and highlight the diverse pathways by which xyleborines spread around the globe.

Flight of the alfalfa bee: determining limiting microclimatic factors affecting first flight

Authors: Earls Kayla[2], Bencomo Jennifer[1], Rinehart Joseph[3] and Greenlee Kendra[2], [1]New Mexico State University, United States, [2]North Dakota State University, United States, [3]United States Department of Agriculture Agricultural Research Service, United States

Abstract: Unfavorable environmental conditions may potentially limit flight in insects, which in turn may limit reproduction and pollination. Temperature and light provide cues that regulate flight. However, it is unknown how other environmental factors, including wind, humidity, and air pressure, can affect flight in combination with light and temperature. Megachile rotundata, a managed pollinator for alfalfa and other crops, is used across a wide range of latitudes; however, unfavorable conditions in northern latitudes limits farmers from using M. rotundata to pollinate early season crops. The purpose of this study was to determine how environmental conditions, including nest microclimate, stimulate first flight in M. rotundata. To test the hypothesis that multiple environmental factors regulate flight initiation, a weather station was constructed around a nesting block to measure 7 different weather variables. GoPros were programmed to capture videos of the nest blocks from 7-11am daily to capture the first flight of individual M. rotundata. First flight of individual bees was measured for a total of 34 days. Temperature was shown to be important, although on three days, bees flew when ambient temperature was below 15?C. Temperature inside the nesting block for those days was around 5?C warmer than ambient and was at least 10?C at the face of the nesting block. Other variables, including light intensity, also appeared to affect flight incidence. Differences in temperature around and within the nesting block may be important factors that influence M. rotundata flight. Our results demonstrate the complexity of environmental variables affecting pollinators in northern latitudes.

Eight years with Drosophila suzukii (Diptera: Drosophilidae) in SW Germany - current state of knowledge on biology and pest control

Authors: Eben Astrid[1], Herz Annette[1], Boehnke Bianca[1], Englert Camilla[1], Briem Felix[1], Vogt Heidrun[1] and Nuss Kerstin[1], [1]Julius Kühn - Institut Federal Research Centre for Cultivated Plants, Germany

Abstract: The cherry vinegar fly, Drosophila suzukii, was first reported for Germany in 2011. In the invaded areas this polyphagous species occupies a previously empty ecological niche due to its capacity to infest healthy, ripe, soft skinned fruits. Eight years of laboratory and field research resulted in extensive information on its biology, ecology and potential means of control. Since 2012 we continuously monitored the abundance of the flies in orchards and wild habitats in relation to temperature and availability of host fruits. We followed the phenotypical colour variation in D. suzukii throughout the year as well as changes in the developmental stage of ovaries in field caught females. In laboratory experiments we screened natural plant compounds for toxicity and behavioural modifications in D. suzukii. The importance of landscape structures with wild host plants for the migration of the flies into orchards and the level of damage caused was evaluated at different field sites. Cultivars of its main hosts were tested for differences in their susceptibility under laboratory and field conditions. Several larval and pupal parasitoids were identified and tested for their potential use as biocontrol agents.

Our results showed that the yearly dynamic of D. suzukii population growth in SW Germany was determined by the fluctuations of temperature and humidity during spring and summer. Populations reached their peak abundance in late summer and fall. During winter and early spring flies were mostly caught along forest edges and on wild host plants. Moreover, all year long flies were most abundant in those habitats. Cherries and soft fruits are main commercial hosts in SW Germany, differences among cultivars were found to have little impact on the probability of infestation. In laboratory assays we identified plant compounds with contact toxicity, compounds that mediated feeding activity, and compounds that reduced oviposition. Migratory behaviour into orchards was mainly affected by the chronological sequence of ripe fruits. Orchards in close vicinity to hedges and wild host plants did not present a higher number of infested fruits compared to more distant or isolated orchards. A comparison of orchards with and without insect netting indicated an increased level of protection through fly exclusion netting. Behavioural experiments and studies on cultivated fruits under insect nets identified potential candidate parasitoid species (i.e. Trichopria drosophilae) for biological control of D. suzukii. The results will be discussed in terms of their potential applications in strategies of integrated pest management.

Consumption rate of different Stethorus gilvifrons Mulsant (Col, Coccinellidae) stages feeding on Tetranychus turkestani (Acari: Tetranychidae) eggs

Authors: Ebrahimifar Jafar[1], Rasekh Arash[2] and Shishehbor Parviz[2], [1]Department of Plant Protection, Agricultural Faculty, Shahid Chamran University of Ahvaz, Iran, [2]Shahid Chamran University of Ahvaz, Iran

Abstract: The strawberry spider mite, Tetranychus turkestani Ugarov & Nikolskii (Acari: Tetranychidae) is on the most important serious pests of field and glasshouse crops in Khuzestan Province, southwestern Iran that cause massive damage to them. The ladybird beetle, Stethorus gilvifrons Mulsant (Col; Coccinellidae), an acariphagous predator, is a native and active predator in Khuzestan province that voraciously fed on different stages of T. turkestani. The purposes of current research were evaluation of consumption rate of adults and larvae S. gilvifrons feeding on T. turkestani eggs on leaf discs the cowpea, Vigna unguiculata L. Walp at the base of Petri dishes (60 mm × 16 mm) under laboratory conditions at 25+ 1 °C, 65+ 5%RH, and a photoperiod 14:10 h (L:D). The results indicated that the consumption rates of larvae and adults of S. gilvifrons were different statistically significant. Consumption rate of the 1st, 2nd, 3rd, 4th, and adult stages of S. gilvifrons on T. turkestani eggs were 18.50, 26.94, 41.75, 69.71, and 75/72 eggs/days, respectively. Likewise, the net predation rate (C0), the stable predation rate (?), the finite predation rate (?), and Qp of S. gilvifrons were 1827.86, 79.73, 89.29 eggs, and 18.19 eggs/ days, respectively. According to these findings, it can be concluded that S. gilvifrons is used in management programs of T. turkestani in field and greenhouse.

Molecular Detection of Bacterial (Anaplasma, Brocella) and Protozoan (Babesia, Theileria) Pathogens from Ticks Collected on Livestock in Northwest of Iran (2017-2018)

Authors: Edalat Hamideh[1], Telmadarraiy Zakkyeh[1], Sedaghat Mahdi[1] and Abdoli Rahimeh[1], [1]Department of Medical Entomology and Vector Control, School of Public Health, Tehran University of Medical Sciences (TUMS), Tehran, Iran

Abstract: Introduction and Objectives: Ticks are among the most important obligate blood-feeding parasites of vertebrates causing transmission of numerous infections, including viral, protozoan, and bacterial and other diseases. The most important diseases transmitted by ticks include the tick-borne relapsing fever, the Crimean-Congo hemorrhagic fever, ehrlichiosis, anaplasmosis, theileriosis, babesiosis and brucellosis. These agents are firstly multiplied in the ticks' body by blood-feeding and are transmitted to the host animal and then to healthy animals or humans by ticks from the infected livestock. Brucella agents are also transmitted to humans directly and through the consumption of unprocessed livestock products such as milk and cheese contaminated with bacteria. This study was conducted to determine the infection of livestock ticks with Anaplasma, Theileria, Babesia and Brucella pathogenic agents using a molecular method in Ahar and Kalibar Counties of East Azerbaijan Province, northwestern Iran.

Materials and Methods: The Ahar and Kalibar Counties are placed in East Azerbaijan, where agricultural and animal husbandry are common. The specimens were collected using crooked pin heads so that the ticks were not damaged and transferred to special tubes. Next, they were inoculated into the test tubes and transferred to the laboratory by placing them in a special flask and were categorized using valid identification keys at the genus and species level. Nested-PCR and single-step PCR techniques were also implemented for the molecular determination.

Results: In this study, 2022 hard ticks were collected from Ahar and Kalibar Counties. Samples were identified including four genera and nine species of Hyalomma anatolicum, Hy. marginatum, Hy. asiaticum, Rhipicephalus sanguineus, Rh. bursa, Haemaphysalis sulcata, Hae. concinna and Hae. punctata. In this study, two agents of Anaplasma sp and Ehrlichia sp. were detected with the Nested-PCR and sequencing methods, also the Brucellaceae was detected in the trapped ticks with rate of 15.04%.

Conclusion: In this study, in addition to the presence of Anaplasma, Ehrlichia, and Brucellaceae in the livestock in the region, four genera of hard ticks were collected and identified as the vector and reservoir, thus, due to the critical role of ticks in the transmission of bacterial and other pathogens, as well as their close relationship with humans and livestock, especially in rural areas, the officials and staff of health centers, veterinary clinics and livestock breeders must consider the status of dissemination and spread of ticks and associated infections to the necessary measures for prevention and control of them and related diseases.

A Study on Species Composition on Mosquito Larvae in Khorramabad County,Western Iran (2018-2019)

Authors: Edalat Hamideh[2], Hasan Kayedi Mohammad[3], Khairandish Sedigheh[1] and Papi Pirjerdi Taher[2], [1]Bushehr University of Medical Sciences, Bushehr, Iran, [2]Department of Medical Entomology and Vector Control, School of Health, Tehran University of Medical Sciences, Tehran, Iran, [3]School of Health, Lorestan University of Medical Sciences, Khorramabad, Iran

Abstract: Introduction and Objectives: Mosquitoes are the most important diptera not only responsible for transmission of diseases but also nuisance for humans and animals. They cause more human suffering than any other vectors and they are responsible for millions death. Therefore, more information on mosquito vectors and their activities essentially need for each specific area particularly where with traffic of passengers of migrants. The aim of current study is to obtain more details about breading places of Culicidae larvae in khorramabad country, Lorestan Province, Iran.

Materials and Methods: A cross sectional study was done on breading places of larvae of Culicidae mosquitoes biweekly from May 2018 - April 2019 in 12 villages of khorramabad Country, Lorestan Province, Iran. The sampling was performed in mountainous, slope and plain areas. Breading places were identified in each area and the larvae collected using dipper and counted. The 3 and 4 larvae stages were kept in conservative solution for 24 hours and then used to identify species. In addition, physiochemical characters of water in breading places was analyzed and recorded.
Results: In the current study, 5770 mosquito larvae were collected which categorized in 4 genus and 10 species including: Anopheles superpictus, An.stephensi, Aedes caspius, Ae. vexans, Culex theileri, Cx. perexicus, Cx. pipiens, Cx.molestus, Cx. mimeticus,Culiceta longiareolata. Among all collected mosquitio larvae, Cx. theileri and Cs. longiareolata were the dominate species.
Conclusions: This is the first official biodiversity survey conducted in Khorramabad as a region with a history of native and incoming malaria. The study of biodiversity in this region is recommended on a continuous basis.

The role of behaviour in inseciticide resistance

Authors: Edison Alitha, University of Muenster, Germany

Abstract: Insecticide resistance can be developed by insect pest populations as an evolved preference for nontoxic hosts over toxic hosts, thus conferring resistance to insecticides through behavior. Previous studies have shown evidence for behavioral traits that may help an insect avoid a toxin. However, it is not clear whether such behavior is heritable and, conclusive proof for increased resistance as a result of behavior is rarely shown. We performed choice bioassays to test the feeding and oviposition preferences of two strains of the insect pest Leptinotarsa decemlineata, also known as the Colorado Potato Beetle, which exhibits different levels of susceptibility to the neonicotinoid insecticide imidacloprid. While the first choices data did not indicate any feeding preferences, the oviposition and movement data suggest that the susceptible D01 strain prefers to inhabit and lay eggs on insecticide-free plants while the resistant E06 strain did not have a preference between insecticide-free or insecticide-treated plants. In later experiments involving crosses and whole genome sequencing, we aim to find out if these differences have a genetic background to show unequivocal proof for the role of behaviour in resistance.

Ten years after the first catch – overview of the recent records of Bactrocera spp. (Tephritidae, Diptera) in Austria

Authors: Egartner Alois[1], Lethmayer Christa[1], Blümel Sylvia[1] and Gottsberger Richard[1], [1]AGES, Institute for Sustainable Plant Production, Austria

Abstract: Fruit flies belonging to the genus Bactrocera (Diptera: Tephritidae) are among the most serious pests worldwide. Within the framework of the survey for the occurrence of Ceratitis capitata in Vienna (Austria), a specimen of the Bactrocera zonata was caught in a trap in 2011. This finding, as well as the frequent reports of introductions of tropical fruit flies at EU entry points (EUROPHYT reports: https://ec.europa.eu/food/plants/plant-health-and-biosecurity/european-union-notification-system-plant-health-interceptions-europhyt/interceptions_en), initiated increased survey efforts for Bactrocera species in Austria since 2012. From 2012 - 2016 these activities focused on sites in Vienna (urban area), where traps with specific lures were employed in allotments, often in close proximity to fruit markets. From 2016 onwards, the survey was gradually extended to eight of nine Austrian federal provinces. In addition, comparisons of the samples by sequence alignment were carried out in order to reveal details about the potential origin of the captured fruit flies.

In total more than 40 individuals belonging to Bactrocera spp. were caught in traps in Vienna (only urban area) in the past decade. Originally, the caught specimens were identified either as B. zonata or as belonging to the B. dorsalis complex. However, recently available diagnostic tools allowed identifying the latter as belonging to B. dorsalis s.l. and one specimen as Bactrocera kandiensis.

The winter conditions unfavourable for the survival of Bactrocera species in Austria and the results of the sequencing support the theory that the captured fruit flies derived from recurrent introductions, most likely by means of transport of infested fruits from various origins.

Fungal and bacterial pathogens threaten mass rearing of the edible grasshopper Ruspolia differens (Orthoptera: Tettigoniidae)

Authors: Egonyu James Peter, International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya

Abstract: Although significant strides have been made to develop protocols for domestication of the edible grasshopper Ruspolia differens (Serville) (Orthoptera: Tettigoniidae), high mortality is still a big challenge due to obscure reasons. In this study, fungi and bacteria were isolated from R. differens collected from Mbarara, Masaka, Hoima, Kampala and Kabale districts in Uganda in 2018, cultured on standard microbial media, identified using molecular techniques and screened for virulence against the insect. Thirteen and nine species of fungi and bacteria were isolated from R. differens, respectively, with the number of isolates varying based on collection site. The most prevalent species of fungal pathogens of R. differens were Aspergillus flavus Link (27.3%), Fusarium equiseti (Corda) (24.2%), Mucor fragilis Fresen (12.1%), Clonostachys rosea (Link) (6.0%) and Aspergillus tamarii Kita (6.0%); whereas those of bacteria were Serratia marcescens Bizio (38.1%), Bacillus thuringiensis (Berliner) (14.3%) and Enterobacter cloacae (Jordan) (14.3%). Nine fungal species namely Clavispora lusitaniae Rodrigues de Miranda, Lichtheimia corymbifera (Cohn), Trichoderma koningii Oudem, F. equiseti, M. fragilis, Aspergillus niger van Tieghem, Epicoccum sorghinum (Saccardo), C. rosea, Penicillium commune Charles Thom; and five bacterial species (Proteus penneri Hickman, S. marcescens, B. thuringiensis, Staphylococcus sciuri Kloos and Enterococcus faecalis (Andrewes and Horder)) were ~5–7-fold and ~4–5-fold, more lethal to third instars of R. differens than untreated controls, respectively. Some of the pathogens of R. differens namely C. lusitaniae, Exserohilum mcginnis Padhye and Ajello, E. sorghinum, P. penneri and E. cloacae have never been reported as insect pathogens. These findings highlight a need to integrate management of these pathogens in the protocols for mass rearing of R. differens.

Potential of edible insects for improved nutrition and livelihoods in East Africa

Authors: Ekesi Sunday[2], M. Tanga Chrysantus[2], Egonyu James Peter[1] and Subramanian Sevgan[2], [1]International Centre of Insect Physiology and Ecology (icipe), Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya

Abstract: Entomophagy is widely accepted among various communities in East Africa. The occurrence of edible insects is highly seasonal, and they are largely obtained through wild harvesting. However, to ensure year-round availability of these insects, icipe and partners have made significant progress towards the development of technologies for indoor mass rearing of 16 edible insect species. We have carried out nutritional profiling of over 28 edible insect species with 92% of the insects having crude protein levels (35 – 73%) that are comparable or superior to that of beef, fish and soya bean. We showed that many of these insects were also rich in amino and fatty acids, flavonoids, vitamins and associated with high Iron and Zinc. Based on the nutrient-rich benefits of these insects, we developed several ways of processing (such as boiling, roasting, bleaching, frying, stewing and curing) to improve their nutritional qualities and sensory attributes. High-quality oils extracted from 10 processed insect species were evaluated for their nutrient quality. Whole insects or insect-based flours were used as ingredients in safe insect-based food formulations such as cookies and other snacks flavoured with ginger, chocolate, lemon, vanilla and strawberry to entice consumers. Consumer acceptability and marketability of some of these products were tested. Our findings revealed that edible insects present unique opportunities for use as ingredients in food fortification to boost the nutritional status of human populations globally. Edible insects also provide opportunities for income generation and employment for youths and women along the value chain (wild harvesting, indoor domestication, processing technologies and marketing).

Pre-release evaluation of Dolichogenidea gelechiidivoris (Hymenoptera: Braconidae), a potential biological control agent of Tuta absoluta (Lepidoptera: Gelechiidae) in Africa

Authors: Ekesi Sunday[1], Ramasamy Srinivasan[5], Zalucki Myron[4], Aigbedion-Atalor Pascal[2], Azrag Abdelmutalab[2], Hill Martin[3] and Mohamed Samira[2], [1]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [3]South Africa, [4]The University of Queensland, Australia, [5]World Vegetable Center, Taiwan

Abstract: Tuta absoluta Meyrick (Lepidoptera: Gelechiidae) is native to South America, but has invaded the Afro-Eurasian supercontinent, where it is currently the most devastating invasive arthropod pest of tomato. As a part of the first classical biological control programme against T. absoluta in Africa, a larval parasitoid, Dolichogenidea gelechiidivoris Marsh (Hymenoptera: Braconidae) of T. absoluta was imported from Peru into the quarantine facility of the International Centre of Insect Physiology and Ecology, Kenya. Here, we report on the host larval preference of D. gelechiidivoris and the host suitability. Also, aspects of the parasitoid's reproductive strategy, including life-time fecundity, and egg maturation dynamics are documented. Dolichogenidea gelechiidivoris females preferentially oviposited into early larval instars (1st and 2nd) of T. absoluta but parasitized and completed development in all four instars of the host. Host instar did not affect D. gelechiidivoris sex-ratio but females reared on the first instar had significantly fewer eggs than when reared in late larval instars (3rd and 4th). Females of the parasitoid emerged with a high mature egg load which peaked 2 d post eclosion. Females of D. gelechiidivoris survived 8.51 ± 0.65 d and produced 103 ± 8 offspring per female at 24 ? 4?C and 50 – 70 % relative humidity (RH) with males present and fed honey-water (80% honey). Increasing maternal age decreased the proportion of female offspring. For laboratory conditions Gross and Net reproductive rates were 72 and 39.5, respectively, while the mean generation time was 20 d. The potential intrinsic rate of natural increase was 0.18 under laboratory conditions. Dolichogenidea gelechiidivoris is a potential biological control agent of T. absoluta, and should be considered for release in Kenya, and across Africa following host specificity testing and risk assessments.

Susceptibility of Black soldier fly, Hermetia illucens L. (Diptera: Stratiomyidae), to entomopathogenic nematodes

Authors: Ekesi Sunday[2], Dicke Marcel[3], Akutse Komivi[1], Tanga Chrysantus M.[2], M. Khamis Fathiya[2], van Loon Joop[3], Subramanian Sevgan[2] and Haukeland Solveig[2], [1]ICIPE, Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology (icipe), Plant Health Unit, Nairobi, Kenya, [3]Laboratory of Entomology Wageningen University, Netherlands

Abstract: Black soldier fly (BSF), Hermetia illucens L. (Diptera: Stratiomyidae) have been widely used to process biowaste and the larvae are high-quality alternative protein to fishmeal in animal feed. Thus, BSF larvae can be an excellent cash flow for smallholder farmers given that the insect-based feeds are more sustainable than conventional fishmeal feeds. Despite the economic importance, relatively little work on factors that might hinder their development has been undertaken. Entomopathogenic nematodes (EPNs) are of potential interest for inhibiting the efficiency of BSF larvae as it feeds on waste organic substrates mixed with soil. Specifically, the larval stage of BSF may present a unique window for attack by EPN, thus threatening their proliferation. For the first time, we tested the capacity of two EPN species with different foraging strategies, Steinernema pwaniensis and Heterorhabditis sp. to cause larval and pupal mortality in BSF across a range of EPN concentrations (50, 100, 200, 500 and 1000 infective juveniles IJs cm-2), substrate moisture (10, 15, 20 and 25% w/v) and temperatures (15, 20, 25 and 30°C). We found that all EPN species tested caused density dependent mortality in the fourth larval instar while pupae were not affected. Steinernema pwaniensis caused significantly higher mortality across different IJ concentrations and over a wider moisture and temperature range than Heterorhabditis sp. High mortality caused by S. pwaniensis and Heterorhabditis sp was more limited to high IJ concentrations with an optimal temperature of 30°C. Our findings highlight the potential of EPNs to negatively impact the efficacy of BSF larvae under different environmental conditions. The implications of EPNs in emerging waste treatment technologies are discussed.

Thermal differences and the potential for sexual conflict in spiders

Authors: Elias Damian[1], Brandt Erin[1] and Rosenthal Malcolm[1], [1]UC Berkeley, United States

Abstract: The behavior of ectotherms, animals that can cannot generate metabolic heat, is intimately tied to temperature. We explored how shifts in biologically relevant temperature ranges affected both male signaling and female choice in spiders. We found large effects of temperature. Interestingly, temperature affected male and female behavior differently suggesting different thermal optima for males and females in regards to mating behavior. Thermal preferences may be an important, often overlooked, aspect of mate choice and sexual selection in ectotherms.

Population dynamics of winter moth in the northeastern US before and after biological control

Authors: Elkinton Joseph[1], Boettner George[2], Chandler Jennifer[2], Pepi Adam[3] and Broadley Hannah[1], [1]Department of Environmental Conservation, University of Massachusetts, Amherst, United States, [2]University of Massachusetts, [3]Tufts University

Abstract: Winter moth (Operophtera brumata L.) is a newly invasive species from Europe to the northeastern United States, which caused widespread defoliation of a wide variety of deciduous trees from 2003-2016. Introduction and establishment of Cyzenis albicans (Tachinidae) collected from Vancouver Island, Canada beginning in 2005 has converted winter moth to a non-pest and ended widespread defoliation. Here we present the results of experiments and Life table analyses that show that predation by pupal predators in the soil now regulate the low-density populations of winter moth, much as they do in Canada and England. Fluctuations in high density populations prior to biological control introductions were caused by asynchrony of winter moth hatch with bu-dburst of oak and maple host trees These high-density populations were regulated by density-dependent dispersal of larvae from partially defoliated hosts.

Cascading effects of insect decline on insectivorous birds

Authors: Elphick Chris[1] and Grames Eliza[2], [1]University of Connecticut, United States, [2]University of Nevada, Reno, United States

Abstract: Declines in the abundance and biomass of insects and other invertebrates could have profound impacts on insectivorous species and disrupt population processes at higher trophic levels. Many birds feed on insects throughout their annual cycle, especially during reproduction when invertebrates provide necessary protein for chick rearing.
It is, perhaps, no surprise then, that concurrent with declines in insect abundance and diversity over the past half century there have been parallel declines in insectivorous birds. Through a systematic review and meta-analysis, we investigated the potential for insect decline to result in parallel declines in insectivorous birds through the proximate mechanisms of reproductive success and chick body condition, the latter of which is linked to annual survival and juvenile recruitment. We found a strong positive effect of insect food availability on bird body condition and reproductive success, providing strong evidence for what has long been assumed: protein food is limiting for many songbirds during the breeding season. The results of our meta-analysis suggest that recent downward trends in insectivorous bird populations can be partially attributed to insect declines, and that future declines in insect abundance and diversity could cause severe consequences for insectivores.

Analyzing Psylliodes chrysocephala periodicity and abundance in Sweden over 50 years

Authors: Emery Sara, Swedish University of Agricultural Sciences, Sweden, United States

Abstract: The univoltine cabbage stem flea beetle, Psylliodes chrysocephala, is a major pest of winter oilseed rape in Europe. P. chrysocephala adults feed on emerging plant leaves in the fall, and the larvae mine leaf petioles in the winter moving in to the stem the following spring. Sweden is on the northern edge of the distribution of this insect. A 50 year data set collected in the south of Sweden is analyzed for periodicity and explanatory environmental factors. The stems of 20-30 winter oilseed rape plants were dissected and larval abundance was recorded in over 3,000 fields in five regions across Skåne, Sweden between 1969 and 2018. Using wavelet analysis and a measure of autocovariance (ACF) it is clear that P. chrysocephala exhibits very strong periodicity in eight-year cycles. An autoregressive model is used to account for density dependence though the mechanism driving the periodicity in this system remains unclear. There is also a trend towards greater larval density in the past five years. Prior laboratory research demonstrated a negative effect of cold temperatures on larval survival, and the field-relevance of this negative effect is supported by a negative relationship between cold winter temperatures and larval densities. The implications of these results are discussed in the context of pesticide-use restrictions, integrated pest management and climate change.

Extraordinary flight performance of miniature Coleoptera

Authors: Engels Thomas [6], Lehmann Fritz-Olaf [6], Onishi Ryo [5], Polilov Alexey[3], Lapina Nadezhda[2], Farisenkov Sergey[2], Petrov Pyotr[2], Kolomenskiy Dmitry[4], Liu Hao[1], [1]Chiba University, Japan, [2]Department of Entomology, Biological faculty, Lomonosov Moscow State University, Russia, [3]Department of Entomology, Faculty of Biology, Moscow State University, Russia, [4]Japan Agency for Marine-Earth Science and Technology, Japan, [5]Tokyo Institute of Technology, [6]University of Rostock

Abstract: The flight of the smallest insects is of special interest for general biology, biomechanics and aerodynamics, but until recently it was barely researched. It has been shown that the smallest insects are capable of active flight, but for many microinsects it is not known how fast they fly especially compared to larger related species. Ptiliidae and other Staphylinoidea present a convenient range of related species with high variety of body size for this task.

We recorded flight of 17 species of Ptiliidae, Staphylinidae and Silphidae by two synchronized high-speed cameras. The beetles were flying in spacious transparent boxes. It allowed beetles to maneuver freely and reach the maximum possible speed. Infrared LED lighting, invisible for insects, made it possible to achieve the necessary exposure for high-speed recording and keep the light level close to natural for beetles. The flight trajectories were reconstructed frame by frame and triangulated. After smoothing, the speeds and accelerations were calculated.
Ptiliids, like the other studied beetles, show continuous maneuverable flight with complex trajectories. The average flight speed is from 5 to 44 cm/s, depending on the species, the maximum speed is up to 98 cm/s; the beetles are capable of accelerating up to 2.4 g. These measurements indicate the ability of active migration in the absence of wind. We have performed regression analysis of speed and acceleration on body length and shown that among staphylinoids with membranous wings speeds and accelerations allometrically increase with increasing body size, but ptiliids fall out of the trend: their flight characteristics are higher than in the other studied beetles of comparable size.
Unlike miniature hymenopterans, thrips and dipterans, flight mechanics of miniature coleopterans have not been studied. To find out what adaptations determine flight performance of Ptiliidae we performed macro high-speed video recording and 3D reconstruction of morphology and kinematics in Paratuposa placentis and explored its flight aerodynamics by using new high precision numerical simulation method with a resolution down to individual setae. Wingbeat cycle of P. placentis and other Ptiliidae is unique to insects. The wings follow a pronounced figure-of-eight loop that consists of subperpendicular up and down strokes followed by claps at stroke reversals above and below the body. The elytra act as inertial brakes, halving the excessive body pitch oscillation. Computational analyses suggest functional decomposition of the wingbeat cycle into two power half strokes, which produce a large upward force, and two down-dragging recovery half strokes. In contrast to membranous wings of the same size, bristled wings produce slightly smaller aerodynamic force due to air permeability. But the motion of light bristled wings requires much less inertial power that significantly reduces cycle-averaged and peak power consumption. Muscle mechanical power requirements thus remain positive throughout the wingbeat cycle, making elastic energy storage obsolete. These adaptations explain how Ptiliidae and other miniature insects could preserve good aerial performance during miniaturization.

Nutritional endosymbionts' Shikimate pathways are susceptible to glyphosate inhibition

Authors: Engl Tobias[2], Kiefer Julian[3], Bauer Eugen[3], Hirota Bin[5], Kaltenpoth Martin[4], Fukatsu Takema[1], [1]Bioproduction Research Institute, Advanced Industrial Science and Technology (AIST), Japan, [2]Department of Insect Symbiosis, Max-Planck-Institute for Chemical Ecology, Germany, [3]Johannes Gutenberg-Universität Mainz, [4]Max-Planck-Institute for Chemical Ecology, [5]National Institute of Advanced Industrial Science and Technology

Abstract: Glyphosate is widely used as a herbicide, but recent studies begin to reveal its detrimental side effects on animals by targeting the shikimate pathway of associated gut microorganisms. However, its impact on nutritional endosymbionts in insects remains poorly understood. Here, we sequenced the tiny, shikimate pathway encoding symbiont genome of the sawtoothed grain beetle Oryzaephilus surinamensis. Decreased titers of the aromatic amino acid tyrosine in symbiont-depleted beetles underscore the symbionts' ability to synthesize prephenate as the precursor for host tyrosine synthesis and its importance for cuticle sclerotization and melanization. Glyphosate exposure inhibited symbiont establishment during host development and abolished the mutualistic benefit on cuticle synthesis in adults, which could be partially rescued by dietary tyrosine supplementation. Furthermore, phylogenetic analyses indicate that the shikimate pathways of many nutritional endosymbionts likewise contain a glyphosate sensitive 5-enolpyruvylshikimate-3-phosphate synthase. These findings highlight the importance of symbiont-mediated tyrosine supplementation for cuticle biosynthesis in insects, but also paint an alarming scenario regarding the use of glyphosate in light of recent declines in insect populations.

Experimental evolution as a tool for improving entomopathogenic fungi as biocontrol agents

Authors: Erdos Zoltan, University of Exeter, United Kingdom

Abstract: Experimental passage has been used to successfully increase virulence of entomopathogens such as baculoviruses. Passage experiments with entomopathogenic fungi are relatively unexplored and showed mixed results at improving virulence. Here, we adopted an approach based on social evolution and evolution of virulence theory using the pathogen Akanthomyces muscarius and an aphid host Myzus persicae, selecting for virulence at different scales of competition within host, between host and between population. The within host and between host treatments resulted in significant increases in virulence. Gains in virulence were dose specific but also led to more rapid killing of an additional aphid species (Brevicoryne brassica) suggesting the achieved changes are robust and not specific to the host used in passage. Sporulation is a key trait of fungal species for biocontrol, however maintaining sporulation throughout passaging has historically been challenging. We observed significant changes to sporulation between treatments, with the between population selection preserving levels of spore production matching the ancestor. Furthermore, we carry out population genomic analysis to identify genetic variants that show convergence within treatments. The current study contributes to the field of virulence evolution and highlights the potential of theory based experimental passage as a tool for improvement of biocontrol agents.

Spatial and Temporal Substrate Dynamics - Critical factors for Saproxylic Forest Biodiversity

Authors: Eriksson Björn[4], Millar Jocelyn G.[2], Westerberg Lars[3], Larsson Mattias[1], Molander Mikael[4] and Zou Yunfan[2], [1]Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Alnarp, Sweden, [2]Departments of Entomology and Chemistry, University of California, Riverside, CA, [3]Linköping University, Sweden, [4]Swedish University of Agricultural Sciences, Sweden

Abstract: During the last century great changes have taken place in the forest landscape with an ever more focused industry optimized for high yields. In Sweden, forests have become more homogenized and dominated by young, dense tree stands that are thinned and harvested at regular intervals. These changes has happened at the expense of many previously common forest habitats and often disrupted century long stand continuities. The effects of these changes on forest biodiversity have historically been challenging to examine, to a large extent due to laborious survey methods for many saproxylic insect species. Utilizing pheromone-based trapping methods it is however possible to conduct efficient, systematic surveys over both large spatial and temporal scales.

During the last few years we have used pheromone baited traps to compare populations of different taxa of threatened saproxylic longhorn beetles on over 200 localities across southern Sweden. By combining systematic trap catches, mark-recapture studies with GIS analyses of landscape data we found stark contrasts in the responses to modern forestry by different groups of longhorn beetles. Transient species, relying on thinner and freshly dead wood, seem to exist on a landscape scale where they quickly can utilize available substrate, i.e. after forest management actions, and then move on with little regard for forest continuity. Other more perpetual species, specialized on later succession stages, are more dependent on long-term habitat persistence in their immediate vicinity and seem to quickly disappear after a breach in continuity. These different responses will require different conservation approaches if we are to maintain a rich forest biodiversity in the future.

Larval odour and social immunity in honey bees

Authors: Erler Silvio, Inst. for Bee Protection, Julius Kühn-Institute (JKI), Halle (Saale), Germany

Abstract: Disease-associated hygienic behaviour is a well-known defence mechanism of honey bees. Detection and removal of diseased individuals are central tasks. Candidate substances or odorant signature mixtures have been studied intensively, however mainly for Varroa mite and fungi (Ascosphaera sp., causing chalkbrood) infected brood. For all diseases, olfactory cues (brood pheromones, signature mixtures, and diagnostic substances) emitted by diseased individuals are key factors for larvae-worker communication to discriminate healthy from infected brood.

Here, we used coupled gas chromatography-mass spectrometry (GC-MS) to measure changes in cuticular hydrocarbon (CHC) and brood pheromone (BEP) profiles of larvae artificially infected with Melissococcus plutonius, the causative agent of European foulbrood. Although chemical profiles did not differ extensively, and no diagnostic substances were found in significant quantities, infection-specific differences were detectable for CHC and BEP profiles. Furthermore, β-ocimene was present in all larvae with highest quantities in healthy young larvae, whereas the necromone oleic acid was present only in old infected larvae. The variable amounts of each substance may shape the characteristic mixture, which is supposed to trigger EFB-associated hygienic behaviour in specialized worker bees. The degree of hygienic behaviour has to be evaluated in future studies to draw conclusions from artificial laboratory infections to in-field relevance.

Study of olfactory response of Cotesia Plutellae towards ten straight chain saturated hydrocarbons

Authors: Eshita[1], Pratyay[2], Kaamya[2] and Kumar Archna[2], [1]Amity University, [2]Amity University Noida

Abstract: Plutella xylostella (Linnaeus), a major pest of economically important cole crops, causes approximately more than 50% loss in crop production. Cotesia plutellae (Kurdjumov), the braconid, endoparasite of diamondback moth, P. xylostella is an important natural enemy of this pest. Application of semiochemical cues especially optimised for the concentrations of straight chain hydrocarbons may be an effective means in enhancement of this parasitoid's efficiency. Keeping these all facts, the proposed study is planned to discern the impact of olfactory response of C. plutellae towards ten straight chain saturated hydrocarbons viz, icosane, henicosane, tricosane, tetracosane, pentacosane, octacosane, nonacosane. For this, two concentrations of all saturated hydrocarbons i.e. 10 ppm and 100 ppm were prepared. Y-tube bioassay method was utilized for the assessment of olfaction capacity. Amongst the targeted hydrocarbons, three hydrocarbons, namely, icosane, octacosane and nonacosane with their percentages being respectively 1200%, 534.93%, 105.78% were observed as highly significant efficient attractant for C. plutellae for both the concentrations. These hydrocarbons may be utilised for preparation of alkane based commercial environmental friendly formulation for efficient management of Plutella xylostella (Linnaeus) in cole crop ecosystem.

Aleyrodid fauna of Eastern and Western ghats of India

Authors: Ethiraj Ragupathy[1] and Balachandran Ravichandran[1], [1]Sri S.Ramasamy Naidu Memorial College, Sattur, Tamil Nadu, India

Abstract: Whiteflies are economically important group of insects infesting a wide range of host plants that cause damage by piercing and sucking the phloem sap and transmitting 19 viruses and numerous virus like agents. Severe infestation may thus adversely affect the hosts, both by excessive sap loss and through sooty-mould interfering with photosynthesis (Marting et al., 2001). These are regarded to be primary pests of vegetable crops, citrus, sugarcane, cotton, ornamental plants, fruit trees like guava, papaya, banana and are also found to infest many more forest trees in India. There are 1556 described whitefly species grouped in 161 genera in the world compared to more than 6000 coccids, 4400 aphids and 2500 jumping plant lice (Martin, 1999) and from india 10 percent of world aleyrodid is reported (Ragupathy, 2018), emphasizing the need for a study of this group of insects particularly in the biologically rich areas of India such as Eastern and Western ghats. Aleyrodid collections were made along the Western ghats from Tamil Nadu (about 8 degree N) and extended up to Gujarat (21 degree N) and up to Orissa in the eastern ghats. The surveyed forest areas include tropical dry ever green forests, tropical forests, evergreen forest and agroecosystem of the ghats region. The study revealed that many economically important crops, medicinally valued herbs and timber yielding trees have been severely infested by whiteflies in addition to endangered and vulnerable flora.

Survey along the Eastern and Western ghats has been carried out during 2000 to 2018 and leaves bearing nymphs of whitefly were observed using a hand lens, collected and secured in specially designed covers containing blotting papers in order to avoid fungal growth due to moisture content of the leaves. The identity of host plants of whiteflies was determined by Botonical survey of India, Coimbatore and Department of Botany, Madras Christian College, Chennai. The whitefly pupal cases were studied using Nikon Alpphaphot YS 2 Microscope.

The present investigation of aleyrodid fauna in the Eastern and Western ghats revealed approximately 950 species which belong to 66 whitefly genera viz.,

Aericerus, Acanthaleyrodes, Acanthobemisia, Acaudaleyrodes, Africaleurodes, Aleurocanthus, Aleuroclava, Aleurocryptus, Aleurolobus, Aleuromarginatus, Aleuroparvus, Aleuroplatus, Aleuroputeus, Aleurothrixus, Aleurotrachelus, Aleyrodes, Arunaleyrodes, Asialeyrodes, Asterochiton, Cohicaleyrodes, Crenidorsum, Crescentaleyrodes, Davidiella, Dialeurodes, Dialeurolonga, Dialeuronomada, Dialeuropora, Distinctaleyrodes, Dumbletoniella, Editaaleyrodes, Fippataleyrodes, Himalayaleyrodes, Icfrealeyrodes, Indica, Indoaleyrodes, Keralaleyrodes, Lipaleyrodes, Martiniella, Massilieurodes, Milleraleyrodes, Minutaleyrodes, Narendramodiella, Neomaskellia, Orientaleyrodes, Paraleyrodes, Parabemisia, Pealius, Psuedcockerelliella, Pseudozaphanera, Pushpasleyrodes, Rabdostigma, Rhachisphora, Rusostigma, Rutaleyrodes, Setaleyrode

I'll have what she's having: Unraveling ant trophic interactions using next-generation sequencing and isotope tracers

Authors: Eubanks Micky[2], Kjeldgaard MacKenzie[2], Sword Gregory[1] and Wulff Jason[2], [1]Texas A&M University Department of Entomology Interdisciplinary Research Program in Ecology and Evolutionary Biology College Station, United States, [2]Texas A&M University, United States

Abstract: Trophic interactions largely influence the abundance and distribution of a species, but they can be difficult to assess, particularly in small, difficult-to-observe taxa such as insects. We examined the utility two techniques to quantify trophic interactions: high-throughput sequencing molecular gut content analysis (HTS-MGCA) and stable isotope tracers. We applied both techniques to the red imported fire ant (Solenopsis invicta; hereafter fire ant), a highly aggressive species that has invaded many parts of the world. We used HTS-MGCA to identify specific taxa that fire ants consumed in several different habitats, and then we used an isotope tracer to examine the effect of queen number on food-sharing between colonies. Because adult fire ant workers rely on their larvae (brood) to digest prey and share it via trophallaxis with the rest of the colony, we sequenced the gut contents of ant brood instead of adult workers to better capture colony diet. Using the Illumina HiSeq, we analyzed the diets of field-collected fire ants and co-occurring arthropod predators. We detected a total of 89 predation events from 16 samples collected across five different sites. Approximately 94% of all predators showed evidence of intraguild predation. All fire ant samples contained sequences from both detritus-based food webs and plant-based food webs. Conversely, only 30% of all arthropod predator samples contained sequences from both food webs. We also fed 15N-labeled glycine to fire ant colonies that varied in queen number to quantify food-sharing between colonies. The current hypothesis is that colonies with multiple queens readily share food with neighboring colonies, whereas, single-queen colonies do not share and are instead highly territorial towards conspecifics. We found that there was very little sharing between colonies in the field, regardless of queen number, even between colonies that were less than 0.5m away from each other. Our results suggest that both HTS-MGCA and stable isotope tracers are broadly applicable techniques that can be used to unravel insect trophic interactions.

A new Massive Open Online Course (MOOC): Bugs 101, Insect-Human Interactions

Authors: Evenden Maya[1] and Domnich Ilan[2], [1]Department of Biological Sciences University of Alberta Edmonton, Alberta, Canada, [2]Faculty of Science University of Alberta Edmonton, Alberta, Canada

Abstract: Bugs 101 is a Massive Open Online Course (MOOC) that was launched on the Coursera platform in June 2019. The content of the course focuses on insect-human interactions, and also introduces learners to insect evolution, biology and ecology. The course has 12 modules each containing several lessons and culminating in a quiz on the material at the end. The first four modules introduce insect diversity, morphology, biology and locomotion. The next four modules focus on ecosystem functions provided by insects including decomposition, herbivory, pollination and disease vectors. Each module has lots of examples on how these functions directly impact human society. The final group of four modules focuses on ways that humans directly interact with insects through sustainable management of insects considered to be pests, conservation of threatened insect populations, and insects as inspiration in music, art, science and literature. Throughout the course, there are 26 interviews with experts on a range of topics from forensic entomology to insects in art. Several interactive learning objects are incorporated into the course so that students can actively interact with the course material. The course is available for free to a wide range of learners from around the world. There are >5500 students enrolled in the class from over 120 countries 2 months after its launch. Here, we explain the process of building a MOOC, highlight the course content and delivery methods and introduce the learning tools that are used to reinforce and assess student learning.

Using an invertebrate's response to low temperature as a criterion for assessing establishment potential

Authors: Everatt Matthew, Department for Environment, Food and Rural Affairs, United Kingdom

Abstract: Augmentative invertebrate biological control agents are defined as mass produced natural enemies that are periodically introduced into a specific environment to suppress pest populations over short periods. These agents were first used in Europe in the 1920s, when the parasitoid wasp, Encarsia formosa, was released to control whiteflies in glasshouses, and are now a common feature of integrated pest management programmes in commercial horticulture. These agents are often polyphagous, and there is a concern that their introduction will lead to permanent establishment outdoors, with undesirable impacts on native species through predation or parasitism. Applications for the release of polyphagous agents cannot usually be based on their specificity to a target pest, and their safety must, instead, be demonstrated by other means. In England, the potential impact of an augmentative agent is commonly assessed by evaluating whether it is likely to establish outdoors in the country and therefore whether any impact it has on non-target hosts will be limited and transient.

Establishment potential is assessed using a number of criteria, including abiotic factors of low temperature and humidity, and biotic factors of host distribution, alternative hosts and other essential species, and competition and natural enemies. Of these, low temperature is often the most important factor, either because the agent is unable to complete its lifecycle or because it is unable to survive the UK winter. In this presentation, the methods for assessing an agent's low temperature tolerance, including the measurement of an agent's thermal budget, lower lethal temperature and lower lethal time, are described, and then discussed in relation to an agent's safety for release in England.

Global patterns of field-evolved resistance to Bt crops

Authors: Fabrick Jeffrey[2] and Carrière Yves[1], [1]University of Arizona, [2]USDA ARS, U.S. Arid Land Agricultural Research Center

Abstract: Crops genetically engineered to produce insecticidal proteins from Bacillus thuringiensis (Bt) have revolutionized control of some key pests, but their benefits are reduced by evolution of resistance to Bt toxins by pests. The global monitoring data reviewed here reveal at least 22 cases of practical resistance to Bt crops, which is field-evolved resistance that reduces Bt crop efficacy and has practical consequences for pest control. Each case represents the responses of one pest species in one country to one Bt toxin. The 22 cases of practical resistance involve resistance of some populations of nine major pests (seven lepidopterans and two coleopterans), six countries, and nine crystalline (Cry) toxins. Field outcomes confirm predictions from theory that abundant refuges of non-Bt host plants can delay evolution of resistance to Bt crops. Also, multi-toxin Bt crops can most effectively delay resistance to Bt crops when each of the toxins is highly effective against the target pest.

Insecticide resistance increases dissemination of West Nile virus in mosquito vectors

Authors: Failloux Anna-Bella[5], Alout Haoues[2], Atyame Celestine[6], Mousson Laurence[4], Vazeille Marie[4], Diallo Mawlouth[3] and Weill Mylene[1], [1]CNRS, Institut of Evolutionary Sciences Montpellier, France, [2]INRA, ASTRE (UMR 117 CIRAD-INRA), France, [3]Institut Pasteur de Dakar, Senegal, [4]Institut Pasteur, Department of Virology, France, [5]Institute Pasteur of Paris, France, [6]UMR PIMIT, University of Reunion Island, France

Abstract: Insecticide resistance has been reported to impact the interactions between mosquitoes and the pathogens they transmit. We investigated whether insecticide resistance mechanisms selected in the mosquito Culex quinquefasciatus would impact vector competence for two arboviruses, Rift Valley Fever (RVFV) and West Nile viruses (WNV). Three Cx. quinquefasciatus lines sharing a common genetic background were used: two insecticide-resistant lines, one homozygous for amplification of the Ester2 locus (SA2), the other homozygous for the acetylcholinesterase ace-1 G119S mutation (SR) and the insecticide-susceptible reference line Slab. Statistical analyses revealed no significant effect of insecticide-resistant mechanisms on vector competence for RVFV. However, both insecticide resistance mechanisms significantly influenced the outcome of WNV infections by increasing the dissemination of WNV in the mosquito body, therefore leading to an increase in transmission efficiency by resistant mosquitoes. These results showed that insecticide resistance mechanisms enhanced vector competence for WNV and may have a significant impact on transmission dynamics of arboviruses. Our findings highlight the importance of understanding the impacts of insecticide resistance on the vectorial capacity parameters to assess the overall consequence on transmission.

The next arboviral threat: Yellow fever

Authors: Failloux Anna-Bella[2], Guillem De Lataillade Lucy[1], Vazeille Marie[1] and YEN Pei-Shi[1], [1]Institut Pasteur Department of Virology, France, [2]Institute Pasteur of Paris, France

Abstract: Yellow fever virus (YFV; Flavivirus, Flaviviridae) is mainly circulating in Africa and South America, causing approximately 29,000 – 60,000 deaths annually. Even though the vaccination against YFV is the primary strategy for controlling this disease, the spillover of the virus from sylvatic cycle to immunologically naïve population is still responsible for several outbreaks, recently in Brazil and in Africa (Angola, Democratic Republic of the Congo and Uganda). YFV is still absent in Asia despite the overall favorable conditions, such as presence of mosquito vectors Aedes albopictus and Aedes aegypti, and majorly unvaccinated populations. However, the rapid growth of international commerce and exchanges between Asia and several YFV epidemic African countries have increased the risk of disease introduction. In 2016, 11 Chinese workers exported YFV into China from Angola during the massive outbreak. Although these incidents did not cause any autochthonous cases, the threat is still there underlining the probability for YFV to be introduced in Asia. Using experimental infections, we have evaluated the vector competence of Asian Ae. aegypti and Ae. albopictus populations to YFV. The results are discussed in the light of potential emergence of yellow fever in Asia.

Worldwide invasion dynamics of Aedes albopictus shaped the vector competence of its populations for chikungunya virus

Authors: Failloux Anna-Bella[4], Gasperi Giuliano[1], Carraretto Davide[1], Malacrida Anna R.[6], Vega-Rúa Anubis[5], Gomulski Ludvik[1], Marconcini Michele[1], Manni Mosè[2] and Madec Yoann[3], [1]Dept. of Biology and Biotechnology, University of Pavia, Pavia, Italy, [2]Dept. of Genetic Medicine and Development, University of Geneva Medical School, and Swiss Institute of Bioinformatics, Geneva, Switzerland, [3]Dept. of Infection and Epidemiology of Emerging Diseases, Institut Pasteur, Paris, France, [4]Institute Pasteur of Paris, France, [5]Laboratory of Vector Control Research, Institut Pasteur of Guadeloupe, Guadeloupe, France, [6]University of Pavia, Italy

Abstract: The mosquito Aedes albopictus is among the 100 most dangerous invasive species. Its worldwide spread has created public health concerns as it is the main vector of arboviruses of public health significance such as chikungunya (CHIKV).Dynamics of different genetic backgrounds and admixture events may have impacted competence for CHIKV in adventive populations. Linking the genetic structure of populations across the expansion areas with their competence for different CHIKV genotypes, we found that: the demographic history of Ae. albopictus populations is a consequence of the rapid complex pattern of historical lineage diversification and divergence and it influenced their ability to transmit CHIKV. Indeed, the history of adventive populations was found associated with the CHIKV genotypes in a genotype-by-genotype interaction which impacted their vector competence. Thus, the knowledge of the demographic history and vector competence of invasive mosquitoes is pivotal for assessing the risk of arbovirus outbreaks in newly colonized areas.

Bioinformatic analysis of antimicrobial peptides identified in the Black Soldier Fly (BSF) Hermetia illucens (Diptera: Stratiomyidae)

Authors: Falabella Patrizia[4], Falabella Patrizia[3], Giglio Fabiana[3], Rinaldi Roberta[3], Boschi Andrea[3], Sgambato Alessandro[1], Scieuzo Carmen[3], Vogel Heiko[2] and Salvia Rosanna[3], [1]Catholic University of the Sacred Heart, [2]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [3]University of Basilicata, Italy

Abstract: Antimicrobial and antineoplastic resistances represent two of the most urgent therapeutic worldwide challenges underlining the need to develop novel alternative treatments. Antimicrobial peptides (AMPs), small molecules ranging from 10 to 50 amino acids, play a key role in the innate immunity, the first line of defence against bacteria, fungi and viruses. They are promising molecules potentially lacking toxicity to healthy cells and unaffected by common mechanisms of resistance. Numerous insect-derived AMP have been reported in the literature and the Diptera Hermetia illucens is one of the most promising sources, since larvae thrive in hostile environments rich in microorganisms. To identify AMPs, we generated de novo transcriptome assemblies from larval and adult specimens. All sequences putatively encoding for AMPs were bioinformatically analyzed to predict their physico-chemical properties (by Antimicrobial Peptide Database Calculator and Predictor (APD3)) and their putative activity. AMPs were analysed on the CAMP database to predict their antimicrobial activity, and by iACP, the AVPpred and the Antifp servers to predict anticancer, antiviral and antifungal activities. These analyses allowed us to identify 57 putative active peptides. These preliminary results will allow the selection of the most promising candidates for heterologous expression/chemical synthesis to obtain peptides for in vitro studies.

African horse sickness virus transmission in Senegal: past and current status

Authors: Fall Assane Gueye[4], SALL Baba[1], Biteye Biram[3], Youssou Ndiaye Elhadji[1], Ciss Mamadou[3], Diop Mariame[3], Ba Gahn Marie-Cicille[3], Lo Mbargou[1], Moustapha Lo Modou[3], Tall SECK Momar[3], Fall Moussa[3], Lancelot Renaud[5], Bada Alambedji Rianatou[2] and Bakhoum Thierno[3], [1]Department of Veterinary Services of Senegal, Ministry of Livestock and Animal Production, Senegal, [2]Inter-State School of Sciences and Veterinary Medicine, Senegal, [3]National Laboratory of Livestock and Veterinary Research, Senegal, [4]National Laboratory of Livestock and Veterinary Research, Senegal, Senegal, [5]UMR Cirad-Inra ASTRE « AnimalS, health, Territories, Risks and Ecosystems, France

Abstract: In Senegal the horse has long been used as a draught animal for work in the farms and for transporting people and goods by horse-drawn vehicles and carts. With the development of horse breeding, African horse sickness (AHS) becomes endemic and constitutes a major constraint to the development of this breeding. AHS, a vector-borne viral disease, affects equids and causes very high mortality rates. To control the disease, mass vaccination remains the only means of prevention implemented by the public authorities in Senegal. Many effective vaccines have been developed and made available to horse owners. Before the 2007 AHS epizootic, the monovalent vaccine against serotype 9 was the only one used in mass vaccination campaigns. This recent epizootic, due to the new introduction of serotype 2, led to the use of a polyvalent vaccine with nine serotypes of AHS virus for control and mass vaccination campaigns. However, vector-borne diseases control couldn't be effective through vaccination alone; integrated control measures taking into account vector control would be required. In contrast to studies carried out in South Africa on AHS vectors, knowledge of West African vectors has been very limited, making difficult the implementation of effective control measures.

This study presents the state of art of AHS transmission in Senegal based on existing literature and entomological and serological surveys carried out after the 2007 epizootic. To determine the circulating serotypes two serological surveys were carried out on donkeys and unvaccinated horses in 7 out of 14 regions and 10/14 regions with high equine densities in 2008 and 2013-2014 respectively. The sera were analysed by the virus neutralisation test using the known serotypes of AHSV1 to AHSV9 with the exception of AHSV6 which is known to cross-react with AHSV9. For vectors collection, two nationwide surveys were carried out in 2012 and 2018-2019 respectively using Onderstepoort Veterinary Institute OVI-light traps to identify vectors potentially involving in AHSV transmission and their relative abundances.

In 2008 a total of 278 sera were collected from donkeys and analysed with the neutralisation test (VNT). The results showed the presence of two serotypes with an overall seropositivity of 56% for AHSV9 and 49% for AHSV2. Whereas in 2013-2014, out of the 987 sera (444 donkeys and 543 horses) collected, all the serotypes tested were detected with spatial variability of serotypes and seroprevalence (seroprevalence for donkeys = 28.5 SD 11.8%; seroprevalence for horses = 33 SD 11.4%). Serological results from 2013-2014 suggest a vectorial transmission of vaccine strains to unvaccinated animals. The abundance of Culicoides imicola and C. oxystoma was determined and their likely role in AHS virus transmission discussed. Also the study highlighted through a regression model, the relationships between age, animal species and vectors abundance and the presence of serotypes.

LIFE PollinAction: Actions for boosting pollination in rural and urban areas in northeast Italy (LIFE19 NAT/IT/000848)

Authors: Fantinato Edy[1] and Buffa Gabriella[1], [1]Ca' Foscari University of Venice, Italy

Abstract: Pollinator populations are negatively affected by the increasing use of agrochemicals, parasites and diseases, local and global environmental degradation and by the loss of natural and semi-natural habitats. The destruction and fragmentation of these habitats and the consequent reduction in wildflowers cause the loss of nectar and pollen as well as breeding, nesting and overwintering habitats for pollinators, triggering population declines and isolation of populations. The project is creating a green infrastructure network, made up of natural and semi-natural areas, in rural and urban landscapes in North-East Italy and Spain. Actions include conversion of arable land to grassland, improvement of species-poor grassland, and the creation of wildlife corridors for pollinators along road infrastructure, riverbanks, public places, and gardens. The project is collecting seeds from native species in the region to produce seedlings to improve foraging habitats for pollinators.

The State of Mosquito and Vector Control in the United States: A Perspective from a Local Mosquito Control District

Authors: Faraji Ary, Salt Lake City Mosquito Abatement District, United States

Abstract: This presentation will cover the current state of mosquito surveillance, control, and research at the local level. The perspective will be provided through a local government agency providing vector control services in Midwestern United States. Highlights will be given to methods of surveillance, control, research, and interaction with other agencies and organizations across the globe.

Host detection by ticks and effect of repellent exposure

Authors: Faraone Nicoletta[1] and Hillier Neil Kirk[1], [1]Acadia University

Abstract: Ticks are obligate blood-feeding ectoparasites of many hosts and are second only to mosquitoes as the most common arthropod pathogen vectors. Ticks use many different strategies to detect suitable hosts for a successful blood meal. Being almost totally blind, ticks rely on chemosensation to identify and locate hosts for a successful blood meal, and the tick chemosensory system represents a new frontier compared with that of insects. We identified key odorants/ blends by collection and chemical characterization of volatile compound (VOC) from hosts (e.g., humans, cats, dogs, etc.). Because no studies have investigated potential long-term disruption and inhibition of tick abilities to detect hosts, we assessed the effects on tick chemosensory system of long-term exposure to repellents, and investigated whether pre-exposure to repellents impact the chemosensory system of ticks. Through a novel electrophysiological approach, we recorded tick responses to host VOCs alone and to butyric acid pre- and post-exposure to repellents using gas chromatography linked electrotarsography. We validated these findings through behavioural bioassays. Understanding the mechanisms behind tick host selection/acceptance and chemical cue perception will provide means to prevent tick bites and thus infections in humans and animals and to develop effective tick repellent products.

Validation of In2Care® EaveTubes as a new malaria intervention paradigm for controlling insecticide-resistant anophelines

Authors: Farenhorst Marit[5], Sternberg Eleanore[1], Cook Jackie[3], Thomas Matthew[4] and N'Guessan Raphael[2], [1]Department of Entomology and Center for Infectious Disease Dynamics, The Pennsylvania State University, PA, United States, [2]Institut Pierre Richet (IPR) / Institut National de Santé Publique (INSP), Bouaké, Côte d'Ivoire, Ivory Coast, [3]London School of Tropical Hygiene and Medicine, United Kingdom, [4]Penn State University, United States, [5]Research and Development, In2Care BV, Wageningen, The Netherlands, Netherlands

Abstract: Malaria remains a serious public health threat as the efficacy of contemporary vector control tools is hampered by insecticide resistance. In2Care® EaveTubes are under evaluation at WHO as a new malaria vector control paradigm. EaveTubes create point-sources in house walls that passively funnel occupant odours and lure anopheline mosquitoes. The innovative static netting inserts block and kill resistant vectors by transfering lethal doses of powder-formulated insecticide through polarity.

A large Phase III two-armed, cluster Randomized Controlled Trial was conducted in 40 village clusters in central Côte d'Ivoire between 2017 and 2019 to evaluate the public health impact. In total, 3069 houses in 20 intervention clusters received window screening and on average 10 beta-cyfluthrin-treated In2Care® EaveTubes per house, with a median village coverage of 73% (range 32% - 100%). All 40 clusters received Long-Lasting Insecticide-treated Nets (LLINs) and in each cluster 50 children (aged 6 months to 10 years) were followed up for two years to monitor clinical malaria incidence via active case detection.

Entomological monitoring results show a 61% reductions in indoor-collected anopheline densities and a 39% reduction in outdoor densities. There was a 73% reduction in the indoor Entomological Inoculation Rate. Epidemiological results show that children living in the intervention villages had a 38% lower risk of having a malaria case (Hazard Ratio 0.62 (95% CI 0.51-0.76; $P<0.001$)). There is evidence of a community effect with significant reductions in malaria case incidence in villages with >60% InCare® EaveTube coverage.

Malaria infection prevalence was measured in two cross-sectional surveys . Results showed similar prevalences between baseline and endline in the control villages, whilst the intervention villages saw a 21% drop in malaria case prevalence between baseline and endline. Comparing the two trial arms directly at endline showed a significant reduction in malaria prevalence risk: OR 0.56 (95% CI 0.45 - 0.71 $P<0.001$).

Experimental hut studies were conducted to gather additional entomological evidence on the results of In2Care EaveTubes as a stand-alone method. Results showed that 90% more mosquitoes were attracted to In2Care® EaveTubes than to open windows and that 87% of the highly resistant malaria mosquitoes were killed within 4 nights.

These results indicate that In2Care® EaveTubes provide protection against malaria on top of universal coverage with LLINs in an area with intense pyrethroid resistance. Future trial designs for validating public health value in a second setting are being discussed with the Vector Control Advisory Group, including smaller non-inferiority and interrupted time series studies, and less expensive RCTs that use malaria prevalence and and passive incidence as outcomes.

Shrub contributes to the follicular cell integrity in the panoistic ovary of Blattella germanica

Authors: Farrús Núria[2], Piulachs Maria-Dolors[3], Maestro José Luis[1], [1]Institut de Biologia Evolutiva (CSIC - Univ. Pompeu Fabra), [2]Institut de Biologia Evolutiva (CSIC - Univ. Pompeu Fabra), Spain, [3]Institute of Evolutionary Biology (CSIC- Univ. Pompeu Fabra). Barcelona, Spain

Abstract: Cytokinesis is the physical process of cell separation in the cell division, in which the cytoplasm of a parental eukaryotic cell divides into two daughter cells. To be carried out the integrity of the cytoskeleton is crucial. shrub encodes a filament-forming subunit of ESCRT-III (Endosomal Sorting Complex Required for Transport) essential in the abscission, the last step of cytokinesis. In female germline stem cells of Drosophila melanogaster, Shrub controls the timing of cell division by recruiting ESCRT-III complex in the midbody before the abscission and its absence stops germinal stem cells division. The current knowledge of the function of Shrub in insect oogenesis is limited to germinal stem cells, and its role in ovarian somatic cells is still unknown. Our objective is to unveil the function of Shrub in the oogenesis of the cockroach Blattella germanica paying attention to the ovarian somatic cells. shrub expression was depleted by RNA interference (RNAi) in young adult cockroaches resulting in sterile females. Basal ovarian follicles didn't grow in shrub-depleted females due to a failure in cytoskeleton proteins assembly. Results obtained show that Shrub-like protein participates in the follicular epithelia integrity during ovarian maturation in B. germanica.

Finding the needle in a haystack: molecules that elicit butterfly egg-killing in plants

Authors: Fatouros Nina[2], Caarls Lotte[4], van Loon Joop[5], Eric Schranz M[3], Bassetti Niccolo[3] and Mumm Roland[1], [1]Bioscience Wageningen University and Research, Netherlands, [2]Biosystematics group Wageningen University and Research, Netherlands, [3]Biosystematics Group Wageningen University, Netherlands, [4]Biosystematics Group Wageningen University, Netherlands, [5]Laboratory of Entomology Wageningen University, Netherlands

Abstract: Plants can defend against insect eggs deposited on their leaves by e.g. the formation of necrotic tissue underneath the eggs. Several brassicaceous plants, including the annual weed Brassica nigra, respond with an egg-killing necrosis to cabbage white butterfly (Pieris sp.) eggs in nature. Knowledge on egg-associated molecular patterns (EAMPs) or elicitors inducing egg-killing is limited and no bonafide egg receptor has been found so far. We aim to isolate and identify the EAMPs that triggers egg-killing necrosis in B. nigra. First, we show that a wash of Pieris eggs elicits a similar response as the eggs themselves. Dissection of eggs from the ovaries of P. brassicae showed that the active compound is only present on fertilized eggs that have passed the oviduct and its associated gland containing egg glue. These results suggest that the elicitor is in secretions covering the eggs or in the egg glue released with eggs. In addition, this induction was shared between four tested Pierid species. To identify the elicitor, we analysed the chemistry of egg washes by LC/MS, and compared inducing and non-inducing washes. Furthermore, active washes were fractionated. Seven compounds are shared between all inducing washes and are present in an active fraction, and are thus good candidates as necrosis-inducing EAMPs. Validation of these compounds is still ongoing and when accomplished will further aid us in identifying the corresponding plant receptor of this egg-killing response.

The evolutionary history of Sternorrhyncha

Authors: Favret Colin, University of Montreal, Canada

Abstract: The Sternorrhyncha, a monophyletic suborder of Hemiptera, is itself composed of four monophyletic infraorders: Aleyrodomorpha, Aphidomorpha, Coccomorpha, and Psyllomorpha, the whiteflies, aphids, scale insects, and jumping plant lice (or psyllids), respectively. Sternorrhynchs are among the most host-specific of insects, their evolutionary history intimately tied to the plants they colonize. Many species are plant pests, vectors of plant diseases transmitted directly to the phloem elements on which the insects feed. Whereas the aphids and scale insects have long been uncontroversially considered sister taxa, the relative phylogenetic positions of the psyllids and whiteflies are variable depending on the types of data and analyses used. Morphological (including fossil) analyses usually group psyllids and whiteflies as sister taxa, mitochondrial genomes place psyllids as sister to the rest of the sternorrhynchs, but transcriptomes put the whiteflies in that position.

As a whole, the phylogenies of each of the four infraorders are poorly resolved. Whitefly phylogenetics has focused almost exclusively on the <i>Bemisia tabaci</i> species complex. Only a couple scale insect phylogenies have been attempted, although there is agreement on the monophyly of the neococcoid families. There is relative congruence among the several psyllid analyses and mitochondrial and nuclear loci largely agree, thus providing a preliminary but useable backbone phylogeny for the group. In contrast with the other infraorders, there has been a disproportionately larger amount of attention paid to the aphids, partly because they are used as models in a number of research domains (e.g., speciation, microbiomics, host-associated evolution). However, apart from the first branching event separating the obligate egg-laying and cyclically viviparous families, a credible aphidomorphan phylogenetic hypothesis has yet to be accepted.

The presentation will describe the current knowledge of sternorrhynchan evolution, including biological, morphological, and fossil data, and with a particular focus on molecular phylogenetics. It will compare the various datasets and methods used, and suggest possible ways forward, including deeper collaboration between researchers working separately on the four infraordinal taxa.

Gene-flow levels differ between the bumblebee Bombus pascuorum and the hoverfly Melanostoma scalare, two pollinators of isolated forest herbs in agricultural landscapes

Authors: Feigs Jannis Till[1] and Kramp Katja[2], [1]Leibniz Centre for Agricultural Landscape Research (ZALF), Germany, [2]Senckenberg German Entomological Institute (SDEI), Germany

Abstract: Two groups of important pollinators are hoverflies and bumblebees. In intensively used agricultural landscapes they can connect populations of isolated forest herbs found in semi-natural forest remnants. Their dispersal during foraging causes pollen-mediated gene flow among plants. The insects' dispersal behaviour and distribution differs depending on both the species-specific effects of the landscape structure and dispersal distances. Dispersal of a species can thereby be estimated via the analysis of the population genetic structure and gene flow.

Here, we study the population genetic structure of the main insect pollinators of two early-blooming herbs characteristic for old, deciduous forests in temperate Europe. Three landscape windows in South Sweden, Western and Eastern Germany, respectively, with at least six remnant old forests per window with populations of the forest herbs Anemone nemorosa and Polygonatum multiflorum were therefore selected. With a pollinator exclusion experiment we collected information about the dependency of the plant species on the pollinators. We established the main pollinators by observation of pollinator species and their visitation rates as well as species proportions in Malaise traps. Based on microsatellite markers we analysed the population genetic structures of the main pollinators sampled in the old forests with Malaise traps and net catches.

The hoverfly species Melanostoma scalare and the bumblebee species Bombus pascuorum were identified as main pollinators of A. nemorosa and P. multiflorum, respectively. We expect the population genetic structure of the two pollinator species to show differences in the degree of gene flow. Thereby, M. scalare is assumed to cover shorter distances than B. pascuorum. Accordingly, a higher genetic differentiation in the population genetic structure of the hoverfly species is expected in contrast to the lower genetic differentiation in the population genetic structure of the bumblebee species.

The study design allows not only generalising conclusions for the species' interaction with the agricultural landscape structure, but also substantiates hypotheses about particular effects of landscape elements. To further study the plant-pollinator interaction we will use the level of gene flow among the forest remnants detected for the pollinator to infer the expected level of gene flow among the plants. Furthermore, this may help to understand how the pollinator contributes to the chance of long-term survival of the plant species.

Why gene flow levels differ between the bumblebee Bombus pascuorum and the hoverfly Melanostoma scalare - a landscape genetics approach

Authors: Feigs Jannis Till[1], Kramp Katja[2], [1]Leibniz Centre for Agricultural Landscape Research (ZALF), Germany, [2]Senckenberg German Entomological Institute (SDEI), Germany

Abstract: For insect pollinators, intensively used agricultural landscapes are challenging in terms of available habitat and its distribution. The landscape structure has species-specific effects on the insects' dispersal behaviour and distribution, thereby affecting the gene flow. Here, we apply a landscape-genetic approach to assess the species-specific influence of landscape structure on population genetic structure patterns of two pollinators, the hoverfly Melanostoma scalare and the bumblebee Bombus pascuorum. They are main pollinators of two early-blooming herbs characteristic for old, deciduous forests in temperate Europe. The level of pollinator dispersal is assumed to affect the plants' gene flow and thus the survival of isolated plant populations.

Three landscape windows in South Sweden, Western and Eastern Germany, respectively, with at least six old forest remnants per window with populations of the forest herbs Anemone nemorosa and Polygonatum multiflorum were selected. Based on microsatellite markers we analysed the population genetic structures of the main pollinators sampled in the old forests. We determined locations of nesting sites of bumblebees outside the forests with a "mean centre" approach based on sibling identification. To characterise the landscape structure we quantified landscape composition and configuration in buffers around and strips among the sampled forests. We then assessed their effects on the respective population genetic structures of the hoverfly and the bumblebee species using GLMMs.

We expect that the landscape structure shaped the population genetic structure of the hoverfly species more distinct than that of the bumblebee species. For M. scalare, the landscape structure in smaller radii around forests should be stronger correlated to genetic diversity due to the relatively smaller dispersal distances covered by the hoverfly. Moreover, a gene-flow facilitating effect of the amount of grassland and hedgerows should be detectable for both pollinator species. In contrast, mass flowering crops should affect only bumblebees, indicating stronger gene flow and lower genetic differentiation near the resources.

Can generalist predator food webs provide stable aphid control in the future?

Authors: Feit Benjamin[1], Jonsson Mattias[1], Straub Cory[3], Daouti Eirini[1] and Branco Leote Pedro Nuno[2], [1]Swedish University of Agricultural Sciences, Sweden, [2]University of Innsbruck, Austria, [3]Ursinus College, United States

Abstract: In general, increased biodiversity is expected to provide more resilient ecosystem processes. This is because in diverse communities there are more species that can contribute to the functions (functional redundancy), and because different species are likely to respond differently to environmental variation (response diversity). Attempts to empirically assess resilience of ecosystem processes in relation to relevant disturbances are few, not least in agricultural landscapes. We will present results from a study investigating functional redundancy and climate resilience of generalist predators predating on pest aphids and a range of other prey types in Swedish barley crops. To assess functional redundancy we developed a new method linking interaction metrics with metabolic theory that allows for a quantification of redundancy at the level of ecosystem processes. To assess response diversity in relation to global warming we investigated the activity niches of a large number of actively hunting generalist predators in relation to temperature and combined them into a metric of climate resilience. Applying these methods to our generalist predator food webs, we found that both redundancy and climate resilience of aphid predation was significantly reduced in simplified landscapes. Thus landscape simplification will likely reduce the reliability of aphid control in the future.

Polydnavirus Mediates Fitness of Parasitoids, Caterpillars, and Plants

Authors: Felton Gary W., Department of Entomology Pennsylvania State University University Park, PA, United States

Abstract: Many parasitic wasps of caterpillars possess obligate mutualistic viruses called polydnaviruses. Along with eggs, wasps inject polydnavirus inside their caterpillar hosts where the hatching larvae develop inside the caterpillar. Polydnaviruses suppress the immune systems of their caterpillar hosts, which enables egg hatch and wasp larval development. Using two parasitoid species including the specialist Microplitis croceipes and the generalist Cotesia marginiventris, we show that the parasitoids and their associated polydnavirus are able manipulate the salivary enzymes of their host caterpillars and consequently impact the expression of plant defenses. These impacts on plant defenses can even extend to impacting fitness of the caterpillar's host plant.

Salivary Glucose Oxidase Mediates the Intersection of Insect and Plant Immunity

Authors: Felton Gary W., Department of Entomology Pennsylvania State University University Park, PA, United States

Abstract: Glucose oxidase is a widely occurring salivary enzyme in caterpillar species and plays a multifunctional role. Through its production of hydrogen peroxide, glucose oxidase (GOX) can provide antimicrobial protection for caterpillars during feeding. Because hydrogen peroxide serves as a secondary messenger in mediating many plant responses to biotic and biotic, GOX has the potential to also drive a number of plant physiological responses to the environment. We have utilized CRISPR-Cas9 genome editing of GOX in the caterpillar to examine the impact of GOX on both insect and plant immunity. Two mutant lines of GOX caterpillars have been developed which are providing the tools to examine the important role of this salivary enzyme in mediating plant-insect-microbe interactions.

Asymmetric responses to climate change: Temperature differentially alters an herbivore salivary elicitor and host plant responses to herbivory

Authors: Felton Gary W.[1], Tomasula Jewe[2] and Rajotte Edwin[1], [1]Department of Entomology Pennsylvania State University University Park, PA, United States, [2]United States

Abstract: Using experimental warming and a combination of biochemical, molecular and herbivory bioassays, we investigated the effect of elevated temperatures on tomato (Solanum lycopersicum var. Better boy) and a generalist herbivore (tomato fruit worm, Helicoverpa zea). We identified a very novel mechanisms of how climate warming may impact the activity of caterpillar salivary elicitor, Glucose oxidase (GOX) and the ability of insects to trigger plant defense responses. GOX activity on caterpillars reared at a warmer temperature was significantly reduced resulting in a low level of induced plant defensive chemicals. In addition to the warming-mediated changes in caterpillars to elicit plant defenses, temperature directly affected induction of temperature-sensitive defensive chemicals and plant resistance. Herbivore growth was significantly reduced when fed on previously damaged leaves compared to undamaged leaves from plants grown under the above-optimum temperature range, emphasizing the importance of induced plant resistance to estimate the impact of climatic changes on insect-plant interactions, which has generally been overlooked in the past studies. Overall, results from our study produced an asymmetric effect between an herbivore and its host plant, illustrating the complexity of changes in insect-plant interactions that could result as the climate warms. We, therefore, assert that any future predictions under climate change that do not take this complexity into consideration will be unconvincing.

microRNA regulation in an ancient obligate endosymbiosis

Authors: Feng Honglin, Boyce Thompson Institute for Plant Research, United States

Abstract: Aphids harbor a nutritional obligate endosymbiont in specialized cells called bacteriocytes, which aggregate to form an organ known as the bacteriome. Aphid bacteriomes display distinct gene expression profiles that facilitate the symbiotic relationship. However, the mechanisms that regulate these patterns of gene expression are unknown. While microRNAs (miRNAs) have been recently identified as regulators of host/pathogen and host/facultative endosymbiont interactions, the role miRNAs may play in mediating host/obligate endosymbiont interactions is virtually unknown. In my study, I identified conserved miRNAs that potentially mediate symbiotic interactions between aphids and their obligate endosymbiont, Buchnera aphidicola. Using small RNA sequence data and reference genomes of Myzus persicae and Acyrthosiphon pisum, I annotated 93 M. persicae and 89 A. pisum miRNAs, among which 69 were shared. I found 14 shared miRNAs that were either highly expressed or differentially expressed in bacteriome (the Buchnera-housing tissue) vs gut (a non-Buchnera-housing tissue). Strikingly, 10 of these 14 miRNAs have been implicated previously in other host/microbe interactions. Then using a custom computational pipeline, I identified 103 miRNA::mRNA interactions shared between M. persicae and A. pisum. Functional annotation of the shared mRNA targets revealed only two over-represented cluster of orthologous group categories: amino acid transport and metabolism, and signal transduction mechanisms. Furthermore, using a dual luciferase assay in mouse NIH/3T3 cell culture, I experimentally validated the computationally predicted interaction between Mpe-miR-92a and the predicted target region of M. persicae bacteriocyte-specific secreted protein 1 (SP1) mRNA. Those results support a role for miRNAs in mediating host/symbiont interactions between aphids and their obligate endosymbiont Buchnera.

Pest insect monitoring in China: Going automatic and smart

Authors: Feng Hongqiang[1], Huang Jianrong[2], Zeng Juan[3] and Jiang Yuying[3], [1]Inst. of Plant Protection Henan Academy of Agricultural Sciences Zhengzhou,China, China, [2]Institute of Plant Protection, Henan Academy of Agricultural Sciences, Zhengzhou, China, [3]National Agro-Technical Extension and Service Center, Beijing, China

Abstract: Benefited from rapid development of computer science, artificial intelligence and internet technology, traditional pest insect monitoring technologies are going automatic and smart. With success of deep learning in image analysis and popularization of smart phone, onsite insect species identification and counting small insects, such as aphids, plant hoppers, whiteflies and so on, became instant. Catches of insects in light-traps could be killed with infrared heating killer and identified timely. The image of insects and number of each species counted were sent to a cloud server, and users could view the light trap results with a computer in office or a smart phone anywhere. The accurate rate of species identification was above 80% for common agricultural pests. A national wide network of smart pheromone traps was established in 2009. The smart pheromone trap counter used double or triple layer of infrared counters to count number of trapped insects accurately and send results to a cloud server. Scanning and vertical looking radars were upgraded and new dual-mode radar was developed for insect monitoring. The comparison of radar monitored data with light trap data indicated that the entomological radar could identify common insect species and record the population dynamics accurately. Long-term monitoring indicated insect pests migrated towards north in May, June and July, but towards south in August and September. The modern insect pest monitoring system was used to monitor newly invaded fall armyworm Spodoptera frugiperda and provided satisfied information.

Observing mass migrating insects on marine research ship

Authors: Feng Hongqiang[1], Tian Caihong[2] and Huang Jianrong[1], [1]Institute of Plant Protection, Henan Academy of Agricultural Sciences, Zhengzhou, China, [2]Institute of Plant Protection,Henan Academy of Agricultural Sciences, China,

Abstract: Although much is known about the movements of insects across the sea on land for many decades, the migration patterns of most species, the impacts of seasonal weather on annual movements across the sea are poorly known. Here we used high altitude light-trap to monitor the adult dynamics of mass insect migration from Huanghai and Bohai sea for three years. The ovarian development of main lepidoptera female adult captured on the sea ie, Helicoverpa armigera, Mythimna separata,Dichocrocis punctiferalis, etc were dissected.Our results showed that about 69 insect species were captured. According to the capturing time, site, and the weather conditions at that time, using the trajectory analysis to estimate the insect origin and flight destination, some of lepidoptera moths might migrate from Taiwan province of China, Japan or South Korea . Ovarian development level of main lepidoptera female adults combined with insect migration was also discussed.

Invasion asymmetry: origins or opportunities for introduction?

Authors: Fenn-Moltu Gyda[1], Liebhold Andrew M, Pureswaran Deepa S, Turner Rebecca, Yamanaka Takehiko, Bertelsmeier Cleo[3] and Ollier Sébastien[2], [1]Department of Ecology and Evolution, University of Lausanne, Switzerland, [2]Ecology, Systematics and Evolution Lab, Department of Biology, University Paris-Sud XI, France, [3]University of Lausanne, Switzerland

Abstract: Certain world regions are overrepresented as donors of alien species, while others are overrepresented as recipients. It has been suggested that asymmetric patterns of establishment are due to regional selection for traits promoting invasiveness, but this has rarely been tested empirically. Insects are among the most widespread and problematic alien organisms, and are largely introduced unintentionally by the movement of commodities. This suggests that varying opportunities for introduction through trade and travel may explain invasion asymmetry in insects. However, the selective pressures filtering species differ throughout the invasion process. It is possible that species introductions could be largely determined by trade flows, while insects from certain regions are indeed more likely to establish once introduced. Here we aim to disentangle the impacts of region of origin, and opportunities for introduction, on species flows during different stages of the invasion process. We used border interception records, comprehensive lists of established insects, and global ant distribution data to quantify flows of species between regions. While certain regions supply more species than others, import value had a significant impact on both the number of species transported between regions, and the number of species which subsequently establish. Our results suggest that while species' origins influence their invasion success, the regional asymmetry in insect establishments can to a large extent be explained by differing opportunities for introduction through human-mediated dispersal. Understanding the mechanisms that drive species introductions, establishment and spread outside their native range is crucial for managing biological invasions.

Vectors of Xylella fastidiosa in Spain: distribution, life cycle and dispersal

Authors: Fereres Alberto[1], Moreno Aranzazu[1], Lago Clara[1] and Cornara Danele[1], [1]ICA-CSIC Madrid, Spain

Abstract: Xylem-feeders insects belong to various families of Auchenorryncha, the most common and widespread in Europe being the superfamily Cercopoidaea, whose members are commonly known as spittlebugs or froghoppers. During the period 2016-2019, we surveyed the potential vectors of X. fastidiosa in the main olive, almond and grapevine-producing regions of the Iberian Peninsula. Our survey shows that Philaenus spumarius and Neophilaenus campestris occur in olive groves in spring and early summer on the ground vegetation but very few are present on the tree canopy. In almond groves and vineyards, spittlebugs were found both in the tree canopy and on the ground vegetation. The sharpshooter Cicadella viridis was also found in vineyards but only on the ground vegetation. The occurrence of spittlebugs is mainly concentrated in cold and humid regions where ground vegetation is present most part of the year. Other factors such as the presence of livestock, riparian and grassland vegetation are suitable for spittlebug profusion.

In addition we conducted a study on the life cycle of the monovoltine P. spumarius to set up the best environmental conditions for indoor rearing and artificially reach up a maximum number of generations per year. Our goal was achieved by disrupting both the ovarial and overwintering diapause, shortening its life cycle and obtaining both nymphs and adults, several months before they become available in the field.

Finally, we have set-up a capture-mark-recapture methodology in combination with flight mills to study the dispersal of spittlebugs. We found that they migrate from their spring hosts (eg olive groves) to their oversummering hosts (eg pine trees) and are able to fly at least 2.5 km in 35 days.

All these studies show that vectors of X. fastidiosa are widely present in the Iberian Peninsula in olive, almond and vineyards although mainly associated to specific climatic conditions and cultural practices.

Contributions to improve current environmental risk assessment procedures of GABCAs in Argentina

Authors: Fernanda Achinelly M.[3], Gabriela Luna M.[2], V. Cédola Claudia[3], Sánchez Marcelo[1] and E. Sánchez Norma[3], [1]Animal and Plant Protection Service (Servicio Nacional de Sanidad Animal y Vegetal, SENASA), Argentina, [2]CEPAVE (CONICET-UNLP-CICBA) & UNSAdA, Argentina, [3]CEPAVE (CONICET-UNLP-CICBA), Argentina

Abstract: Argentina has over 100 years of experience in classical biological control, mostly based on the importation of GABCAs against arthropod pests and weeds. Historically, introductions were requested by provincial or national ministries of agriculture and the National Institute of Agricultural Technology (Instituto Nacional de Tecnología Agropecuaria, INTA), and only a few, if any, risk or non-target effect analyses were made prior to entering the organisms. Since the late 1990s, the process for requesting, evaluating and making decisions to import, quarantine, release and post-release monitoring of exotic biocontrol agents is carried out by the the Animal and Plant Protection Service (Servicio Nacional de Sanidad Animal y Vegetal, SENASA) at national level. Safety of introductions is also regulated at international level, by the Plant Protection Committee (Comité de Sanidad Vegetal, COSAVE) formed by Argentina, Brazil, Chile, Peru, Bolivia, Uruguay and Paraguay to accomplish the International Standard for Phytosanitary Measures (ISPM 3). As a part of the process, the evaluation of environmental risks and potential non-target organisms threatened of importing such exotic agents is requested to specialists from academic and scientific sectors. Experts usually face the lack of published information or previous research work done on the biology of the invasive pest, the native natural enemies communities, and at larger scale, the effects on non-target species; thus, they are mostly reluctant to inform positively on those petitions. Lastly, this situation creates tensions among scientists, producers and decision makers to import exotic GABCAs. In this paper, we present the state of the art of the procedures and regulations for the importation of GABCAs in Argentina during the last two decades, summarizing main classical or commercial biocontrol initiatives and discuss the potential risks involved in such introductions. To cope with that, we focused our analysis on the petition to import 18 GABCA species (15 parasitoids and three predators) done from 1996 to date, reported by SENASA and COSAVE websites. We summarized their host/prey range, biogeographical origin, target crop and pest, year of requested importation, experimental or commercial purposes, and denied or approved request (year) by searching information on the species in Google Scholar, CABI and other biological databases as well as that published in primary literature sources, non-peer review papers (technical reports, etc.). We also ranked the species following the ERA-GABCA categories for Likelihood of Establishment (LE) for the exotic agents and Adverse Effects (AEi) on non-target species. We are aimed to provide, from this study, indications and recommendations for scientific researchers, agricultural producers, practitioners and decision makers to improve the current evaluation for GABCA introductions, in a social, environmental and economic safer productive context.

Biological control of Bemisia tabaci biotype B in protected tomato cultivation: dynamics of mortality factors and predation potential of Amblyseius tamatavensis

Authors: Fernandes Odair[2], Álvaro José[1] and Castilho Raphael[2], [1]Higher Polytechnic Institute of Gaza, Chókwè., Mozambique, [2]São Paulo State University, FCAV/Unesp, Jaboticabal, SP, Brazil

Abstract: The whitefly Bemisia tabaci (Gennadius) (Hemiptera: Aleyrodidae) biotype B is one of the main agricultural pests in Brazil and worldwide. The objective of this study was to evaluate the predation potential of Amblyseius tamatavensis Blommers (Acari: Phytoseiidae) in protected tomato cultivation, as well as the dynamics of whitefly mortality factors. Experiments were carried out in laboratory and greenhouse. Initially, the predation preference for eggs and nymphs of B. tabaci was evaluated. Subsequently, the functional and numerical response of A. tamatavensis on immature B. tabaci was determined. The efficiency of A. tamatavensis to control B. tabaci on tomato plants was also evaluated. Finally, the dynamics of natural whitefly mortality factors were compared between B. tabaci infested tomato crops in the presence and absence of the predator A. tamatavensis. The results showed that A. tamatavensis has a preference for early stages of B. tabaci (eggs, first- and second-instar nymphs). The functional response is type II and the mite feeding upon B. tabaci eggs can oviposit 1.4 eggs/day. The release of 26 or 78 predatory mites/m2 soon after whitefly infestation are efficient to keep whitefly population under control. Individuals of the predaceous mites were observed after 4 weeks of release confirming they could develop and remain in the crop. Also, predation is an important mortality of whiteflies regardless the release of A. tamatavensis. This work established the foundation for a whitefly biological control program in tomatoes.

The genome sequence of the iconic pest grape phylloxera.

Authors: Fernández Rosa[5], Legeai Fabrice[3], Rispe Claude[6], Tagu Denis[4], Delmotte Francois[2] and D.N. Nabity Paul[1], [1]Department of Botany and Plant Sciences, University of California, United States, [2]French National Institute of Agricultural and Environmental Research (INRAE), France, [3]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, France INRIA, IRISA, Genscale, Campus Beaulieu, Rennes, France, [4]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, France, [5]The Barcelona Institute for Science and Technology, Spain, [6]Unité BioEpAR INRA ONIRIS 1300, Oniris, France

Abstract: Although native to North America, the invasion of the aphid-like grape phylloxera (Daktulosphaira vitifoliae) across the globe altered the course of grape cultivation. For the past 150 years viticulture relied on grafting resistant North American Vitis species as rootstocks, thereby limiting genetic stocks tolerant to other stressors such as pathogens and climate change. Limited understanding of the insect genetics resulted in successive outbreaks across the globe when rootstocks failed. In the scope of the International Aphids Genomics Consortium, we report the 294-Mb genome of D. vitifoliae, and its annotation, available at the BioInformatics Platform for AgroEcosystems Arthropods (BIPAA. http://bipaa.genouest.org), as a basic tool to understand host-plant manipulation, nutritional endosymbiosis, and enhance global viticulture.

As a result, our study, supported by a highly complete genome and an uncommon community effort on curated annotation revealed that phylloxera (like aphids) has a high number of coding genes compared to other arthropods, metabolic pathways are similarly represented in phylloxera and aphids, despite the absence of obligate bacterial symbiosis, and we identified an extraordinarily large expansion of a novel gene family of putative effectors. Finally, a large genome-wide sequencing of phylloxera samples from both the native (North America) and introduced populations (Europe and New World vineyards) shows that phylloxera populations of the upper Mississippi River basin, feeding on the wild species Vitis riparia, are likely to be the principal source of the invasion to Europe. Subsequent invasions of South America and western Australia were the result of secondary introductions, from European sources.”

Selection following gene duplication shapes recent genome evolution in the pea aphid Acyrthosiphon pisum

Authors: Fernández Rosa[7], Legeai Fabrice[4], Robin Stéphanie[2], Pegueroles Cinta[1], Tagu Denis[6], Richard Gautier[5], Marcet-Houben Marina[1], Gabaldón Toni[1] and Wucher Valentin[3], [1]Bioinformatics and Genomics Unit, Centre for Genomic Regulation, The Barcelona Institute for Science and Technology, Barcelona, Spain, [2]BIPAA Platform, INRAE, IGEPP, Le Rheu GenOuest Platform, INRIA/IRISA, Rennes, France, [3]CRG, Barcelona, Spain, [4]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, Le Rheu, France INRIA, IRISA, Genscale, Campus Beaulieu, Rennes, France, [5]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, Le Rheu, France; Max Planck Institute of Immunobiology and Epigenetics, Freiburg, Germany, [6]IGEPP, INRA, Agrocampus Ouest, Université de Rennes 1, Le Rheu, France, [7]The Barcelona Institute for Science and Technology, Spain

Abstract: Ecology of insects is as wide as their diversity, which reflects their high capacity of adaptation in most of the environments of our planet. Aphids, with over 4,000 species, have developed a series of adaptations including a high phenotypic plasticity and the ability to feed on the phloem-sap of plants, which is enriched in sugars derived from photosynthesis. Recent analyses of aphid genomes have indicated a high level of shared ancestral gene duplications that might represent a basis for genetic innovation and broad adaptations. In addition, there is a large number of recent, species-specific gene duplications whose role in adaptation remains poorly understood. Here, we tested whether duplicates specific to the pea aphid Acyrthosiphon pisum are related to genomic innovation by combining comparative genomics, transcriptomics, and chromatin accessibility analyses. Consistent with large levels of neofunctionalization, we found that most of the recent pairs of gene duplicates evolved asymmetrically, showing divergent patterns of positive selection and gene expression. Genes under selection involved a plethora of biological functions, suggesting that neofunctionalization and tissue specificity, among other evolutionary mechanisms, have orchestrated the evolution of recent paralogs in the pea aphid and may have facilitated host-symbiont cooperation. Our comprehensive phylogenomics analysis allowed to tackle the history of duplicated genes to pave the road towards understanding the role of gene duplication in ecological adaptation.

Effect of entomopathogenic fungi and pyrethrum combinations on pests and beneficial insects

Authors: Fernandez-Grandon Mandela[1], Harte Steven[1], Haynes Laura[1], Bray Daniel[1] and Stevenson Phil[1], [1]Natural Resources Institute, University of Greenwich

Abstract: Entomopathogenic fungi (EPF) and botanical pesticides, such as pyrethrum, are recognised as promising tools for pest control in sustainable agriculture. They are favoured for their low impact on the environment and human health, however, the short period of activity for pyrethrum and the delay from application to effective control for EPF have limited their utility for growers. A combination of both pyrethrum and EPF could overcome these limitations by creating an environmentally benign pesticide which is fast acting through the activity of the pyrethrum, and long lasting through the sustained control from the EPF. Furthermore, it is hoped this multimodal approach may enhance efficacy and challenge the development of insecticide-resistant pest species.

We present findings of our studies of combinations of pyrethrum with EPF strains of Metarhizium anisopliae and Beauvaria bassiana on the mortality of aphids, Aphis fabae, and fall armyworm, Spodoptera frugiperda. Additionally, we explore the impact of a combination treatment on mortality and oviposition behaviour of an important pollinator species, the hoverfly Eupeodes corollae.

Oviposition strategies of container breeding mosquitoes: an investigation into the site search and internal site behaviour of gravid Aedes aegypti.

Authors: Fernandez-Grandon Mandela[2], Bray Daniel[1], Joiner Jillian[2], Hawkes Frances[2], Gibson Gabriella[2] and Hopkins Richard[2], [1]Chemical Ecology and Plant Biochemistry Group, Natural Resources Institute, University of Greenwich, United Kingdom, [2]Natural Resources Institute, University of Greenwich, United Kingdom

Abstract: Aedes aegypti (Diptera: Culicidae), vector of the yellow fever, dengue, chikungunya and Zika viruses, oviposit in a variety of man-made containers in urban environments. Some containers (e.g. water storage units and plant pots) have been identified as more productive in numbers of pupae produced, but the extent to which Ae. aegypti actively seek these sites in which to oviposit remains unclear. Many containers in urban environments appear relatively limited in potential resources but still receive eggs. Understanding this fundamental aspect of mosquito behaviour is essential for developing evidenced-based policies for Ae. aegypti control, and for testing theories of whether insects can reliably select oviposition sites which produce the most offspring (the preference-performance hypothesis).

Here, we examined Ae. aegypti oviposition responses to water from plant pot dishes, a common oviposition site in Brazil. It is believed these may be a preferred and productive container due to organic matter from the soil supporting bacterial growth as a larval food source. We tested whether Ae. aegypti chose to lay in this ecologically relevant substrate under cage bioassay and wind tunnel conditions, and if it conferred any benefits for offspring. We also examined if Ae. aegypti modulate how eggs are placed within an oviposition site (on the side of the container or directly on the water) in response to the water contents, and the potential adaptive benefits of such behaviour.

Our initial results indicate that in standard oviposition cage assays, more female Ae. aegypti laid eggs in plant pot water compared to both deionised water and a brewer's yeast suspension. However, larval survival in plant pot water was not higher than in deionised water and was significantly less than in the brewer's yeast suspension. This suggests that, under these standard test conditions, mosquitoes did not choose the most productive oviposition substrate. Furthermore, female Ae. aegypti modulated the placement of eggs within an oviposition site according to the contents of the water. We are currently investigating whether this strategy promotes bacterial growth and larval survival.

In wind tunnel assays, individual females laid more eggs in pots containing plant pot water than deionised water. However, the relative position of plant pot water within the wind tunnel air stream affected the relative number of eggs laid. This may indicate a role for volatile chemicals in locating or discriminating between potential oviposition sites and suggests a more opportunistic behaviour when the preferred pots were in a more cryptic location. Through 3D flight tracking, we are currently investigating the number of visitations per site in relation to the total number of eggs laid, and the order in which sites were visited. Together, these results may indicate how and why Ae. aegypti come to lay more eggs in preferred oviposition sites, even if they are not necessarily the most productive.

Community genomics and comparative behavioural assays shed light on host-specific chemosensory evolution in plant-associated drosophilids.

Authors: Ferreira Erina Ava[1] and Yassin Amir[1], [1]EGCE - CNRS, Université Paris Saclay, IRD, France

Abstract: Host plant shift is a major source of diversification in herbivorous insects implying the evolution of multiple behavioral, physiological and morphological traits. However the evolutionary context of the early stages of host shifts, such as resource availability and escape from competition, remains often unclear. We investigate the recent specialization on the island of Mayotte of the generalist African fly (Drosophila yakuba) on the toxic fruits of Asian noni (Morinda citrifolia). Population genomics suggested D. yakuba to be present on the island 29,000 years ago, far before early human colonizers would have been able to plant noni or inadvently bringing other Drosophila competitors on the islands. We use chloroplast DNA and genome wide polymorphisms (RADseq) to infer the expansion date of noni into the Western Indian Ocean islands. We also use comparative population genomics, behavioural assays (taste preference) and physiological experiments (survival) in multiple Drosophila species that have also been bred from noni on Mayotte. The results suggest that a combination of historical events and ecological interactions facilitates host plant specialization in generalist insects.

Improving monitoring and control of black vine weevil (Otiorhynchus sulcatus) in soft fruit and ornamental crops

Authors: Fezza Eugenia, Harper Adams University, United Kingdom

Abstract: The black vine weevil, Otiorhynchus sulcatus (Coleoptera: Curculionidae) is one of the most economically important pests of soft fruit and ornamental crops. To develop an effective and reliable monitoring system for vine weevil adults a series of experiments were completed under laboratory condition in order to determine the influence of colour, height and entrance position on the efficacy of a model monitoring tool. Results indicate that dark, tall refuges with entrances around their base were preferred by vine weevil adults.

Additional experiments have investigated the behavioural responses of vine weevil to a range of olfactory cues associated with host plants or conspecifics. The aim, here, was to understand which olfactory cues stimulate positive behavioural responses in vine weevil adults in order enhance the efficacy and reliability of monitoring tools for this species through inclusion of a semiochemical lure. Results indicate that response olfactory cues are determined by the time of the day when the experiment was completed.

This study improves our understanding of the visual and olfactory preferences of vine weevil. Improved understanding of these behavioural responses can be exploited in the design of more effective and reliable monitoring tools for this species that may be used within IPM programmes.

Key lessons learned from recent insect biocontrol programs

Authors: FH Sforza René, USDA-ARS-EBCL, France

Abstract: The intensification of commercial trade over the last three decades has increased the rate of new pest introductions worldwide. It has also resulted in new pathways in the transportation of pests from countries not traditionally known as suppliers, such as central and south East Asia for North America and Europe, and South America for Europe and Africa. Recently introduced pest case studies will be used here as a baseline for understanding trends that are currently driving classical biological control (CBC). We will attempt to draw guidelines with respect to target selection, host range testing for regulatory approval and risk assessment, and measurement of economic, ecological and social impacts. As per target selection, the choice of pests with rapid expansion and high negative impact varies upon different factors. Pests impacting high-value added crops (spotted lanternfly and spotted wing drosophila on grapevine, the fall armyworm on cropped cereals), or crops having a great natural and cultural value (Asian chestnut gall wasp), or crops with a high demand from the farming industry (Bagrada bug on cole crops, brown marmorated stink bug on various fruits, vegetables, and ornamentals), have been prioritized. In addition, it became common to select targets that have been successfully controlled with known and evaluated beneficial agents in one place, to be introduced in another (Anagyrus kamali on the pink hibiscus mealybug, Mastrus ridens against codling moth, Neodryinus typhlocybae against the citrus planthopper). Thus, biocontrollers reduce the number of species for host range testing and maximize their chance of success and avoiding adverse impacts. Over 140 years of records in CBC, only 1.5% of worldwide programs had one or more non-target effect record. However the trend is to reduce this ratio for getting approval for release, and the most suitable species are selected for testing and that the resulting data provide the most rigorous test of the risk hypothesis of no adverse effect. Filtering on main criteria such as, spatial, temporal and morphological attributes on one hand, and species availability on the other hand, typically leads to a short list of species that may be tested (case studies of Bagrada bug and Brown marmorated stink bug). The test list is also based on phylogenetic relatedness, sympatry of target and non-target species (spotted-wing Drosophila). Finally, measurements of economics and ecological impacts show an extremely positive feedback on cost-effectiveness of CBC (Clover root weevil in New Zealand, mealybugs in agricultural systems). As a result, although the rate of new biocontrol agents introduced has been decreasing since the 1980s, a better success in the rate of success and establishment of BCAs has been observed. This trend could be partly due to all factors detailed above, like a better selection of non-target species to test, reducing the ecological risks that were the center of discussions in the 1990s.

Are eggs of Hermetia illucens L. (Diptera: Stratiomyidae) suitable for mass rearing predatory mirids?

Authors: Figueiredo Elisabete[2], Duarte Gonçalo[3], Borges da Silva Elsa[1] and Caldas Filipa[2], [1]CEF, Forest Research Centre, School of Agriculture, University of Lisbon, Portugal, [2]LEAF, Linking Landscape, Environment, Agriculture and Food, School of Agriculture, University of Lisbon, Portugal

Abstract: The black soldier fly (BSF) Hermetia illucens L. (Diptera: Stratiomyidae is mass produced for biowaste conversion, protein meal, insect oil and fertilizer. BSF production is expected to increase after the European Commission authorized the use of insect-based protein in aquaculture feed. Higher market demand and production may reduce the cost of BSF products, including eggs, in the next years.

The market of commercial biological control agents is growing worldwide. Mass production of many generalist predators is dependent on the use of factitious prey like insect eggs. The eggs of Ephestia kuehniella Zeller (Lepidoptera: Pyralidae) and Sitotroga cerealella (Olivier) (Lepidoptera: Gelechiidae) are currently the staple food source used in commercial production of many natural enemies.

Mirid bugs (Hemiptera: Miridae) are among the most important natural enemies in protected crops. In order to reduce the cost of E. kuehniella eggs, the production of mirid bugs (mostly species in the genera Dicyphus, Macrolophus and Nesidiocoris) uses a mix of E. kuehniella eggs and Artemia sp. (Anostraca: Artemiidae) cysts.

BSF based diets have been previously studied on vertebrates like fish, pigs and poultry. However, there are few studies that evaluate the effect of H. illucens diet on other insects.

In this study we assessed the suitability of BSF eggs as factitious prey for predatory mirids. We chose the mirid Dicyphus cerastii Wagner (Hemiptera: Miridae) that is found from Portugal to Turkey on differerent crops.

Nymphal development time, nymphal mortality, adult longevity, weight and progeny were compared between D. cerastii nymphs reared on: 1) eggs of BSF; 2) eggs of E. kuehniella; 3) eggs of E. kuehniella + Artemia sp. cysts. Nymphal development time was not different between diets containing E. kuehniella eggs. However, it was significantly longer when reared on BSF eggs, suggesting it may be a lower quality diet compared to E. kuehniella.

Protecting processing tomato crop against Tuta absoluta (Meyrick) in Ribatejo region

Authors: Figueiredo Elisabete[3], Paula Nunes Ana[1], Valério Elsa[2] and Godinho Maria[2], [1]COTHN, Portugal, [2]ESAS, Polytechnical Institute of Santarém, Portugal, [3]LEAF, Linking Landscape, Environment, Agriculture and Food, School of Agriculture, University of Lisbon, Portugal

Abstract: Tuta absoluta (Meyrick) has been a key pest of tomato processing crop in the Portuguese region of Ribatejo since 2011, causing significant losses in some seasons.

In order to develop friendly to use tools for decision-making process to protect this crop a partnership bringing together growers' organizations, universities, technological centres and industrial companies) developed a plan supported by the project - PRODER 4.1 "Protomate" - Development of a new tool to support the management of the tomato crop to guarantee the quality of the final product". We aimed at improving risk assessment methods and the timing of the treatments and decreasing its number with better efficiency. A partnership network was built allowing a permanent interchange with knowledge, results and experience sharing routines in time during the crop cycle. In 2013 and 2014 crop seasons, adults of T. absoluta were monitored with delta pheromone traps and plants were checked for eggs and larvae according to a stablished protocol. Insects were collected for laboratory observation. Damage risk factors were identified at farm and regional scales. Risk maps were performed based on development parameters and temperature registered by satellite. The risk assessment program was applied in each field taking into account these maps, the adults in the delta traps, crops in the vicinity and their harvesting dates. The success of control methods was monitored. A diagram for decision-making in processing tomato is presented.

Critical role of the food K:Na ratio for ecology and evolution of herbivorous and detritivorous insects

Authors: Filipiak Michal[2], J. Saville David[1], Veronesi Emiliano[1], N. C. Grainger Megan[3], W. Shields Morgan[1] and M. Cairns Sarah[1], [1]Bio-Protection Research Centre, Lincoln University, New Zealand, [2]Institute of Environmental Sciences, Faculty of Biology, Jagiellonian University, Kraków, Poland, [3]School of Science, University of Waikato, Hamilton, New Zealand

Abstract: The functioning of herbivorous and detritivorous insects is affected by nutritional limitation originating from general trait of plant tissues and products, i.e. low concentration of sodium (Na), required by consumers in high proportions. Therefore, Na availability influences survival, fitness, and abundance of consumers feeding on plant matter as well as shapes ecological interactions, and food webs. However, considering only one nutrient at a time is neither physiologically nor ecologically relevant, and the effect of Na on consumers may be regulated by the K:Na ratio. Sodium and potassium (K) are physiologically bound and excessively high K:Na ratio in food have detrimental effect for consumers even if Na concentration is high. Our preliminary studies on Apis mellifera have shown that, contrary to common knowledge, bees prefer specific K:Na ratio, not solely Na concentration in food and water. However, the concentrations of the two elements in pollen eaten by bees are closely linked and the K:Na ratio in pollen is stable and high. Moreover, the K:Na ratio in pollen is too high regarding the bee needs and Na must be supplemented from other sources to allow for adequate overall food K:Na balance. We therefore propose use of the K:Na ratio in studies considering ecology and evolution of bees and other herbivorous and detritivorous insects to broaden our understanding of plant-insect interactions and lay the grounds for better understanding of: (1) general ecology and evolution of insects, (2) evolution of bees, especially regarding trade-offs experienced when evolving from carnivory to herbivory, and (3) the role of soil-plant-consumer pathway in nutrient cycling in ecosystems.

How to really help bees: nutrient demand and supply in a changing environment

Authors: Filipiak Michal[3], Denisow Bozena[1], Stawiarz Ernest[1] and Maria Filipiak Zuzanna[2], [1]Department of Botany and Plant Physiology, Laboratory of Plant Biology, University of Life Sciences in Lublin, Lublin, Poland, [2]Faculty of Biology, Institute of Environmental Sciences, Jagiellonian University, Kraków, Poland, [3]Institute of Environmental Sciences, Faculty of Biology, Jagiellonian University, Kraków, Poland

Abstract: Wild bees often cannot access the optimally balanced diet required for their survival because local and global changes affect which pollen varieties are available to them in the environment. Understanding how the nutritional quality of various pollens affects bees could help us determine whether and how floral diversity and composition shape bee communities and populations. Therefore, to study how the nutritional quality of pollen influences wild bee fitness-related traits (survival, cocoon development and body and cocoon sizes), we asked questions about bee functioning in environments offering various nutrient diversities and compositions via available pollen species. Utilizing a feeding experiment, we show that the nutritional quality of the pollen diet eaten by bee larvae is shaped not by pollen diversity per se but by a specific pollen species composition that results in specific nutrients being scarce or sufficient and affects bee fitness-related traits. Suboptimal concentrations of certain nutrients in pollen produced by specific plant species resulted in increased mortality, decreased size and underdeveloped cocoons, and the strength of the observed negative effect was sex dependent and alleviated if scarce nutrients were added to the pollen diet. Therefore, nutritional stress caused by habitat loss and transformation and further alterations due to global changes, e.g., pollen nutrient dilution associated with rising atmospheric CO2 levels, may be direct drivers of observed wild bee declines. Accordingly, we propose that the functioning of bee populations and communities may depend on the floral diversity of the local habitat, which determines whether a nutritionally balanced pollen diet obtained from certain species can be provided to bee larvae. Considering bee fitness and health holistically in this manner could reveal important interactions between bees and other parts of the food web as well as lead to new ways of conserving bees and the critical roles they play in ecosystems.

Efficacy of neem and coconut oil for treatment of Tungiasis in Kilifi County, Kenya

Authors: Fillinger Ulrike[4], Elson Lynne[1], Feldmeier Hermann[3] and Randu Kithi[2], [4]International Centre of Insect Physiology and Ecology, Kenya, [1]CGMRC, KEMRI-Wellcome Trust Research Programme, Kilifi, Kenya andNuffield Department of Medicine, Oxford University, UK, Kenya, [3]Institute of Microbiology and Infection Immunology, Charité University Medicine, Berlin, Germany, [2]Human Health Theme, International Centre of Insect Physiology and Ecology, Nairobi, Kenya

Abstract: Background: Tungiasis is a neglected tropical skin disease caused by female sand fleas (Tunga penetrans) which burrow into the skin causing immense pain, itching and debilitation as they grow. There is currently no simple, effective and affordable method of treatment available in Kenya. However, communities in Kilifi County have been successfully using a locally made blend of neem and coconut oil.

Methods: Ninety six school children aged 6-14 years with at least one clear viable, embedded flea at Fortaleza stage 3 were enrolled. They were randomized to be treated with either the study product, a blend of 20% virgin neem (Azadirachta indica) seed oil in virgin coconut (Cocos nucifera) oil or with the current standard of potassium permanganate (KMNO4) followed by vaseline. All embedded fleas were treated. Up to two viable fleas were selected for each participant and were monitored every other day for 7 days after treatment using a digital handheld microscope for signs of viability and abnormal development. Acute pathology was assessed on all areas of the feet. The children were asked to assess their level of pain and itching using visual analogue scales. The trial was approved by KEMRI-SERU, PPB-ECCT and registered on PACTR.

Results: The study product only left 22% of the fleas fully viable by Day 7, compared to 48% of the fleas treated with KMNO4 (OR 0.29, 95% CI=0.10-0.88, $p=0.029$) and a significantly higher proportion of fleas (62%) were rapidly aged by day 7, than those treated with KMNO4 (26%, OR 4.7, 95% CI: 1.6-13.9, $p=0.005$) The neem and coconut oil also significantly reduced the tungiasis-associated acute pathology ($p<0.005$), and the proportion of children reporting no pain or itching doubled (pain OR2.2, $p=0.05$, itching OR2.15, $p=0.007$). On the other hand, the acute pathology of children treated with KMNO4 did not decrease and significantly more children reported increased pain and itching on Day 7 (OR3.6 more pain and OR2.6 more itching). Conclusions: The 20% neem in coconut oil is a very promising treatment for tungiasis. Further trials are needed to assess what dosage will completely kill the majority of embedded fleas within 7 days.

Beyond consumption: Rethinking the role of multi-species wasp assemblages in aphid suppression

Authors: Finke Debbie, University of Missouri, United States

Abstract: Predator–prey interactions have traditionally focused on the consumptive effects that natural enemies have on prey. However, enemies can also reduce the abundance of prey through behaviorally-mediated non-consumptive effects. Furthermore, non-consumptive effects of natural enemies can also extend to non-prey herbivore populations (i.e., suppression by non-enemies). We investigated the relative contributions of consumptive and non-consumptive effects to aphid suppression by a multi-species wasp assemblage containing both enemies and non-enemies. We examined the response of two aphid species with different defensive strategies, pea aphids (Acyrthosiphon pisum) that drop from their host plant to the ground and green peach aphids (Myzus persicae) that remain on the plant and walk away, with the expectation that riskier defensive behaviors would result in larger non-consumptive effects. We found that, despite differences in defensive strategies, the non-consumptive effects of wasps on aphid abundance were more than twice the consumptive effects for both aphid species. Additionally, we found that non-consumptive effects arise from interactions with both enemy and non-enemy wasps and that both contribute to aphid control when part of a broader community. In fact, the presence of non-enemy wasps prevented aphid outbreaks and contributed to population stability over multiple generations. We conclude that the presence of non-enemy species in a multi-species assemblage may contribute directly to aphid suppression and provide insurance against fluctuations in the size of consumptive enemy populations.

Plant primacy in the effect of drought on aphids and their natural enemies

Authors: Finke Debbie[1] and Kansman Jessica[1], [1]University of Missouri, United States

Abstract: Climate change is increasing the frequency and intensity of drought events. More extreme and variable precipitation patterns are predicted to have widespread impacts on productivity, species interactions, and ecosystem processes. Water limitation affects the quality and quantity of plant resources for herbivorous insects, leading to cascading effects for higher trophic levels. Physiological changes in response to water stress may make plants more nutritious for insect herbivores, but it comes at the cost of increased plant defensive responses, declining biomass, and restricted access to the phloem. These changes in the plant have direct effects on natural enemies by changing the attractiveness of the habitat, and indirect effects by changing the quality of their prey. Our study examined the response of an arthropod community to water limited wheat (Triticum aestivum L.) in a field setting, with a focus on the response of aphids and their natural enemies. We used rainout shelters to exclude precipitation and irrigated raised bed plots to create three levels of water availability. Any amount of water limitation negatively affected the abundance of arthropods detected in weekly surveys, including aphids and their natural enemies; however, the composition of the arthropod community was reliant on the magnitude of water stress the plants were experiencing. Through structural equation modeling, we determined that aphids were more affected by stress induced changes in plant properties other than plant biomass, whereas natural enemies were strongly affected by changes in plant biomass. This effect was exacerbated as plant stress intensity increased. Interestingly, the reciprocal response of aphids and natural enemies was not significant, indicating that the contribution of top down effects were dampened by the strong bottom up effects driven by plant water limitation. By incorporating multiple levels of drought stress and assessing the response of the whole arthropod community into this study, we are better able to predict field scale responses of aphids and natural enemies to drought. Understanding such impacts is critical to predicting the consequences of altered precipitation patterns for the sustainable provisioning of ecosystem goods and services.

Impact of feeding strategies on venom composition in aquatic Heteroptera

Authors: Fischer Maike[2], Yepes Vivas Sol Andrea[1], Wielsch Natalie[6], Heckel David[4], Vilcinskas Andreas[5] and Vogel Heiko[3], [1]Department of Biochemistry, MPI for Chemical Ecology, Germany, [2]Department of Insect Symbiosis, MPI for Chemical Ecology, Germany, [3]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [4]Emeritus Group Entomology, MPI for Chemical Ecology, Germany, [5]Institute of Insect Biotechnology, Justus-Liebig University, Germany, [6]Research Group Mass Spectrometry/Proteomics, MPI for Chemical Ecology, Germany

Abstract: True water bugs (Nepomorpha) are mostly predacious insects occurring in aquatic habitats around the world. Their venomous saliva facilitates capture and extra-oral digestion of prey animals. In Germany, various nepomorphan species from different families co-occur in the same habitat, however, their feeding ecology including venom composition and deployment is largely unknown. Using an integrated-proteomic-transcriptomic approach, we could show that the ecological niche strongly determines venom composition in four water bug species sharing the same habitat. We found considerable species-specific differences in the composition of digestive enzymes and identified venom components that likely evolved as adaptations to a particular food source, foraging strategy, or microhabitat. The outstanding differences of Corixa punctata venom to strictly predatory species, and the high abundance of herbivory-associated proteins suggest a mostly plant-based diet for C. punctata. Our study shows that the venom composition in Heteroptera is a dynamic trait that can differ considerably between species even though they share the same habitat and ecological niche. However, further research is required to confirm diet-associated patterns, since reliable conclusions cannot be drawn based on saliva composition alone.

Principles of Insectary Design

Authors: Fisher William, International Insect Rearing Workshop Mississippi State University Mississippi State, Mississippi, United States

Abstract: Preliminary considerations for designing an insect-rearing facility include understanding the rearing requirements for the species of interest, recognizing the functions of an insectary, identifying design elements that will satisfy both the requirements and functions, and creating a preliminary design that incorporates those elements. Rearing requirements consist of the biological and environmental needs of the insects; customer expectations for insect quantity, quality, and delivery; procedures such as diet preparation, handling insects, and collecting and packaging insects; program scale-up requiring additional facilities, equipment, and automation; prevention and management of microbial and arthropod contaminants; sanitation and disposal of waste products; potential health and safety hazards for employees; and familiarity with other insectary operations. The facility functions to achieve the following: 1. Contain insects. The type of larval and adult containment devices, whether reusable, single-use, or a combination of both significantly impacts facility design, utilities, flow plan, equipment, and cost. The type should be determined early in the design phase. 2. Control insectary contaminants. Microorganisms, natural enemies, arthropod competitors, and nuisance species can adversely impact product quality and production efficiency. Principles of control consist of preventing contaminants from entering the facility, maintaining conditions that inhibit their growth, keeping them from spreading, and installing barriers that prevent their transfer to succeeding cohorts. 3. Provide a hygienic environment. Incorporate "clean" construction materials and methods into the design such as smooth wall, ceiling, and floor coatings; coved floor/wall junctions; solid ceilings in holding rooms; and smooth door thresholds. 4. Isolate critical rooms and activities. These include insect-holding room(s), a dirty workroom designed to contain and remove contaminants, a clean workroom that excludes contaminants, and a quarantine area that is physically separated from the primary cultures where arthropods from anywhere outside the insectary are received and held. 5. Establish a logical flow plan. The route that insects, materials, and employees move within the facility determines the location of insectary rooms and eliminates the backflow of contaminants. Flow-plan success depends on the thorough understanding of all activities performed in each room. 6. Provide optimal conditions for the insects. These include temperature, humidity, airflow pattern, airflow rate, air-pressure differential between rooms, ventilation, and air cleanliness. Avoid temperature stratification and buildup of heat, CO2, and moisture in high-density vertical racks. Experienced insect-rearing personnel play a significant role within the design team, particularly during the initial phases of the process.

Chickpea pod borer, Helicoverpa armigera IPM in Ethiopia

Authors: Fite Tarekegn[5], Tefera Tadele[4], Negeri Mulugeta[2], Damte Tebekew[1], and Sori Waktole[3], [1]Debre Zeit Agricultural Research Center, Debre Zeit, Ethiopia, [2]Department of Plant Sciences, Ambo University College of Agriculture and Veterinary Science, Ambo, Ethiopia, [3]Ethiopian Horticulture Producer Exporters Association, Addis Ababa, Ethiopia, [4]International Center of Insect Physiology, Ethiopia, [5]International Centre of Insect Physiology and Ecology (ICIPE), Addis Ababa, Ethiopia

Abstract: Helicoverpa armigera (Hubner) (Lepidoptera: Noctuidae), is a destructive pest of chickpea that has proven difficult to control using conventional methods. It is considered as the main production constraints of chickpea under field condition in Ethiopia. We evaluated botrack lure with funnel type efficient and specific pheromone trap for H. armigera. Population build up starts in September and climbing up for the highest peak during February. Besides, we identified five species of hymenopteran and dipteran larval parasitoids on H. armigera in chickpea. Moreover, we developed a management options including botanicals (Azadirachta indica and Milletia ferruginea) extracts and bio-pesticides (Beauveria bassiana, Metarhizium anisopliae and Bacillus thurengiensis) for the management of H. armigera under field conditions. Molecular characterization of H. armigera indicates high haplotype and low nucleotide diversity in six populations of H. armigera in Ethiopia with high gene flow. High percentages of variation between within populations were also evident. Selective and low dose synthetic insecticides can be used at peak time followed by bio-pesticides and botanical extracts.

The role of insulin signaling in shaping life-history variation

Authors: Flatt Thomas, Department of Biology, University of Fribourg, Switzerland

Abstract: The insulin/insulin-like growth factor signaling (IIS) pathway provides an excellent example of how mechanistic and evolutionary insights might be combined to gain a more comprehensive understanding of the ultimate and proximate determinants of life-history variation, including plasticity. Since the 1990s a great deal has been learned about the genetic, developmental and physiological effects of this pathway on fitness-related traits, especially in model organisms. This work has shown that loss-of-function mutations in the IIS pathway have major, often evolutionarily conserved effects on growth, size, reproduction, lifespan and stress resistance in insects (e.g., Drosophila), the nematode worm C. elegans, and the mouse. The functional characterization of this pathway thus promised an opportunity for evolutionary biologists to identify naturally occuring, segregating variants in IIS that might be involved in life-history adaptation. Today, we have indeed growing evidence that variation in IIS can make an important contribution to life-history evolution (and plasticity) in flies and other insects (as well as in worms, fish, reptiles and mammals). The aim of my talk is to give a brief overview of some of this work.

The impact of viruses on honey bees at the individual and cellular levels

Authors: Flenniken Michelle[2], McMenamin Alex[1], Parekh Fenali[1], Daughenbaugh Katie[2] and Brutscher Laura[3], [1]Department of Microbiology and Immunology, Pollinator Health Center Montana State University, Bozeman MT, United States, [2]Department of Plant Sciences and Plant Pathology, Pollinator Health Center Montana State University, Bozeman MT, United States, [3]Pollinator Health Center Montana State University, Bozeman MT, United States

Abstract: Honey bee colony losses are influenced by multiple abiotic and biotic factors, including viruses. To investigate the effects of RNA viruses on honey bees, we infected bees with a model virus (Sindbis-GFP) in the presence or absence of dsRNA. In honey bees, dsRNA is the substrate for sequence-specific RNAi-mediated antiviral defense and is a trigger of sequence-independent \ antiviral responses. Transcriptome sequencing identified more than 200 differentially expressed genes, including genes in the RNAi, Toll, Imd, JAK-STAT, and heat shock response pathways, and many uncharacterized genes. To confirm the virus limiting role of two genes (i.e., dicer and MF116383) in honey bees, we utilized RNAi to reduce their expression in vivo and determined that virus abundance increased. To evaluate the role of the heat shock stress response in antiviral defense, bees were heat stressed post-virus infection and virus abundance and gene expression were assessed. Heat stressed bees had reduced virus levels and greater expression of several heat shock genes compared to controls. To determine if these genes are universally associated with antiviral defense, bees were infected with another model virus (flock house virus) or deformed wing virus and gene expression was assessed. Dicer expression was greater in bees infected with either FHV or Sindbis-GFP compared to mock infected bees, but not in deformed wing virus infected bees. To further investigate honey bee antiviral defense mechanisms and elucidate the function of key genes (dicer, ago-2, MF116383, and Hsps) at the cellular level, primary honey bee larval hemocytes were transfected with dsRNA or infected with Lake Sinai virus 2 (LSV2). These studies indicate that MF116383 and Hsps mediate dsRNA detection and that MF116383 is involved in limiting LSV2 infection. Together, these results further our understanding of honey bee antiviral defense, particularly dsRNA-mediated antiviral responses, at both the individual bee and cellular levels.

Bridge or interlude: the role of the insect egg stage in symbiotic interactions with bacteria

Authors: Florez Laura V., University of Copenhagen

Abstract: Many insects engage in symbiotic associations with bacteria, ranging from flexible interactions with environmentally acquired microbes to highly specific partnerships involving stable and dependent co-existence. The establishment of a reliable transmission route from parents to offspring involving the egg stage can be a turning point in the evolution of increasingly dependent symbiosis. However, there can be different selective pressures and constraints influencing the evolution of symbiont transmission via the insect egg. As other extracellularly transmitted symbionts, bacteria smeared on the egg surface by Lagria beetle females must survive this environmentally exposed stage. Then, the bacteria must re-colonize the insect host making their way to the symbiotic organs where they are housed throughout larval development. Using manipulative assays with a culturable symbiont strain, we determined the timing of re-entry in the host and the bacterial population bottleneck during colonization. Also, we used random mutagenesis to predict candidate colonization factors. Notably, in Lagria beetles the egg is not only a key stage for bacterial transmission, but is also a relevant scenario for interactions with other microbes. Microbe-microbe competition is likely important to warrant symbiont colonization in this insect, and at the same time benefits the host by hindering pathogen infections.

IPM of stable fly populations affecting beef cattle production in North America

Authors: Foil Lane[1], Hogsette Jerome[2], [1]Louisiana State University Agricultural Center, United States, [2]USDA–ARS, Center for Medical, Agricultural and Veterinary Entomology, Gainesville, FL, United States

Abstract: The stable fly, Stomoxys calcitrans, is considered to be the second most important economic pest of livestock in the United Sates. Stable flies also are considered to be mechanical vectors of many livestock disease agents worldwide. Adult stable fly management has been challenging because of the fly's dispersal behavior and its tendency to remain on the host only a few minutes each day while feeding. Different types of traps have been used to survey adult stable fly populations and in some cases reduce population levels. Durable insecticide-treated targets made from blue and black cotton fabric developed for tsetse fly management in Africa have been found to be attractive to stable flies. The results of target evaluations and toxicant studies that have been conducted in Louisiana and Florida will be presented.

For many years, the stable fly was not considered to be a problem with pastured cattle because of the lack of habitats for larval development. However, following the advent of large, round hay bale use in livestock agriculture, larval habitats of hay trodden upon by cattle, and mixed with dung and urine are now plentiful. A summary of studies conducted on larval habitat management will be presented; and finally, the elements of potential IPM programs for stable flies will be summarized.

The role of an abundant male nuptial gift protein in sexual conflict in the decorated cricket

Authors: Foquet Bert[2], Albo Maria[3], McKermitt Jack[1], Sadd Ben[1], Sakaluk Scott[1] and Hunt John[4], [1]Illinois State University, [2]School of biological Sciences, Illinois State University, United States, [3]Universidad de la Republica Montevideo, [4]Western Sydney University, Australia

Abstract: Sexual reproduction is a cooperative endeavor, but the interests of the sexes frequently diverge, leading to sexual conflict, which is common among insects. Males often attempt to manipulate female behavior and physiology to increase their share of paternity. One hypothesis posits that males of some species use a nuptial food gift, comprised of materials other than sperm and offered to females at copulation, to achieve this. In the decorated cricket, Gryllodes sigillatus, nuptial food gifts take the form of a spermatophylax, a gelatinous mass forming part of the male spermatophore and consumed by the female after mating prior to her removing the sperm-containing ampulla. Spermatophylax feeding deters females from prematurely terminating sperm transfer, thereby enhancing the paternity share of the male, and may be a route through which the male further manipulates females to their own fitness benefit. In this study, we focused on the effect of SPX1, which is the most abundant protein in the spermatophylax of male decorated crickets. We used RNA interference to generate a knockdown of SPX1 expression, and tested its effect on spermatophylax feeding duration and the latency to remate in females. We found that females fed for a shorter time on spermatophylaxes generated by SPX1 knockdown males, and that these same females fed longer on the spermatophylax offered to them during a second mating with a control male. As such, SPX1 seems to play an important role in mediating sexual conflict in this species, enhancing paternity by increasing a male's sperm transfer time, while decreasing that of a competitor in the next mating.

Tales from the Crypt: A parasitoid manipulates the behavior of its parasite hosts

Authors: Forbes Andrew[1], Ward Anna[1] and Egan Scott[2], [1]Department of Biology, University of Iowa, Iowa City, Iowa 52242, United States, [2]Department of BioSciences, Rice University, Houston, Texas, United States

Abstract: Sand live oaks (Quercus geminata) and Southern live oaks (Quercus virginiana) in the United States harbor a community of manipulators. This community is comprised of cynipid gall wasps, which manipulate the trees into producing galls that protect the wasps from natural enemies. These manipulators can also be manipulated. For example, the crypt gall wasp, Bassettia pallida, manipulates live oaks into producing "crypts", in which the wasp undergoes development before excavating an emergence hole and escaping as an adult. The crypt gall wasp is susceptible to manipulation by the crypt keeper wasp (Euderus set). This parasitoid manipulates its host into excavating a small emergence hole out of the crypt and then dying with its head plugging the hole. The crypt keeper wasp then consumes it host, and emerges through the host's head. This manipulation benefits the parasitoid, as crypt keeper wasps who have to excavate emergence holes themselves are three times more likely to die trapped in the crypt. E. set was recently found to manipulate at least six additional, taxonomically diverse gall wasp species. While more work is needed to confirm the range of hosts E. set infects and manipulates, it appears that the gall wasp host's extended phenotype (i.e., the structure of the gall it induces oaks to produce) is an important factor dictating the host range of this master manipulator.

Integrating heterogenous data sources to assess the status and risk of butterflies to Anthropogenic threats in the western United States

Authors: Forister Matthew[4], Halsch Christopher[4], Grames Eliza[4], Burls Kevin[8], Carroll Cas[4], Bell Katherine[4], Jahner Joshua[7], Bradford Taylor[4], Zhang Jing[5], Cong Qian[6], Grishin Nick[5], Glassberg Jeffrey[1], Shapiro Arthur[3] and Riecke Thomas[2], [1]North American Butterfly Association, [2]Swiss Ornithological Institute, [3]University of California Davis, [4]University of Nevada Reno, United States, [5]University of Texas Southwest Medical Center, [6]University of Washington, [7]University of Wyoming, [8]Xerces Society for Insect Conservation

Abstract: Ongoing declines in insect populations have led to calls for action. However, even for relatively well-studied groups, like butterflies, information relevant to species-specific status and risk is mostly scattered in field guides, the scientific literature, and agency reports. Thus much attention and resources have been spent on a vanishingly small fraction of insect diversity, including a few well known butterflies like the monarch (Danaus plexippus). Here we bring together heterogenous sources of information for 396 species to provide what is, to our knowledge, the first regional assessment of butterflies for the 11 western US states. For 183 species, we use observational data (e.g., from monitoring programs) to characterize historical and projected trends in population abundance; for another 213 species (for which observational data is not available), we use exposure to climate change, development, geographic range, host breadth and other factors to rank species for conservation concern. We also organize information relevant to subspecific risk and prioritize a top 30 subspecies for further attention. Notably, many of these species have broad geographic ranges, which perhaps highlights a new era of insect conservation in which small or fragmented ranges will not be the only red flags that attract conservation attention.

Do host plants influence the evolution of sexually selected weaponry?

Authors: Forthman Michael[2], Miller Christine[2] and Kimball Rebecca[1], [1]Department of Biology, University of Florida, United States, [2]Entomology & Nematology Department, University of Florida, United States

Abstract: The weapons of sexual selection are surprisingly diverse across taxa and even within groups of closely related species. A major hypothesis for weapon shape diversity is changes in selection via fighting styles. As fighting styles diverge, so should weapon shapes. Yet, we know little about the ecological factors that might start this process of divergence. Here, we investigate the evolution of diverse weapon shapes in leaf-footed bugs and allies (Hemiptera: Coreoidea) using phylogenetic comparative methods. We performed a molecular phylogenomic analysis with ultraconserved elements, with weapon shape reconstructed at ancestral nodes. We then investigated how changes in habitat (i.e., host plant use) have selected for altered weapon forms. Our results showed that weapon morphology (e.g., femur enlargement, presence of spines, tibial expansions) exhibits convergent evolution throughout the evolutionary history of Coreoidea, which suggests ecological factors are promoting weapon diversity. Understanding ecological correlates in shaping trait morphology are critical in the present time of anthropogenic change, where modifications to habitats may alter the evolutionary trajectories of populations.

Bioassays to evaluate bednet performance in the laboratory and field

Authors: Foster Geraldine[1], McCall Philip[1], [1]Liverpool School of Tropical Medicine, United Kingdom

Abstract: Long-lasting insecticidal nets (LLINs) are essential for sustainable reduction and eventual elimination of malaria in Africa. Widespread pyrethroid resistance in vector populations and reduced performance of standard LLINs has driven substantial investment into the search for novel insecticides suitable for delivery on bednets. So far, a small number of new LLINs are being evaluated in the field, with unknown numbers of additional insecticides, both new and repurposed, further upstream in development pipelines. To accelerate these efforts, we have developed a suite of bioassays suitable for use at initial screening of chemistries for insecticidal properties to evaluating performance of the final LLIN product in situ in Africa.

Previously, testing efficacy relied on World Health Organization (WHO) recommended bioassays that measured immediate knock down or mortality after 24 (and 48+ hrs) hours, in non-blood fed adult female mosquitoes exposed in a suitable way to the active ingredient. The new suite of 3 tests generates data on knockdown, mortality at 24, 48+ hrs, repellency, contact irritancy, duration and location of LLIN contact, blood feeding (duration, volume, rate, inhibition) and temporal changes in these responses. Maintaining mosquitoes post-exposure allows detection of delayed or sub-lethal effects e.g. refeeding ability, oviposition and hatching rates, and longevity until natural death. As the tests simulate exposure under natural conditions during all stages, they are also suitable for characterising responses to LLINs in targeted vector populations targeted, before and after control.

Results will be presented from studies on a range of standard pyrethroid and next-generation combination LLINs, from initial developmental work performed in the UK to field implementations in East and West Africa. Laboratory studies on various novel treatments demonstrate that the new combination LLINs provoke a range of behavioural responses which, in most cases, are dependent on the presence of a host attractant during exposure. Additionally, responses are frequently strain-specific, further compounding the complexity of determining the ‘correct’ LLIN to deploy, especially in locations where more than one vector population may be present.

Our assays permit the relatively rapid characterisation of behavioural modes and post-exposure effects in vector populations exposed to single- and multiple-active ingredient LLINs. Together with data from experimental hut trials, detailed predictions regarding the likely success of an LLIN product against specific vector populations can be generated, creating a ‘performance index’ of products. This characterisation provides the key evidence necessary for decision-making when selecting the most appropriate LLIN for any location, and therefore should be fundamental to any pre-deployment LLIN evaluations.

Optimum placement for Drosophila suzukii (SWD) control approaches

Authors: Fountain Michelle[1] and Walker Adam[1], [1]NIAB EMR, United Kingdom

Abstract: Drosophila suzukii (SWD) remains a challenging pest to control in a arrange of fruit crops and has jeopardised Integrated Pest Management practices used for other pests. Although some crops are gaining adequate SWD control through a mixture of efficient crop hygiene and insect excluding mesh, the majority of crops are reliant on routine sprays of insecticides from a restricted range of modes of action. In addition, insecticide resistance is beginning to occur in some cropping systems.

The winter form of SWD is not reproductively active in the UK in the winter. However, it remains mobile in woodlands and native hedgerows adjacent to fruit crops on mild days, and continues to be attracted into baited traps . Whilst many studies have focussed on mass trapping inside crops during the growing season this study exploits SWD physiology and behaviour in the winter form. This is an ideal opportunity to reduce overwintering numbers to supress spring invasion into crops the following season.

Using a large number of trapping devices we have continued to trap SWD through replicated woodlands compared to untreated woodlands on the same farms. Results will be presented on the populations trapped and the optimum location for placing traps, through habitat scoring. In addition, we aim to present results on numbers of eggs laid in fruit from emerging overwintered SWD in adjacent crops in the spring.

It is vital that non-insecticidal methods are incorporated for SWD control on farms to slow the occurrence of insecticide resistance, reduce residues in fruit, and damage to the surrounding environment. This optimised integrated control method could have season long impacts for reducing fruit damage.

Drosophila suzukii resistance monitoring: results from South East England

Authors: Fountain Michelle[3], Shaw Bethan[1], Deakin Greg[2] and Wijnen Herman[4], [1]NIAB EMR, East Malling, Kent; University of Southampton, Biological Sciences, Southampton, United Kingdom, [2]NIAB EMR, East Malling, Kent, United Kingdom, [3]NIAB EMR, United Kingdom, [4]University of Southampton, United Kingdom

Abstract: Since its global dispersal, insecticides have played a vital role in supressing D. suzukii (SWD) populations in susceptible crops. However, in 2018 the first report of insecticide resistance was published by researchers based in The USA. Within the UK we are also concerned with detecting whether resistance could be developing in conventional cropping systems. Within this presentation, we will discuss the results from resistance monitoring in South East England, United Kingdom to commonly used insecticides over the past 4 years. These results are vital for early detection of resistance in cropping systems and should be used to raise awareness of insecticide resistance development. Direct spray of formulated products were applied to field collected strains and tolerance recorded. There were significant differences in mortality between strains treated with the same dose of three commonly used insecticides over time and between collection sites. In addition, within season susceptibility was assessed with further incidences of variation in mortality between sites.

Exploitation of interspecific signals to deter oviposition by spotted wing drosophila (Drosophila suzukii, SWD)

Authors: Fountain Michelle[4], Harte Steven[5], Bray Daniel[1], Tungadi Trisna[3], Shaw Bethan[2], Hall David[5], Farman Dudley[5], Powell Glen[3] and Wijnen Herman[6], [1]Chemical Ecology and Plant Biochemistry Group, Natural Resources Institute, University of Greenwich, United Kingdom, [2]NIAB EMR, East Malling, Kent; University of Southampton, Biological Sciences, Southampton, United Kingdom, [3]NIAB EMR, East Malling, United Kingdom, [4]NIAB EMR, United Kingdom, [5]University of Greenwich - Natural Resources Institute, United Kingdom, [6]University of Southampton, United Kingdom

Abstract: The worldwide invasive fruit pest, Drosophila suzukii; commonly known as spotted-wing drosophila (SWD), lays its eggs in soft- and stone-fruit before the fruit can be harvested. It has spread from Southeast Asia to Europe and the US and has become the most serious pest threatening the future of horticulture industries in these countries (Asplen et al., 2015). SWD is one of two species of drosophilids that can lay eggs in pre-ripened fruit. Larvae degrade fruit rapidly as they feed on the pulp and the oviposition holes allow entry of fungal and bacterial pathogens. Currently growers rely extensively on increased numbers of applications of insecticides but increased regulatory restrictions on pesticide usage, ecological impacts and likely emergence of insecticide resistance make this strategy unsustainable in the longer term. Extensive pesticide usage may also compromise other pest management programmes that growers use, which often involves using beneficial natural enemies of the insect pest.

This project aims to exploit the strong natural interspecific interactions between SWD and its sister species within the Drosophila melanogaster species group to develop novel approaches to control SWD. We found that SWD females are deterred from laying eggs (ovipositing) on artificial media where eggs have been laid by D. melanogaster previously (Shaw et al., 2018). This suggest that SWD detect a signal released by D. melanogaster and that this signal deters SWD from egg laying.

The first aim of this project is to determine the origin of the oviposition deterrent to SWD, and whether the signal originates from D. melanogaster adults, larvae, or eggs. Secondly, to identify the mechanism through which SWD detect the oviposition deterrent (i.e : through olfaction or gustation). This will be critical to its exploitation as field-based oviposition deterrent in the future. Thirdly, to identify the chemical compound or composition of the chemicals that deter SWD from ovipositing. Lastly, we will investigate if other drosophilid species beside D. melanogaster exhibit a similar inhibitory effect on SWD oviposition .

The highs and the lows: an overall economic analysis of classical weed biocontrol in New Zealand

Authors: Fowler Simon[1], Groenteman Ronny[1] and Paynter Quentin[1], [1]Landcare Research, New Zealand

Abstract: Research and development costs across all weed biocontrol programmes in New Zealand (NZ) from 1926 to 2019 were US$75 million PV (Present Value, 8% discount rate). Net Present Value (NPV) analyses for the five most successful programmes produced results ranging from a US$2.3 billion benefit for St John's wort (an agricultural weed) to a US$1.9 million loss for heather (an environmental weed). The overall benefit:cost (b:c) ratio for productive sector weeds was a strongly positive 72:1, but for environmental weeds it was -0.9:1; a negative return of -US$0.9 for every US$1 invested. Environmental weeds in NZ are usually targeted for biocontrol when other forms of weed control are being abandoned because of expense, ineffectiveness, and/or non-target impacts. Hence, successful biocontrol of environmental weeds in NZ resulted in a saving in other weed control costs of just US$0.16 million in 2019. In contrast, the annual benefit from biocontrol of productive sector weeds in NZ was US$67 million in 2019, largely due to increases in productivity of large areas of low value grazing land cleared of St John's wort, and to reduced control costs for ragwort in the dairy sector. Annual investment in research and development for all weed biocontrol programmes in NZ was US$1.4 million in 2019, only 2% of the current annual benefit. Several other biocontrol programmes against productive sector weeds in NZ are showing promising results, so annual benefits and b:c ratios are likely to increase substantially in future. For environmental weed biocontrol in NZ, biodiversity and ecosystem benefits are more important drivers than monetary benefits or b:c ratios.

Fifty years of Lepidoptera monitoring in Great Britain: trends and drivers of change

Authors: Fox Richard, Butterfly Conservation, Sustainability Institute, University of Exeter, United Kingdom

Abstract: British butterflies and macro-moths are among the most comprehensively monitored insect taxa in the world, with spatially-extensive data on species distribution and population abundance dating back to the 1970s. These data, contributed mainly by citizen scientists, enable the calculation of robust long-term trends for c.450 species and provide a detailed and balanced assessment of biodiversity change. I will introduce the data sources and analysis techniques, before summarising the results of 50 years of monitoring Lepidoptera in Great Britain. The findings present a complex picture of winners and losers, challenging the contemporary narrative of insect armageddon, while remaining consistent with overall patterns of global biodiversity loss.

Much progress has been made in elucidating the drivers of change among Britain's Lepidoptera and I will review the evidence from 20 years of research, highlighting individual and synergistic effects, as well as the remaining key knowledge gaps.

Indirect effects of predators on herbivore host switch: an eco-evolutionary experiment

Authors: Frago Enric[1], Tighiouart Karim[2], [1]Centre for Biology and Management of Populations, Montpellier, France, [2]CIRAD - UMR PVBMT, Réunion

Abstract: Most herbivores are plant specialists and depend on certain chemical and morphological plant characteristics to thrive. A little explored question is whether plant specialization depends on the presence of natural enemies or competitors. We hypothesize here that an insect herbivore will switch from its host plant to a plant of suboptimal quality based on the density of its interspecific competitors, and on the presence of its competitors' natural enemies. In a long-term laboratory experiment, we found that the thrips Echinothrips americanus switched to a plant of suboptimal quality at large densities of its competitors. This switch, however, did not occur when natural enemies of these competitors were introduced in the community. Further experiments revealed that host plant switch led to the evolution of particular traits that may allow development on a suboptimal nutritional source. The presence of the natural ennemy induced changes in adaptive traits of the thrips by reducing survival rate and development time. This experiment is an example of an eco-evolutionary dynamics triggered by indirect effects of natural enemies. Our study has implications for biological pest control and for the emerge of novel pests. The species we worked with, Echinothrips americanus, is an important and polyphagous pest, and we show here, that predator indirect effects can lead to this species to become pest of a novel plant.

The effect of natural enemy diversity on herbivore suppression and community stability

Authors: Frago Enric[1], Tighiouart Karim[2], Sanders Dirk[4], Montoya Daniel[5], Montoya José[5] and Nibouche Samuel[3], [1]Centre for Biology and Management of Populations, Montpellier, France, [2]CIRAD - UMR PVBMT, Réunion, [3]CIRAD-3P, UMR PVBMT, Saint Pierre, La Réunion, France, [4]Environment and Sustainability Institute, University of Exeter, United Kingdom, [5]Theoretical and Experimental Ecology Station (SETE-CNRS), UMR 5321, Moulis, France

Abstract: In diverse natural enemy assemblages, herbivore suppression is usually stronger and community stability (i.e. temporal variation in species density and persistence) larger. This has been demonstrated in natural arthropod communities, and by means of theoretical modelling. However, the mechanisms underlying these effects, in particular on stability, are still poorly understood, and experimental demonstrations are lacking. In addition, it is not yet clear whether these positive relationships can be dampened when natural enemies engage in antagonistic interactions like intraguild predation (i.e. when two predators feed on each other, but also on a shared resource). To explore this question, we worked with a community that can be found in greenhouse agroecosystems, and which is composed of four herbivores and four natural enemies. The natural enemies included both generalist and specialist species, some of them engaging in intraguild predation. This assemblage of species was manipulated to create eight different communities along a gradient of natural enemy diversity. These communities were replicated in population cages and their long-term dynamics monitored over several months. We hypothesise that network parameters like the number of predatory links will relate positively with herbivore suppression and with community stability, but this effect will be dampened when a large amount of intraguild predation links are present. Our results revealed that herbivore suppression and community stability was mostly driven by few, highly-influential species, with strong impacts on overall community dynamics. In this talk I will particularly focus on the conditions that allowed the long-term persistence of the aphid parasitoid Aphidius colemani. Our work reveals experimentally that the structure of natural enemy networks can determine the dynamics of terrestrial ecosystems, and the services these communities provide, particularly pest biocontrol.

Microbial brokers of plant-insect interactions: a facultative endosymbiont modulates the response of pea aphid to rhizobacteria-harboring plants

Authors: Francis Frederic[1], Barrera Andrea[3], Quaghebeur Celeste[1], C. Ramirez Claudio[5], Serteyn Laurent[1], Molina-Montenegro Marco[2] and Cabrera Nuri[4], [1]Functional and Evolutionary Entomology, Gembloux Agro-Bio Tech, University of Liege, Gembloux, Belgium, [2]Laboratorio de Ecología Vegetal, Instituto de Ciencias Biológicas, Universidad de Talca, Talca, Chile Centro de Estudios Avanzados en Zonas Áridas (CEAZA), Univ, [3]Laboratorio de Ecología Vegetal, Instituto de Ciencias Biológicas, Universidad de Talca, Chile, [4]Laboratorio Interacciones Insecto-Planta, Instituto de Ciencias Biológicas, Universidad de Talca, Chile

Abstract:
- The effects of microorganisms on plant-insect interactions have been usually underestimated. While plant growth-promoting rhizobacteria (PGPR) are known to induce plant defenses, endosymbiotic bacteria hosted by herbivorous insects are often beneficial to the host. Here, we aimed to study whether PGPR-induced defenses in broad bean plants could impact pea aphid reproduction and probing behavior, depending on the presence of a facultative endosymbiont.
- We estimated aphid reproduction, quantified defense- and growth-related phytohormones by GC-MS, and measured different plant growth and physiology parameters, after PGPR treatment. In addition, we recorded the feeding behavior of aphids by electropenetrography.
- We found that PGPR treatment of broad bean plants reduced the reproduction of the pea aphid that did not harbor the endosymbiont H. defensa. We highlighted a phenomenon of PGPR-induced plant defenses priming, but no noticeable plant growth promotion. Main changes in the aphid probing behavior were related to salivation events into phloem sieve elements.
- Endosymbiont H. defensa played a key-role in plant-insect interactions, possibly helping aphids to counteract plant induced resistance and allowing them to develop normally on PGPR-treated plants. Our results suggest that plant- and aphid-associated microorganisms add greater complexity to the outcome of plant-centred multitrophic interactions.

Food webs in vineyard landscapes: optimizing the delivery of natural pest control services.

Authors: Franck Pierre[7], Rusch Adrien[8], Barraquand Frederic[2], Sauve Alix[1], Mouden Charlotte[4], Aluome Christelle[6], Vacher Corinne[4], Papura Daciana[5], Thiéry Denis[5] and Roux Pascale[3], [1]University of Bordeaux, Integrative and Theoretical Ecology, LabEx COTE, France, [2]CNRS - University of Bordeaux - Institute of Mathematics of Bordeaux, France, [3]Ecole Normale Superieure of Lyon - UMR Institute of functional genomics, France, [4]INRA - UMR Biodiversity, Genes and Communities, France, [5]INRA - UMR Health and Agroecology of vineyards, France, [6]INRA - UMR Interactions Soil Planet Atmosphere, France, [7]INRA - UMR Plants and horticultural systems, France, [8]INRA, UMR SAVE - Villenave d'Ornon, France

Abstract: Predicting the delivery of pest control services based on farming system intensity and landscape context is necessary to support the expansion of agroecological farming systems. However, the optimal food web structure that maximized pest control services remain largely unknown. Organic farming and semi-natural habitats in the landscape are expected to increase the diversity of both predator and prey species. However, increasing the diversity of natural enemies could lead to higher complementarity between species and enhance the level of pest control but could also dilute the effect of natural enemies to control pest species due to intraguild predation for instance. To explore this question and test these hypotheses, we sampled a large set of natural enemies of pests on 21 pairs of vineyards (one organic and one 'conventional') selected along two orthogonal landscape gradients. We described their diet using a meta-barcoding approach and estimated the level of biological pest control potential by exposing sentinel preys (eggs of Lobesia botrana) in the field. Such approach provides a mechanistic understanding of the relationships between the structure of the natural enemy community and the delivery of pest control services and suggest opportunities to predict these services in other contexts.

Genetic structure of codling moth populations from worldwide to farm spatial scales

Authors: Franck Pierre[1], Gauffre Bertrand[1] and Olivares Jérôme[1], [1]INRAE

Abstract: The genetic diversity and structure of codling moth (Cydia pomonella L.) populations at several spatial scales were carried out with a panel of microsatellite markers. First, the codling moth evolutionary history based on the genetic differentiation between 25 worldwide populations sampled in apple and walnut orchards was analyzed to sheds light on the main centers of diversification, the routes of colonization, and specialization to host plants. Secondly, key population demographic parameters (dispersal, reproduction) and their variations depending on agricultural practices and landscape characteristics were estimated from the comparison of the genetic variability between individuals. Dispersal was assessed from spatial autocorrelations of the genetic structure (isolation by distance) at the scales of the European continent, a production basin (lower Durance valley, France), and a cluster of orchards in a farm. All these works confirmed the low dispersal of the codling moth in spite of the ability of the pest to move on long distance and to attack various fruits.

Hedgerows and flower strips differentially support predator abundance and predation in organic apple orchards

Authors: Franck Pierre[2], Sigsgaard Lene[1] and Kramer Jacobsen Stine[1], [1]Department of Plant and Environmental Sciences, University of Copenhagen, Denmark, [2]INRA - UMR Plants and horticultural systems, France

Abstract: Management of plant diverse habitats surrounding crop area can promote the occurrence of natural enemies and have suppressive effects on the pest populations. Each year, growers experience yield losses due to pest damage in organic apple orchards in Denmark. This means that there is a present need for developing sustainable pest control strategies enhancing pest natural enemy abundance and diversity. We examined the impact of hedgerows and flower strips on the predation contribution to control of the rosy apple aphid, Dysaphis plantaginea Passerini (Hemiptera: Aphididae) by the predator complex in organic apple orchards in Denmark. Sampling of the most abundant predators in the orchards was conducted at the beginning of flowering of the apple trees, after flowering and at June drop (the second fruit fall). This was done in the apple row near the hedge, the row near the flower strip and in the middle row of apples with equal distance to these two habitat structures. Abundance of D. plantaginea was assessed visually, and abundance of the predator species was assessed by beating samples. Predators sampled were primarily spiders (Linyphiidae, Tetragnathidae, Philodromidae, Theridiidae), flower bugs (Deraeocoris flavilinea, Atractotomus mali), anthocorids (Anthocoris nemorum), nabids (Himacerus apterus), coccinellids (Coccinella septempunctata), and earwigs (Forficula auricularia). A molecular gut contents analysis was used to detect if predators had remains of D. plantaginea DNA in their gut. Spiders were more abundant early in the season, both spiders and insects were abundant after flowering, while flower bugs were more abundant at June drop. Preliminary results suggest that there were more insect predators screening positive for DNA of D. plantaginea in the row near the flower strip, than in the middle row and in the row near the hedge, after flowering, while the proportion were more evenly distributed at June drop. The highest proportion of insect predators screening positive for DNA of D. plantaginea was D. flavilinea, followed by F. auricularia. Flower bugs were more abundant near the flower strip, while anthocorids were more abundant near the hedge, and more anthocorids from the middle row screened positive for DNA of D. plantaginea. The preliminary results suggest that an orchard can benefit from both hedgerows and flower strips for increasing the natural enemy community, and thereby encourage the natural regulation of D. plantaginea and other pests in organic apple orchards.

Population genetic structure of the Codling Moth in Chile and Argentina: implications for area wide management programs

Authors: Franck Pierre[5], Fuentes-Contreras Eduardo[1], Soleño Jimena[3], I. Cichón Liliana[6], A. Rodríguez Marcela[4], Montagna Mónica[2], Guiñazú Natalia[2] and Garrido Silvina[6], [1]Center in Molecular and Functional Ecology (CEMF), Facultad de Ciencias Agrarias, Universidad de Talca, Chile, [2]Centro de Investigaciones en Toxicología Ambiental y Agrobiotecnología del Comahue (CITAAC)-CONICET, Universidad Nacional del Comahue Facultad de Ciencias del Ambiente y la Salud, Universidad Nacional del Comahue, Argentina, [3]Centro de Investigaciones en Toxicología Ambiental y Agrobiotecnología del Comahue (CITAAC)-CONICET, Universidad Nacional del Comahue. Facultad de Ingeniería, Universidad Nacional del Comahue, Argentina, [4]Departamento de Zoología, Facultad de Ciencias Naturales y Oceanográficas, Universidad de Concepción, Chile, [5]INRA - UMR Plants and horticultural systems, France, [6]Instituto Nacional de Tecnología Agropecuaria, Estación Experimental Alto Valle, Argentina

Abstract: The codling moth, Cydia pomonella (L.), is an invasive pest of pome fruits introduced to the Americas during the 19th century. In the southern cone of South America this pest is widespread at both sides of the Andes range separating Argentina and Chile, where the largest area of pome fruit production of the southern hemisphere is located. We performed an analysis of the population genetic variability and structure of C. pomonella in Argentina and Chile using microsatellite markers. We sampled C. pomonella from apple as the main host-plant along its distribution area (approx. 1,800 km) in both countries. Significant genetic differentiation among samples from Argentine and Chile (FSC = 0.045), and between all localities (FST = 0.085) was found. Significant isolation by distance (IBD) was found for each country and also when samples from both sides of the Andes range were pooled, although with a lower correlation coefficient. By using a Bayesian individual assignment method (Structure) we found different populations in the Chilean and Argentinian sides of the Andes, which suggest independent invasion events and subsequent genetic isolation between countries. In summary, our results indicate a high genetic exchange of C. pomonella within countries, but with significant genetic differentiation between countries. Our results could be explained by C. pomonella dispersal mediated by human activities related to fruit production in each country with little exchange between them, because the Andes range is a significant barrier for dispersal by flight and quarantine barriers prevent the movement of plant material or infested fruit between countries.

The evolution of an underwater tape: uncovering the genomic basis of caddisworm (Insecta: Trichoptera) silk

Authors: Frandsen Paul, Department of Plant and Wildlife Sciences, Brigham Young Univ, Provo, UT, USA, United States

Abstract: Caddisflies (Insecta: Trichoptera) are among the most diverse freshwater insects, both in terms of species number and ecological diversity. Caddisfly larvae, or caddisworms, inhabit most freshwater habitats with one family existing exclusively in marine tidal pools, an anomaly among insects. Caddisflies are reciprocally monophyletic with Lepidoptera (moths and butterflies) and share the ability to spin silk from modified salivary glands. Caddisworms use underwater silk to construct a variety of underwater architectures, including portable tube cases, silken capture nets that resemble spider webs, and underwater funnels. These innovations, made possible through their use of silk, are thought to be central to their diversification underwater. Caddisworm silk consists primarily of two proteins, the heavy and light fibroins (h-fibroin and l-fibroin). The h-fibroin protein consists of n and c termini with a large repeating sequence in between and is thought to be the primary component of caddisworm silk. Early efforts to sequence the h-fibroin gene using short-read sequencing resulted in partial assemblies. However, recently, the full gene was sequenced for the first time using long-read sequencing of whole caddisfly genomes. Here, we combine proteomics, SEM-EDS imagery, TEM protein imagery, and whole-genome? sequencing to shed light on silk use in Trichoptera. By linking phenotypic data with genomic data, we are beginning to uncover some of the secrets of this remarkable underwater bioadhesive.

Connecting Taxa: How does nonnative vegetation affect arthropod diversity and biomass in urban forest fragments?

Authors: Frank Steven[1], Mitchell J. Christina[2] and D'Amico Vincent[3], [1]North Carolina State University, United States, [2]North Carolina State University, United States, [3]USDA Forest Service NRS-08, University of Delaware, United States

Abstract: As human populations grow and development expands, urban forests are threatened by habitat loss and fragmentation. Forests contribute to the preservation of native species and habitat, carbon sequestration, and atmospheric cooling. Increased urbanization of forest fragments lead to invasions of nonnative plant species, which changes ecological communities and alters forest function.

We studied urbanization effects on forest communities in 24 forest research fragments in two cities along the eastern coast of the United States. We sampled two cities to understand if interactions change under different temperatures, providing insight to how a warming climate may affect urban systems. Newark, Delaware represented a high latitude city and Raleigh, North Carolina represented a mid-latitude city. Sites ranged from 1 to 25 hectares and in level of urbanization. Within each forest, we established 10 locations to sample plants, soils, and arthropods. In 2017, we quantified the vegetation community using metrics of vegetation density, canopy cover, and species abundance. Soil samples were collected to determine pH, organic matter, and micronutrients per site. Ground arthropods were sampled in 2017 and 2018 using pitfall traps. Arthropods on understory vegetation were sampled in 2019 using a bug vacuum.

We sampled two categories of arthropod taxa to understand how nonnative plant invasion and forest structure influence arthropod communities. We sampled carabid beetle (Coleoptera: Carabidae) species, model organisms to track community change, to determine how urban vegetation affects ground-dwelling arthropods. Canopy openness correlated with increased nonnative plant invasion and understory density, and nonnative plant invasion in turn reduced forest specialist species and increased open area specialist species. All carabids declined with increased understory vegetation density, ground cover vegetation, and leaf litter volume. These results support conserving forests with intact canopies to reduce long-term nonnative plant invasion, while removing dense nonnative vegetation, especially nonnative ground cover, to manage forests short-term.

We then expanded our scope of inference to all arthropods on understory vegetation, and investigated relationships between total, nonnative, and native vegetation structure and arthropod abundance, biomass, richness, and diversity. Arthropod abundance and biomass increased with greater total, nonnative, and native structure, while richness and diversity declined with greater nonnative structure. This suggests urban forests invaded by nonnative plants may provide adequate arthropod biomass as food for other taxa, like birds, but may fail to provide unique ecological services required in forests, as the number of species filling unique niches declines.

Urban forests are not negligible ecosystems and support diverse, native biotic communities. However, nonnative plants reduced urban forest arthropods and forest specialist species. Forest specialist arthropods are likely not the only organisms negatively affected by nonnative plant invasion in urban forests. These results outline the need to establish regional invasive management plans to strategically remove invasive species from urban forests and improve forest quality for native communities.

Drivers of insect biodiversity in urban green spaces: A review and meta-analysis

Authors: Frank Steven[2], Martinson Holly[1] and Raupp Michael[3], [1]McDaniel College, United States, [2]North Carolina State University, United States, [3]University of Maryland College Park, United States

Abstract: Urban forests provide critical ecosystem services by capturing carbon, mitigating pollution, reducing energy costs, improving human health, and providing habitat for wildlife. However, urbanization increases heat and pollution, fragments natural habitats, and alters the composition of the urban biota through the introduction of exotic species. Such stressors threaten the services urban forests provide and may alter the ability of these green spaces to support biodiversity. In this study, we use review and meta-analysis to synthesize the recent literature on the effects of urbanization on urban forest arthropods. We characterize published studies by spatial scale (between city, rural-urban gradient, within-city), taxonomic resolution (whole-assemblage, order, family, species), taxon, environmental variable (city size, distance to urban center, impervious surface cover, temperature, tree diversity, patch size, edge effects), and response variable (survival, fecundity, abundance, species richness, herbivory, predation, parasitism). When possible, we also quantify the magnitude of the difference in arthropod responses between high and low levels of urbanization and calculate effect sizes for meta-analysis. Through these two complementary methods, we identify key patterns of altered urban forest structure, including changes to the density, diversity, and geographic origin of trees and the ubiquity of the urban heat island effect. We tie these changes to arthropod demographic parameters, abundance, diversity, and rates of interaction. Notably, only a few taxa, including Lepidoptera and Carabidae, are well studied historically in cities, and our knowledge remains limited regarding the responses of many other groups. For the studies reporting comparable quantitative data, increasing urban pressures (such as higher impervious surface cover, lower vegetation cover, and small patch sizes) generally lead to declines in arthropod species richness, though effects on abundance are more variable and depend on the taxon and taxonomic resolution reported. Similarly, the increased proportion of exotic species in cities has led to a variety of outcomes, including reduced tree health, outbreaks of herbivores, loss of arthropod diversity, or no discernable effects. We propose that the outcome of potential novel plant-herbivore interactions, in which plants and herbivores without co-evolutionary history encounter each other, is often influenced by a combination of abiotic conditions, defense-free space, herbivore host-switching ability, and the potential for enemy escape. Our study highlights the major trends in the study of arthropod responses to urbanization, quantifies the relationships between particular urban environmental variables and arthropod responses, and points to the need for targeted future studies and the preservation of biodiversity in urban green spaces.

Human health risks of pine processionary caterpillars increase with urban warming

Authors: Frank Steven[5], Roques Alain[2], Backe Kristi[4], Bernard Alexis[3] and Rousselet Jérôme[1], [1]INRA, URZF, Orléans, France, [2]INRAE, Zoologie Forestière Orléans, France, [3]Institut National de la Recherche Agronomique, Unité Zoologie Forestière UR633, France, [4]North Carolina State University, Department of Entomology and Plant Pathology, United States, [5]North Carolina State University, United States

Abstract: Urban warming may alter organisms' development or survival. For organisms that are hazardous to people, these changes in development or survival may magnify or reduce the risks the organisms pose to people. Larvae of the pine processionary moth (Thaumetopoea pityocampa; Lepidoptera: Notodontidae; "PPM") are covered in urticating setae that cause allergic reactions in humans and other vertebrates. Though PPM larvae are common in urban areas, they have primarily been studied in forests, where human population density is low. Here, we report the results of a field study conducted in Orléans, France, to determine whether PPM colonies in cities have altered phenology and/or survival compared to PPM colonies in forests. We find that PPM larvae in the city spend a longer time in the fifth, most dangerous instar than larvae in forests because urban warming causes unequal shifts in the beginning and end of the fifth instar. In addition, urban warming indirectly increases winter survival by advancing larvae to later, more cold-tolerant instars before the winter cold period. These results indicate that the risks PPM pose to people are currently underestimated in cities. As PPM continues to expand its range with climate change, cities may alter the effects of this expansion for people.

Latitude and habitat affect herbivore density on urban trees

Authors: Frank Steven[2], Long Lawrence[1] and D'Amico Vincent[3], [1]Department of Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, [2]North Carolina State University, United States, [3]USDA Forest Service NRS-08, University of Delaware, United States

Abstract: The effects of urbanization, particularly high temperatures, can harm urban trees by increasing herbivory by arthropod pests. However, benefits for herbivore fecundity, survival, and population growth depend on background temperature of a site and the extent of urban warming. We predict that herbivores living at high latitudes or in cool forest fragments will exhibit lower fecundity, density, and population growth than those in warmer locations. Moreover, we predict that herbivores from northern latitudes will thrive when moved to warmer southern latitudes, a simulation of how they may be affected by climate change. The scale insects Melanaspis tenebricosa and Parthenolecanium quercifex are common pest of urban trees that reach higher densities due to the urban heat island effect. In a mid-latitude city, Raleigh, North Carolina, US, trees in forest fragments were 1.3° cooler and had significantly less M. tenebricosa and P. quercifex than trees in ornamental landscapes. However, there was no difference in scale density between forest and landscape trees in Newark, Delaware 4 degrees of latitude north. When P. quercifex were moved from Newark south to Raleigh their population growth was higher and they reduced tree growth more than scales from Raleigh. Our results suggest that relatively innocuous herbivores can become damaging pests as climate change and urbanization position them closer to their thermal optimum.

ABC transporters and target-site mediated resistance to Bt toxins

Authors: Franz Laura[2] and Nauen Ralf[1], [1]Bayer AG, Crop Science Division, Germany, [2]Bayer AG, Germany

Abstract: Spodoptera frugiperda, fall armyworm (FAW), is a major lepidopteran pest and recently invaded the Eastern Hemisphere. FAW pest management strategies are based on synthetic insecticides and transgenic crops expressing Bacillus thuringiensis (Bt) insecticidal proteins. Continuous selection pressure resulted in populations resistant to Bt crops, e.g., transgenic corn expressing the Bt toxin Cry1F, particularly in Brazil. Our group recently characterized the molecular mechanism of Cry1F resistance in Brazilian FAW populations and it was shown to be linked to mutations in the ATP-binding cassette transporter C2 (ABCC2). Here, we employed a cell-based assay to study the interaction of recombinantly expressed ABCC2 transporter variants and Bt insecticidal proteins to elucidate mechanisms of resistance in noctuid pests. Our study confirmed the importance of indels in the ABCC2 extracellular loop 4 (ECL4) for Cry1F resistance in S. frugiperda. Whereas Cry1A toxins seem hardly affected by most of the ABCC2 mutations in ECL4 detected in Brazilian field populations of FAW.

Adult learning, rather than larval experience or transgenerational acclimation, affects female host plant preference in Pieris butterflies

Authors: Friberg Magne[1], Wiklund Christer[2] and Petrén Hampus[1], Sweden, [1]Department of Biology, Lund University, Sweden, [2]Department of Zoology, Stockholm University

Abstract: Traditionally, the overwhelming majority of specialized phytophagous insects has been explained by the preference-performance hypothesis, which poses that females that prefer to oviposit on plants that maximize the performance of their offspring are favored by selection. Often, however, the female preference hierarchy among potential hosts deviates substantially from the larval performance on these plants, indicating that alternative selection pressures and phenotypic plasticity affects the female host choice. Recently, several studies have found evidence for an impact of larval experience on adult female host preference. These findings have led to a resurged interest in a potential general importance for Hopkins' Host Selection Principle, and it has been hypothesized that HHSP is particularly adaptive in combination with transgenerational acclimation, so that females both allocate and adapt their offspring to the same type of host they experienced as larvae. Such a scenario could facilitate host shifts and thus promote diversification. Here, we use Pieris butterflies as model to test the impact of larval host plant, female adult learning and transgenerational effects on the willingness to oviposit on two alternate host plants of different nitrogen content. A previous study has indicated that these butterflies alter their within-species host choice depending on the nitrogen content of the host individual they were feeding upon as larvae. Our study shows that adult learning, rather than HHSP or transgenerational effects affects female host preference, and reports negative transgenerational effects on larval performance. The larval offspring of mothers developed on a suboptimal host grew slower on both host plant species, and especially on the suboptimal host. Our results thereby contrast to previous studies.

Genomic signatures of adaptation to Bt-expressing transgenic crops in the agricultural pest, Helicoverpa zea

Authors: Fritz Megan[2], Taylor Katherine[2], Hamby Kelly[2] and Gould Fred[1], [1]North Carolina State University, [2]University of Maryland, United States

Abstract: Insect adaptation to management tools, or resistance, is common in agricultural landscapes. Loss of efficacy of insect management tools has economically significant consequences for growers. An ability to detect emerging adaptive changes prior to widespread resistance-associated crop damage by insects would benefit the agricultural community. It has been hypothesized that new genomic approaches could track molecular signals of emerging resistance and trigger efforts to pre-empt widespread damage. We tested this hypothesis by quantifying genomic changes in the North American pest, Helicoverpa zea, over a 15 year period concurrent with commercialization and subsequent loss of efficacy of transgenic Bt-expressing crops. Our results demonstrate the complex nature of adaptation in agricultural ecosystems and provide insight into the potential and pitfalls of using genomic approaches to track emerging resistance.

Herbivore abundance and species-level network characteristics can predict their apparent competitive effects on other herbivores

Authors: Frost Carol, Department of Renewable Resources University of Alberta, Canada

Abstract: Apparent competition is an important indirect interaction mechanism that structures host-parasitoid communities. In several applied scenarios it would be useful to be able to use traits to predict which host species will cause and be affected by apparent competition. Using temperate forest plant-caterpillar-parasitoid quantitative food web data I tested whether there are traits, including trophic traits related to network position, which can predict species' involvement in apparent competition. Host abundance and network generality and vulnerability (both binary and quantitative) were related to the strength and direction of apparent competition between pairs of host species. Host body size was not. These results could have great utility in the provision of alternative hosts for conservation of natural enemies for biological control, in predicting food-web impacts of invasive species, and in modeling community-wide responses to disturbance.

Fungal endophytes mediate insect pest control and shape trophic networks

Authors: Fuchs Benjamin, Biodiversity Unit University of Turku, Finland

Abstract: Current research highlights plant-associated microbes as key players shaping multi-trophic interactions in terrestrial ecosystems. For example, microbially mediated plant-herbivore interactions can have both bottom-up and top-down cascading effects in food chains. Here we focus on systemic and vertically transmitted fungal endophytes of cool-season grasses, which mediate plant defense by the production of toxic and deterring alkaloids. Due to the obligate dependence of the fungus on its plant host, we hypothesized a close chemical crosstalk between the partners, where herbivory can shape the chemical profile of the plant by inducing the production of specialized metabolites. Besides an herbivore-species-specific induction of fungal origin alkaloids, we found that plant age and seasonal timing strongly modifies the amount of alkaloids produced in a grass-endophyte symbiotum.

To be able to predict the plants benefit of microbe-mediated plant defenses it is necessary to include their effect on higher trophic levels. Feeding on endophyte-infected grass decreased the fitness of several herbivorous insects but further several predatory insect species experienced fitness losses. Applying modern chemical-analytical methods, we showed the stability of endophyte derived alkaloids within the food chain being responsible for fitness disadvantages in aphids and aphid predatory insects. Interestingly, we found that predatory insects considered to be especially resistant to environmental pollutants were unaffected by potentially cascading alkaloids within the food chain.

Besides the deterring effects of alkaloids we found first results indicating that olfactory foraging predatory insects may prefer endophyte-infected over uninfected plants exposed to aphid herbivory, likely caused by an endophyte-mediated manipulation of herbivore-induced plant volatiles (HIPVs).

Applying plant-associated microbes in sustainable pest control has a great potential circumventing the heavy use of pesticides but may additionally shape entire insect communities in grassland ecosystems.

Comparing the efficacy of various aerial spraying scenarios using Bacillus thuringiensis to protect trees from spruce budworm defoliation

Authors: Fuentealba Alvaro[2], Dupont Alain[3], Hébert Christian[1], Bauce Éric[2], Berthiaume Richard[2] and Quezada-García Roberto[2], [1]Laurentian Forestry Centre, Natural Resources Canada, Canada, [2]Laval University, Canada, [3]SOPFIM, Canada

Abstract: Large-scale aerial spray operations against the spruce budworm (Choristoneura fumiferana (Clemens)) (SBW) with the biological insecticide Bacillus thuringiensis ssp. kurstaki (Btk) aim at maintaining trees alive during outbreaks. This objective is thought to be achieved when=50% of current-year foliage is preserved until the end of the outbreak. This protection target is associated with low balsam fir (Abies balsamea [L.] Mill.) mortality. However, it is unknown whether this approach is always needed or whether less frequent interventions could provide similar results at a lower cost. Between 2010 and 2016, we conducted field experiments in Quebec's Côte-Nord region to determine the efficacy of five different Btk spraying scenarios for protecting balsam fir, white spruce (Picea glauca [Moench] Voss) and black spruce (P. mariana [Mill.] BSP) in mixed stands. We used the residual photosynthetic capacity (RPC) to evaluate the efficacy of the five scenarios. RPC makes it possible to take into account the impact of SBW defoliation on foliage contribution to tree photosynthetic effort over several years, and can be used as a proxy of the risk of tree mortality. We hypothesized that less frequent Btk applications could maintain the required RPC level to keep trees alive. Our results show that areas not protected resulted in great losses of RPC in balsam fir and white spruce. Btk applications every 3 years kept RPC above 50% for 2 years in balsam fir and 4 years in white spruce. RPC losses were above 62% after 4 years in both species. The strategy currently employed in Quebec (spraying every year after a first year of moderate-severe defoliation) and the intensive protection scenario (Btk applications every year) meet the protection goals for these hosts. However, their cost prevents their application at a large scale. Btk applications every 2 years seems a relevant alternative to the current strategy to protect balsam fir and white spruce stands given the adequate level of protection provided (RPC above 39%) and the reduction in the number of Btk applications required (36% fewer applications over 7 years, resulting in 36% lower cost), particularly if the objective is to maintain trees alive. Black spruce maintained at least 54% of its RPC, even without protection. Btk applications every 3 years might be a valid alternative to reduce growth losses in black spruce-dominated stands. The use of different spraying scenarios may allow us to develop cost-efficient treatment strategies to protect Quebec's forests.

Nordic conquest: Evolutionary history of lunar-rhythmic and lunar-arrhythmic reproduction in marine midges may identify candidate genes for the enigmatic circalunar clock

Authors: Fuhrmann Nico[1] and S Kaiser Tobias[1], [1]Max Planck Institute for Evolutionary Biology, Germany

Abstract: The intertidal midge Clunio (Chironomidae, Diptera) has a synchronized reproduction to the lowest low-tides around new moon and full moon, by combining circadian and circalunar clocks. After the last glacial period, Northern Europe was colonized by lunar-rhythmic Atlantic Clunio populations. In adaptation to the tide-free habitat in the Baltic Sea and to constant daylight above the Arctic Circle, two lunar-arrhythmic ecotypes have evolved.

We established seven Clunio laboratory strains from the Baltic Sea, Norway and the West European Atlantic coast and characterized their lunar-rhythm ecotypes under constant conditions. In order to investigate their evolutionary history, we sequenced 168 individual genomes from the same locations. Analysis of a set of > 700,000 SNPs showed strongest genetic differentiation according to geographic location. The data indicate that the Baltic Sea and the high Arctic were colonized in two independent events, suggesting that the two lunar-arrhythmic ecotypes evolved convergently. Near Bergen (Norway) a lunar-rhythmic and a lunar-arrhythmic strain co-exist in sympatry. There is strong gene flow between the two strains, indicating that ecotype is not a strong isolation barrier.

Molecular mechanisms and evolution of self-sacrificing gall repair in the social aphid, Nipponaphis monzeni

Authors: Fukatsu Takema[2], Moriyama Minoru[3], Kutsukake Mayako[1], [1]AIST, Japan, [2]Bioproduction Research Institute, Advanced Industrial Science and Technology (AIST), Japan, [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Abstract: Aphids contain more than 80 social species with individuals altruistic to their colony mates, called soldiers. Their primary social role is colony defense, but some gall-forming social species also perform altruistic tasks such as gall cleaning and gall repair. Gall repair is a unique social behavior reported from the social aphid, Nipponaphis monzeni, that forms a completely closed gall on the host tree. Since the plant tissue of the growing gall is soft and thin, gall-feeders such as lepidopteran larvae often invade the gall by tunneling through the wall. When a hole was bored in the gall wall, the soldiers immediately gathered around the hole, discharged a large amount of body fluid from their cornicles on the damaged area, and mixed the fluid with their legs. The discharged fluid soon became viscous and solidified, whereby the hole was filled up completely. Here, we uncovered the molecular and cellular bases of this social behavior, especially the mechanisms of body fluid solidification. The body cavity of soldiers is filled with peculiar soldier-specific “large globular cells (LGCs)” that accumulate a large amount of phenoloxidase, a key enzyme involved in melanization and scab formation in insects, and lipids, whereas their hemolymph contains high levels of tyrosine and a unique repeat-containing protein (RCP). After discharge of the body fluid, the LGCs rupture and release phenoloxidase and lipids to the hemolymph. The lipids form a soft clot immediately, whereas the activated phenoloxidase oxidizes tyrosine to dopa, which is followed by generation of highly-reactive quinones through the melanin synthesis pathway. The reactive quinones crosslink surrounding proteins including RCP, whereby the clot is solidified and hardened. Transcriptome analyses of N. monzeni and its allied species revealed that they possess at least five paralogous phenoloxidase genes, one of which shows fast molecular evolutionary rate and highly up-regulated expression especially in soldiers of N. monzeni. These results indicate that the soldiers of N. monzeni enhance their innate immune and wound healing mechanisms and co-opt them for colony defense.

Development of microsatellite markers for the endangered butterfly, Leptidea amurensis (Lepidoptera: Pieridae)

Authors: Fukuda Rinnosuke[1], Hirai Norio[1], Ueda Shouhei[1] and Yago Masaya[2], [1]Osaka Metropolitan University, Japan, [2]The University Museum, The University of Tokyo, Japan

Abstract: The eastern wood white butterfly, Leptidea amurensis (Lepidoptera, Pieridae), is an endangered butterfly species in East Asia. In Japan, this species inhabits semi-natural grasslands but available habitat is declining owing to the rapid loss of grasslands, including farmlands, pastures and riverbanks, and the abandonment of regular grassland management. Here, we developed 16 microsatellite loci for L. amurensis based on de novo genome sequence data and observed that nine loci exhibited polymorphisms in 16 individuals collected from various habitats in Japan. Using these microsatellite markers, we analyzed 49 individuals collected from five distant habitats, Aomori, Miyagi, Fukushima in Honshu Island, Kumamoto in Kyushu Island, in Japan. The structure analysis based on this genetic information revealed genetic differentiation among four Honshu and one Kyushu habitats. Value of the gene diversity (Hs) was relatively high with 0.46–0.57 in the four Honshu habitats, whereas low with 0.14 in Kumamoto. Similarly, allelic richness (AR) was 2.5–3.2 in the four Honshu habitats, whereas 1.4 in Kumamoto. Our results suggest that genetic diversity of Kumamoto population has decreased due to the habitat fragmentation and isolation and that this population should quickly be targeted for conservation.

Insecticidal property of novel meta-diamide compound TENEBENAL™

Authors: Fukuzawa Mai[2], Naoi Atsuko[2], Kawase Ayumi[2], Sato Kazuyuki[1], Nomura Michikazu[2], Matsubara Naritaka[2], Kawaguchi Seima[2] and Obayashi Takashi[2], [1]Japan, [2]Mitsui Chemicals Agro, Inc., Japan

Abstract: TENEBENAL™ (common name; Broflanilide) is a novel di-amide compound invented by Mitsui Chemicals Agro, Inc., Japan. This compound is under global development for the purpose of crop protection, sanitary pest control, vector control and wood protection in collaboration with BASF. In this study, we evaluate insecticidal activity and property of TENEBENAL™.

1. Property for crop protection.
TENEBENAL™ acts on nerve as GABA-gated chloride channel allosteric modulator. It is classed in new group "30" by Insecticide Resistance Action Committee (IRAC). TENEBENAL™ shows insecticidal activity at low dosage rate against important crop pest order, such as Lepidoptera, Coleoptera and Thysanoptera. This compound is effective against existent resistant pests.
The efficacy test using larvae of common cut worm and diamond back moth showed that the insecticidal activity of TENEBENAL™ is stronger in oral ingestion than percutaneous ingestion. Preferable antifeeding effect is observed due to the good insecticidal activity and rapid action of the compound.

2. Property for sanitary pest and vector control
TENEBENAL™ shows good efficacy against sanitary pests and vectors including Hemiptera, Blattaria, Diptera, Siphonaptera and Acari. In particular, the efficacy was observed against cockroaches, mosquitoes and bedbugs which are highly developed resistance difficult to control.

3. Property for wood protection.
TENEBENAL™ shows good efficacy against termites and bark beetle. It controls termites equally or prior to the existent termiticide. It does not show repellency for termites in laboratory tests.
Due to these preferable and good properties, TENEBENAL™ is expected to contribute to the crop protection, hygiene and wood protection.

Rediscovery of a Lost Semi-aquatic Leaf Beetle in the Huleh Valley

Authors: Furth David[1], Montagna Matteo[2], Magoga Giulia[2], [1]Smithsonian Institution, Washington, D.C. USA and Steinhardt Museum of Natural History, Tel Aviv, Israel, United States, [2]Universita degli Studi di Milano

Abstract: Between 1951-1959, most of the Huleh Lake and its surrounding swamps in the Upper Jordan River (Rift) Valley of Israel were drained with the supposed purposes to eliminate Malaria and to reclaim land for agriculture; both reasons later proved to be unnecessary decisions. With the paucity of biological knowledge of the Huleh region, especially its aquatic invertebrates, accurate assessment of the environmental damage from this drainage is still being realized. Based on natural history museum collection records the pre-drainage presence of some aquatic insect species have verified. Among these is Donacia bicolora a member of a semi-aquatic subfamily (Donaciinae) of Leaf Beetles and whose Israeli populations were thought to have gone extinct because of the drainage of the Huleh and other locations. Recently this species was rediscovered in extremely isolated populations. Here this recent re-discovery is detailed and its conservation status discussed. Also new molecular data suggests this is Donacia simplex rather than D. bicolora.

LIFE 4 Pollinators: Involving people to protect wild bees and other pollinators in the Mediterranean (LIFE18 GIE/IT/000755)

Authors: Galloni Marta[4], Dante Giovanna[3], Petanidou Theodora[5], Navarro Luis[6], Traveset Anna[2] and Bortolotti Laura[1], [1]CREA - Agriculture and Environment, [2]Mediterranean Institute for Advanced Studies-UIB-CSIC, [3]University of Bologna, [4]University of Bologna, Italy, [5]University of the Aegean, [6]University of Vigo

Abstract: A significant proportion of the EUs wild bees are threatened with extinction and data are lacking for over 50%. Information is particularly scarce from the Mediterranean basin which is considered a biodiversity hotspot. Additionally, there is a general lack of awareness about the role of wild pollinators and the importance of conserving their diversity. The project aims to encourage a change of behavior in key stakeholders (farmers, beekeepers and park managers) and civil society, improving the application of pollinator-friendly practices across the Mediterranean region. A series of actions are being implemented, ranging from education to dissemination, information and environmental governance, using a citizen science approach to foster public outreach and engagement. Wild pollinators are monitored in 12 agricultural pilot areas in northern Italy and additional sites in target countries to assess the impact of pollinator-friendly actions, such as reduction in the use of pesticides, planting flower strips, placement of "bee-hotels", but also managers and visitors awareness. Through events, citizen science activities and providing training to key stakeholders, the project is increasing awareness of the importance of, and threats to wild pollinators across Italy, Greece, Spain and Slovenia.

Arthropods as an Experiential Learning Strategy

Authors: Gálvez Rosa[2], Bermejo Angela[2], López de Felipe Marcos[2] and Hidalgo Francisco[1], [2]Universidad Autónoma de Madrid, [1]Insectalia

Abstract: We developed and described the impact of an educational project targeted at schools and designed to introduce living arthropods in the classroom. This project, implemented during the 2021-2022 academic year, arises from a university-company collaboration assembled through a specific collaboration agreement (code number 2021/0293) between the Universidad Autónoma de Madrid and Insectalia, a new generation company dedicated to the sustainable production of insects as animal and human food.

Among the activities offered by this project are the installation of different species of insects in the classrooms (Tenebrio Molitor and Grillo Acheta) and the development of activities of some insects (Messor barbarus, Danaus plexippus and Phlebotomus perniciosus).

Specific objectives are: 1) to recognize animal models far from the classic perspective, 2) to identify the different phases of the scientific method and the skills developed in each of them, 3) to promote attitudes focused on the love for nature, 4) to work science from a STEAM (science, technology, engineering, art y mathematics) perspective

A total of 5 schools participated in the project getting involved a total of 413 students from preschool, elementary, medium and high school. We analyzed the interviews conducted with 20 teachers who implemented these activities in their classrooms.

Gene expression responses to latitudinal clines of stonefly communities in Japan

Authors: Gamboa Maribet[1], Landaño Arnelyn[1], Watanabe Kozo[1], [1]Ehime University, Japan

Abstract: Environmental heterogeneity continuously produces a selective pressure that results in genomic variation and selected gene expression profile differences among organisms. Although genetic variation in natural populations is common, those expressions at the community level and the genetic basis for this difference is scarce. We aim to unravel the process that dominates the evolutionary adaptation of the organisms by observing gene expression pattern and the potential coevolution of genes within a population shedding the light to local adaptation pathways and physiological responses. We investigated RNA-seq and proteomics dataset of seven stoneflies species from four geographical regions along latitudinal gradient in Japan. We detected 1077 gene distributed among geographical regions principally dominant with cellular process and metabolic functions. We examine physiological changes and community turnover as the underlying mechanisms shaping community adaptation to environmental variation. Here we will present the preliminary results of this analysis.

Sperm with wings: Inbreeding avoidance via male dispersal in a stingless bee

Authors: Garcia Bulle Bueno Francisco[3], Oldroyd Benjamin[2], Gloag Ros[2] and Latty Tanya[1], [3]University of Sydney, Australia, [2]University of Sydney, Australia, [1]The University of Sydney

Abstract: Inbreeding costs are a major driver of dispersal behaviour in animals. In taxa with restricted female gamete dispersal, inbreeding avoidance rests largely on the movement of male gametes. In eusocial bees of the tribe Meliponini (stingless bees), dispersal of reproductive females (queens) is restricted because daughter nests must be within short flight distance of parent nests, on which they initially rely for resources. Here we confirm that in the Australian stingless bee Tetragonula carbonaria, long-distance dispersal of males acts to offset this restricted movement of females. T. carbonaria colonies invest in a constant supply of males, which leave the colony when mature and do not return. To assess the distance males disperse, we manipulated colonies into rearing virgin queens and then sampled the males that formed mating aggregations outside these colonies. Based on genotypes, the distribution of brothers across swarms was relatively homogenous at scales of 400 km2, indicating that males readily disperse up to 10 km from their natal nests (20 times typical flight distance of females). These distances were consistent with mark-recapture studies of males, which indicated that they can travel at least 1km per day, and live for 21 days. The surprising dispersal ability of male T. carbonaria suggests that stingless bees can readily avoid inbreeding, even in fragmented landscapes. Furthermore, we propose that the genetic diversity of mating aggregations can serve as a tool for estimating population health and colony densities of stingless bees, analogous to strategies developed for honey bees (Apis sp.).

Assessing the tissue-specificity of adaptive immunity in Aedes aegypti

Authors: Garcia Knight Miguel[1], Coffey Lark[3], Tassetto Michel[2], Andino Raul[2] and Louie William[3], [1]Department of Microbiology and Immunology University of California, San Francisco, United States, [3]Department of Pathology, Microbiology and Immunology, University of California, Davis, United States, [2]Department of Microbiology and Immunology, University of California, San Francisco, United States

Abstract: A detailed understanding of antiviral responses in insect vectors is crucial to improving surveillance and controls strategies for arboviruses. Recent findings in flies and mosquitoes suggest that the central antiviral pathway, the RNAi pathway, can elicit a form of adaptive immunity. Key to this process if the formation of viral DNA, a product of the reverse transcription of viral RNA carried out by retrotransposons active in the host genome. Whilst detailed studies in Drosophila melanogaster have determined that vDNA is specifically produced in phagocytic immune cells called haemocytes, it is unclear whether similar tissue-specificity is observed in vDNA formation in the mosquito vector Aedes aegypti. To address this, female Ae. aegypti (Puerto Rico strain) were mock infected or infected with 1.25x106 pfu/ml Zika virus (Brazilian strain ZikaSPH2015) by blood feeding. Engorged females were collected at 14 days post feeding and haemolymph was extracted (N=14 mock, N= 16 infected) and mid guts ovaries and carcasses were dissected (N=13 mock, N= 18 infected); tissues from mock and infected individuals were pooled. RT-qPCR done individually using RNA extracted from legs and wings indicated that 88% of individuals used to extract haemolymph and to dissect midguts, ovaries and carcasses had disseminated viraemia. Circular DNA was extracted from pooled tissues either using a miniprep plus RNAse A treatment or by treating RNAse A-treated total DNA with Plasmid Safe DNAse to remove linear genomic DNA. NGS libraries of circular DNA samples were made and sequenced on a HiSeq instrument (Illumina). Preliminary qPCR analysis of NGS libraries using a single primer pair targeting NS5 indicates amplification of Zika vDNA in libraries from infected midguts and in libraries made from Zika-infected Aag2 cells at 48 hours post infection. Ongoing sequence analysis will enable assessment of the tissue-specificity of vDNA production and of the molecular species that predominate including any retrotransposon-vDNA hybrid reads that may provide insight into vDNA biogenesis in Ae. aegypti.

Characterization of egg parasitoids to implement future biological control against native and exotic Pentatomidae in France.

Authors: Gard Benjamin[1], Bout Alexandre[4], Caravel Claire[3], Clerc Henri[5], Streito Jean-Claude[3], Lambion Jérome[2], Cesari Lily[3], Bonneti Nicolas[3], Ris Nicolas[6] and Hamidi Rachid[7], [1]CTIFL, centre de Balandran, France, [4]INRAE, France, [3]INRAE, France, [5]INVENIO, France, [2]GRAB, France, [6]National Research Institut for the Agronomy, France, [7]UNICOQUE, France

Abstract: The Pentatomidae family is a large taxonomic group, which includes major pests of agricultural crops. Reduction of pesticide use and biological invasions has caused the emergence of various pests from this family, urging the development of new biological control strategies. In France, these initiatives are implemented against the native pests Nezara viridula in horticultural crops, Eurydema spp. on cabbage and Palomena prasina in orchards. We are also interested in the exotic black marmorated stink bug Halyomorpha halys.

In a first step, the natural biodiversity of captured egg parasitoids was characterized via DNA barcoding. For this we exposed 40 000 sentinel eggs in 16 different locations in France during 2018 and 2019. Although expected, we did not detect the presence of Trissolcus. japonicus, an exotic parasitoid of H. halys that recently established in some European countries. In a second step, we estimated the influence of rearing hosts (N. viridula vs H. halys) on the quality of T. basalis strain. We evidence complex and opposite results while the development in H. halys seems to improve physiological traits but negatively impact the morphological ones with regards to N. viridula. So, we conclude that frozen mass eggs of H. halys could be used as a substitution host for the routine rearing of our Trissolcus strain, even if some vigilance must be kept. In the last step, (semi-) field experiments were carried out to test the effects of number released and frequency of releases on the efficacy of pest control. Two years of trials under compartmented greenhouse highlighted the best control of N. viridula on eggplants with the release of 1 parasitoid/m^2/week.

A new hope for the biological control of Aculops lycopersici (Acari: Eriophyidae) with the predatory mite Typhlodromus (Anthoseius) recki Wainstein (Acari: Phytoseiidae)

Authors: Gard Benjamin[2], Bardel Amélie[1], Douin Martial[3] and Tixier Marie-Stéphane[3], [2]CTIFL, centre de Balandran, France, [1]CTIFL centre de Balandran, [3]UMR CBGP, Institut Agro, INRAE, CIRAD, IRD, Univ. Montpellier

Abstract: Currently, no natural enemy is efficient enough to control Aculops lycopersici at field level. We found interesting predatory ability of the Phytoseiid mite Typhlodromus (Anthoseius) recki in lab conditions. The present study aims to determine the efficiency of this species in semi-field conditions. As this predator is found on mints, we used it as companion plant to introduce T. (A.) recki. Firstly, mints and tomatoes were co-planted in plastic containers, at two ratios (1:1 and 1:2). The mints were inoculated with 20 females of T. (A.) recki, and tomato plants infested or not with A. lycopersici. T. (A.) recki is able to colonise and settle on tomato plants. This dispersal is much higher when tomato plants are infested by A. lycopersici, suggesting that the presence of the prey attracted T. (A.) recki. The second experiment was conducted in greenhouses. Thirty predators were introduced per tomato plant by placing branches of mints in the axil of the first tomato leaf. Tomato plants were artificially infested with A. lycopersici. The introduction of T. (A.) recki significantly reduces the length and the intensity of stem russeting and the number of A. lycopersici on tomato plants. Experiments are needed to investigate strategies of introduction.

Life in a contaminated habitat: How heavy metal contamination effects colony fitness of the common eastern bumblebee, Bombus impatiens

Authors: Gardiner Mary M.[2] and Sivakoff Frances[1], [2]The Ohio State University, United States, [1]The Ohio State University, United States

Abstract: Heavy metal contamination is a byproduct of industrial and urbanization processes that can have negative and prolonged impacts on biota. Cities are oftentimes contaminated with heavy metals (HM), however, also support a diversity of bee species. Currently, little is known about the impacts of HM contamination on bee fitness. Bumblebees are prolific pollinators that are common in cities and whose foraging behavior potentially exposes them to a plethora of contaminants such as HMs. We examined how exposure to environmentally relevant concentrations of the HMs arsenic, cadmium, chromium, and lead within nectar sources influence bumblebee brood survivorship. Using HM concentrations from bumblebee-collected honey in hives located in Cleveland, OH we developed a replicated foraging experiment to measure the fitness effects of these contaminants. We conducted 15 d foraging experiments within 13.5 m3 tents, where nectar treatments were compared: arsenic (0.84 mg/L, n=4), cadmium (0.84 mg/L, n=4), chromium (0.76 m/L, n=4), lead (0.265 m/L, n=4), all HM's (n=4) and an uncontaminated control (n=12). Treatments were arranged in a randomized design. Each tent contained a nectar feeder with respective HM concentrations, a pollen feeder, and one colony with approximately 70 workers, allowed to forage ad libitum. After the exposure period, all colonies were weighed, dissected, and brood and adults counted. We found similar brood abundance across treatments, but a significantly higher proportion of dead brood in HM exposed hives. These data illustrate that even environmentally relevant concentrations of HMs found within cities can negatively influence bee fitness and threaten urban conservation efforts.

Disentangling landscape and local drivers that structure ground-dwelling beetle communities in urban greenspaces

Authors: Gardiner Mary M.[2], Perry Kayla I.[2] and Phelan Larry[1], [2]The Ohio State University, United States, [1]Ohio State University, United States

Abstract: Community assembly is the process by which local communities are organized and maintained from the regional species pool. Urbanization strongly regulates insect community assembly, but the relative importance of landscape and local drivers of assembly are understudied in urban ecosystems. Understanding processes of insect assembly are of interest in 'shrinking' cities where an overabundance of vacant land is being redesigned into alternative greenspaces such as pocket prairies. These greenspaces represent viable conservation spaces for insects such as beetles that contribute to essential ecosystem services including pest suppression, decomposition, and nutrient cycling. The objective of this study was to investigate the landscape and local drivers of ground-dwelling beetle community assembly in greenspaces that vary in habitat design, local management intensity, and landscape context in Cleveland, Ohio using a functional trait-based approach. Functional traits with a strong predictive capacity for ecological functions were measured on beetle species collected via pitfall traps in 2018 and 2019 in four habitat management treatments: 1) vacant lots mown monthly; 2) urban pocket prairies seeded with wildflowers; 3) Metropark forests; and 4) old fields. Understanding how insect communities are structured in urban landscapes will provide context for observed patterns in biodiversity and advance conservation biodiversity efforts.

From potential to practical: balancing the needs of people and pollinators to achieve urban conservation goals.

Authors: Gardiner Mary M.[2], Turo Katherine[1], Scott Sarah[2], [2]The Ohio State University, United States, [1]The Ohio State University 2021 Coffee Road Columbus, OH 43210, United States

Abstract: The documentation of many rare or declining bee species in urban green spaces has led to a recent focus on cities as conservation targets. However, for pollinator conservation to succeed long term, we argue that the opinions and values of local community members must be prioritized more explicitly. In our experience, conservation is difficult to achieve when the aesthetic and safety concerns of urban residents are not reconciled with the goals and habitat designs of conservation practitioners. Similarly, from a bee ecology perspective, many questions concerning optimal design and management practices for pollinator habitats in cities remain unresolved. It is our hope that frank discussion of the challenges associated with urban pollinator conservation in public green spaces will inspire thoughtful consideration of how best to implement new initiatives in cities.

Trophic interactions between native parasitoids and invasive alien species: identification of host shifts and new associations in biological control

Authors: Gariepy Tara, Agriculture and Agri-Food Canada, Canada

Abstract: The establishment of invasive alien species in a new location has the potential to impact species interactions in a given invertebrate food web. Invasive species may provide a new host resource for native parasitoids, resulting in host-shifts or new associations that were previously undescribed. The detection and quantification of these interactions can be difficult using traditional rearing and dissection techniques, particularly when the interaction is non-viable (i.e., unsuccessful parasitoid development). The development and use of molecular diagnostic tools has the potential to provide rapid and accurate identification of hosts and parasitoids, and can provide more complete information on species interactions. In particular, it can provide conclusive evidence of host-shifts and/or new associations that would otherwise have gone undescribed. Case studies in a variety of systems are presented here to outline the utility of molecular diagnostics in the identification of trophic links between native parasitoids and invasive alien insects, and the impact that these interactions may have in the context of biological control.

Can the parasitoid wasp, Trissolcus japonicus (Ashmead) parasitize and develop on stink bugs native to Ontario, Canada?

Authors: Gariepy Tara[1], Scott-Dupree Cynthia[4], MacDonald Caitlin[3] and Fraser Hannah[2], [1]Agriculture and Agri-Food Canada, Canada, [4]University of Guelph, Canada, [3]University of Guelph Agri-Food and Agriculture Canada, Canada, [2]Ontario Ministry of Agriculture, Food and Rural Affairs, Canada

Abstract: Trissolcus japonicus (Ashmead) (Hymenoptera: Scelionidae), is an Asian parasitoid wasp known to be an egg parasitoid of Halyomorpha halys (Stål) (Hemiptera: Pentatomidae), the brown marmorated stink bug (BMSB). Brown marmorated stink bug is a serious invasive agricultural pest in Europe and North America, and insecticides appear to be of limited efficacy. Trissolcus japonicus is considered a candidate for classical biological control agent in many regions where BMSB has established. Given the recent discovery of adventive populations of T. japonicus in the US, Europe, and Canada, surveys to determine the establishment and spread of adventive populations in Ontario, Canada are being conducted. Data collected in the summer of 2019 demonstrated that T. japonicus populations persist in London, Ontario, but has not yet been found in other areas of southern Ontario. Results from testing T. japonicus host range suggest that it can parasitize and develop on a subset of native stink bugs, but the extent to which it will attack them is unknown. As a result, a study is being conducted to investigate whether T. japonicus will parasitize and develop on 11 non-target stink bugs native to Ontario.

Ontogeny and defensive induction explain the phloem chemistry of two species of ash (Oleaceae: Fraxinus) in New Hampshire, USA

Authors: Garnas Jeff[1], Gould Juli[2], Johnson Todd D.[1], [1]Department of Natural Resources and the Environment, University of New Hampshire, United States, [2]USDA-APHIS-PPQ, 1398 West Truck Road, Buzzards Bay, MA 02542, United States

Abstract: Since its introduction into North America three decades ago, the invasive emerald ash borer, Agrilus planipennis Fairmaire (Coleoptera: Buprestidae) has spread rapidly across the United States and killed millions of ash trees (Oleaceae: Fraxinus). This has resulted in billions of dollars in economic losses, as well as severe ecological damage to natural and managed forests. In North America, Fraxinus do not share a coevolutionary history with A. planipennis, allowing the beetle to quickly colonize and kill its hosts. While most Fraxinus are susceptible to A. planipennis, smaller diameter trees experience reduced colonization by A. planipennis compared to larger trees. We hypothesize that patterns of colonization by A. planipennis are explained by the chemical profiles of Fraxinus, and predict that ash of different ages have different chemical profiles. Our hypothesis was evaluated with two species of North American Fraxinus across four size classes with three treatments: no colonization, colonization by A. planipennis, or defensive induction with methyl jasmonate. Preliminary analysis identified 115 unique compounds across all samples. Non-metric multidimensional scaling of the four size classes of Fraxinus prior to treatment indicates some compounds are shared amongst size classes, but that there is a large divergence in the chemical composition of ash phloem after defensive induction. Ongoing analyses will identify compounds driving these interactions and evaluate quantitative differences among compounds identified in our study. Our research will increase our understanding of defensive strategies of Fraxinus, informing horticultural or silvicultural strategies to maintain Fraxinus, in light of the current invasion by A. planipennis.

Impacts of a climate-driven range shift of the Southern pine beetle (Dendroctonus frontalis) on gallery-associated arthropod communities

Authors: Garnas Jeff[2], Kanaskie Caroline[1], Stephen Fred[4] and Dodds Kevin[3], [2]Department of Natural Resources and the Environment, University of New Hampshire, United States, [1]Department of Natural Resources and the Environment (NREN), University of New Hampshire, United States, [4]University of Arkansas; Department of Entomology, United States, [3]United States Forest Service, United States

Abstract: Climate-driven range shifts are increasingly common in today's warming world. Together with biological invasion, distributional change via climate tracking results in the creation of novel assemblages or arthropods, microbes, plant hosts, etc. Species richness and composition the novel communities can have important impacts on population ecology of range-shifting species, and on best management practices in case of pest species. Differences in the identity, abundance, and behavior of key natural enemies, competitors, mutualists, and other associates can have major consequences for equilibrium abundances and/or dynamics (i.e., the frequency and amplitude of population cycles where they exist). Thus, the degree to which these communities differ from those in the core of a species' historical range, could help predict aggressiveness or impacts, among other factors of interest. The Southern pine beetle (SPB), Dendroctonus frontalis Zimmerman, (Coleoptera: Curculionidae), is an aggressive tree killing bark beetle native to southern North America as well as to parts of Central America. SPB, among the region's most destructive pine pests, has recently established in pitch pine (Pinus rigida) barrens in New York and Connecticut, over 100 km to the north of historical range limits. In 2017-18, we intensively sampled SPB-associated arthropod communities in infested pine. Resulting diversity, abundance, and composition estimates were then compared with a parallel dataset collected from 1975-1997 in four forests across three states within the core southern range in the beetle. Rarefied arthropod richness was marginally higher in northern sites when pooling sampling methods. Key community members (i.e., fly and beetle predators and hymenopteran parasitoids as well as Ips engraver and longhorn beetle competitors) were present in both the northern and southern regions, though overall community composition and relative abundances differed markedly. One ecologically important predator, the clerid beetle Thanasimus dubius (Fabricius) (Coleoptera: Cleridae) was present in approximately equal densities across regions. Fly, wasp, Ips engraver beetle richness was also similar between regions, but abundances were substantially lower in northern sites. Low frequency and abundance of Ips avulsus – a dominant, widespread interactor in southern sites – could in part explain patterns of higher bole utilization by SPB observed in the North, as this beetle appears to displace SPB in the tops of trees in southern site. Our results show that despite potentially important differences in abundance and perhaps in behavior, SPB-associated communities are compositionally similar among sites in the south v. the novel northern range. Ongoing research on the community as it relates to SPB dynamics in the North will add to core understanding of key feedbacks and their implications for management.

Effects of exposure to Metarhizium-colonized plants on the cotton leafworm Spodoptera littoralis

Authors: Garrido-Jurado Inmaculada[2], Montes-Moreno David[3], Quesada-Moraga Enrique[1] and Sanz-Barrionuevo Pilar[3], [2]Department of Agronomy, ETSIAM, University of Cordoba, Cordoba, Spain, [3]Department of Agronomy. University of Cordoba, Spain, [1]Department of Agronomy, ETSIAM, University of Cordoba, Cordoba, Spain

Abstract: It has been recently reported by several researches that exposition of lepidopteran larvae to entomopathogenic fungi-endophytically colonized plants may lead to medium to low mortality rates not related to fungal outgrowth, with the underlaying cause of death not well understood. The aim of the current work was to investigate the effects of the ingestion of M. brunneum EAMb 09/01-Su strain colonized melon plants on S. littoralis survival and reproduction. The fungus was able to colonize melon plants (Cucumis melo var. Galia), with 45.0% leaf colonization at 48 hours post-inoculation. Larvae feeding on fungus-colonized leaves showed a 53.3% mortality and 7.3 d average survival time (AST) that differed significantly from the 16.7% mortality and 6.5 d AST detected in the controls. It was noteworthy that neither signs of fungal outgrowth nor apoptosis related to caspases 1, 3/7 and 8 activities were detected in the cadavers. Meanwhile, fecundity of adult females coming from fungus challenged surviving larvae, 71.2 eggs laid per female, was significant lower than that of the controls, 219.7 eggs laid per female. These results were discussed in terms of their significance to the mode of action of entomopoathogenic fungi when they are offered via colonized plant tissues and on the impact of such colonization of the control of the pest.

A novel high-resolution melt assay for xenomonitoring of Human African Trypanosomiasis

Authors: Garrod Gala[2], Adams Emily[1], Saldanha Isabel[2], Cunningham Lucas[2] and Torr Steve[3], [2]Dept. of Vector Biology, Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [1]Dept. of Tropical Disease Biology, Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [3]Liverpool School of Tropical Medicine, United Kingdom

Abstract: With elimination of Human African Trypanosomiasis (HAT) targeted by 2020 and complete interruption of transmission by 2030, it is increasingly important to identify remaining active cases, foci of transmission and areas of disease resurgence. With declining numbers of cases, active screening programmes are no longer cost-effective and there is a need for a screening tool which can be maintained sustainably post-elimination. Screening vectors for parasites, known as xenomonitoring, provides a low-cost and simple monitoring method which can measure trypanosome transmission dynamics within an area in real time. Traditionally, xenomonitoring of HAT has been reliant on detection of trypanosomes by microscopy or using PCR. High resolution melt (HRM) is a closed tube post-PCR method which is highly sensitive and specific, and has a faster time to result than gel-based PCRs. We have developed a multiplexed HRM assay for the detection of both sub-species responsible for Human African Trypanosomiasis: T. b. rhodesiense and T. b. gambiense. The assay contains novel primers for T. b. rhodesiense designed to target the serum resistance-associated gene (SRA) and previously published T. b. gambiense primers designed based on the T. b. gambiense-specific glycoprotein gene (TgsGP). An additional primer set designed to amplify a single-copy phospholipase-C gene (GPI-PLC) expressed by all members of the Trypanozoon group were included to indicate whether sufficient DNA is present for the amplification of single copy genes. The HRM was found to be highly specific with no-cross reactivity when tested with a range of pathogenic animal trypanosome DNA. The limit of detection was found to be 10^4 tryps/mL. The assay sensitivity was compared to TgsGP PCR and was found to be as sensitive for T. b. gambiense detection and tenfold more sensitive when compared to SRA PCR at detecting T. b. rhodesiense. Further testing of assay performance is being performed on samples of T. brucei s.l. infected tsetse containing confirmed T. b. rhodesiense caught in 2015 from the Serengeti National Park and associated game reserves in Tanzania.

Our results indicate that this novel high-resolution melt assay could provide a highly sensitive and specific method of screening tsetse flies for pathogenic trypanosomes. With tsetse often caught as part of HAT control, this method could be implemented as part of elimination programmes and used within long-term HAT surveillance.

Culicoides Latreille (Diptera: Ceratopogonidae) taxonomy: The tree that hides the forest.

Authors: Garros Claire[4], Mignotte Antoine[2], Huber Karine[3], Bakhoum Thierno[5] and Balenghien Thomas[1], [4]Cirad (Montpellier), France, [2]ASTRE, Univ Montpellier, Cirad, INRAE, Montpellier, France Cirad, UMR ASTRE, F-34398 Montpellier, France, [3]CIRAD - French Agricultural Research Centre for International Development, UMR ASTRE, F-34398 Montpellier, France, [5]National Laboratory of Livestock and Veterinary Research, Senegal, [1]ASTRE, Univ Montpellier, Cirad, INRAE, Montpellier, France Cirad, UMR ASTRE, F-34398 Montpellier, France Institut Agronomique et Vétérinaire Hassan II, Unité Pa

Abstract: Culicoides Latreille biting midges (Diptera: Ceratopogonidae) cause a significant biting nuisance to humans, livestock and equines, and are the biological vectors of a range of internationally important pathogens of both veterinary and medical importance. Despite their sanitary and economic significance, the delimitation and identification of species and evolutionary relationships between species within the genus remains at best problematic. To date no phylogenetic study has attempted to validate the subgeneric classification of the genus and the monophyly of many of the subgenera remains doubtful. Many informal species groupings are also known to exist but few are adequately described and validated, further complicating accurate identification.

Recent contributions to Culicoides taxonomy and systematics using molecular analyses have revised the systematic scheme of the main subgenera and revealed the existence of cryptic species within important vector groups in the Palearctic region. This communication highlights two recent studies aiming at revising the current taxonomic scheme using species delimitation models: one analyzing the phylogenetic relationships in the Avaritia subgenus in the Afrotropical region (Bakhoum et al 2017) and one characterizing and mapping the cryptic diversity within the Obsoletus/Scoticus Complex at the European level using a multi-marker methodology (Mignotte et al 2020).

Landscape genetics and vector-borne diseases: Culicoides obsoletus (Diptera: Ceratopogonidae), a livestock virus vector species in the Palearctic region, is not a bad flyer!

Authors: Garros Claire[4], Mignotte Antoine[2], Rakotoarivony Ignace[3], Huber Karine[3], Gardès Laetitia[5], Gilbert Marius[7], Jacquot Maude[6], Duhayon Maxime[3], De Wavrechin Maya[3], Dellicour Simon[7] and Balenghien Thomas[1], [4]Cirad (Montpellier), France, [2]ASTRE, Univ Montpellier, Cirad, INRAE, Montpellier, France Cirad, UMR ASTRE, F-34398 Montpellier, France, [3]CIRAD - French Agricultural Research Centre for International Development, UMR ASTRE, F-34398 Montpellier, France, [5]Cirad, UMR ASTRE, F- 97170 Petit-Bourg, Guadeloupe, France, Guadeloupe, [7]Spatial Epidemiology Lab (SpELL), Université Libre de Bruxelles, Brussels, Belgium, [6]INRAE, UR346 Animal epidemiology, Saint Genès Champanelle, France, [1]ASTRE, Univ Montpellier, Cirad, INRAE, Montpellier, France Cirad, UMR ASTRE, F-34398 Montpellier, France Institut Agronomique et Vétérinaire Hassan II, Unité Pa

Abstract: Since 2006, recurrent and major epizootics of bluetongue (BTV) and Schmallenberg virus (SBV) have been reported in the Palearctic region. They are both transmitted by native hematophagous midges of the genus Culicoides (Diptera: Ceratopogonidae). These viruses affect domestic cattle, sheep, goats and wild ruminants. Culicoides dispersion is referred to as a stratified dispersion. This is a combination of dispersion processes occurring actively at short distances and passively or semi-actively at long distances, allowing dispersion jumps of hundreds of kilometers. Culicoides obsoletus has been identified by previous studies as an abundant and widespread main vector species of BTV and SBV over western and northern Europe. The objective of this work was to identify the meteorological and environmental factors that promote or limit gene flow within and among C. obsoletus populations and infer their impacts on Culicoides dispersal. The study was conducted at two geographical levels (i) country scale (France, 46 sampling sites), and (ii) continental scale (from Scandinavia to Northern Africa, 36 sampling sites). A wide range of meteorological (temperature, rainfall) and environmental (land cover, altitude, host type and density) factors was used together with genetic data obtained using 11 microsatellite markers. Both univariate and multivariate analyses were applied to assess the correlation between differentiation and environmental factors. The latter analyses were performed following two complementary and distinct approaches: a pairwise approach in which genetic distances are compared with environmental distances computed with circuit theory and second a point approach in which local genetic dissimilarity measures are compared with local environmental conditions.

Culicoides obsoletus showed a low genetic structuration level at the national scale, highlighting a high dispersal capacity. Similarly, at the continental level, a low genetic structure is detected. Despite this overall low level of genetic differentiation, three genetic clusters were detected at the continental level: one Mediterranean cluster, one Northern European cluster, and one cluster related to the Canary Islands. The main environmental factors having a significant impact on the genetic dissimilarity of C. obsoletus populations are the host density and the land cover. On the contrary, wind speed and direction are the two main factors having a significant impact on the genetic similarity of C. obsoletus populations. These results will be confirmed by simulation approaches.

In conclusion, we have quantified for the first time the effects of landscape heterogeneity on gene flow of one main Palearctic vector species and identify the wind as a main environmental factor to explain genetic similarity between populations. This result allow to discuss the long distance dispersal of Culicoides and implication for virus transmission, most often underestimated.

Pest Adaptation in a Transgenic Landscape: Western Corn Rootworm and Bt Maize

Authors: Gassmann Aaron, Iowa State University, United States

Abstract: In the United States, the western corn rootworm, Diabrotica virgifera virgifera (Coleoptera: Chrysomelidae), is among the most serious pests of maize. Current management relies heavily on planting of transgenic maize that produces insecticidal toxins derived from the bacterium Bacillus thuringiensis (Bt). In some regions of the United States, western corn rootworm has evolved resistance to Bt maize. The first cases of Bt resistance involved maize that produced Bt toxin Cry3Bb1. Over time, the magnitude of Cry3Bb1 resistance has increased, and cross-resistance has been found among Cry3Bb1, mCry3A and eCry3.1Ab. More recently, evidence has emerged of resistance to Cry34/35Ab1 maize in some populations, and of widespread resistance to Cry3Bb1 maize. Management of corn rootworm resistance to Bt maize has focused on non-Bt refuges and pyramiding of multiple Bt toxins. However, non-recessive inheritance of resistance, minimal fitness costs of resistance, and use of Bt traits singly before pyramiding have all likely reduced the resistance-management benefit of these approaches. In general, it is clear that better use of integrated pest management, in particular a more diversified approach, will be essential to achieve sustainable management of western corn rootworm with current and future transgenic technologies.

The Evolution of the State-University Partnership in New Jersey Mosquito Control

Authors: Gaugler Randy, Rutgers University, United States

Abstract: The State of New Jersey's emergence as a pioneer in mosquito control followed directly from John B. Smith's appointment to Rutgers University in 1889. Stressing that "research must guide the mosquito movement," Professor Smith's studies showing mosquitoes were a statewide rather than merely a local issue resulted in state legislators authorizing and funding the creation of local mosquito control units in 1912. Professor Headlee later established those units as well as state, regional, and national mosquito control associations, all ideas widely emulated nationally and internationally. Drawing on state funding, Headlee further built a world-class mosquito research program. In 1956 the state formed a commission to manage mosquito control efforts previously run by Rutgers. New funding was infused into local programs to support aerial spraying, equipment, biological control, and water management, but state funding for research subsequently withered. In 1976 Professor Crans developed a plan for statewide surveillance of mosquitoes and arboviruses centered on robust local, state and university cooperation and interdependence. The surveillance program has been highly successful and should be a model for re-envisioning other aspects of New Jersey mosquito control.

Over its long history the State-University partnership has often appeared mired in competitiveness and mistrust. New leadership, however, could present new opportunities for sweeping changes in institutions which have been largely refractory to change including: expanding the mission to additional vectors, encouraging applied research in local units, moving the state and local units into health departments, increasing efforts against urban species, promoting professionalism in local units, and joint efforts to aggressively seek new funding across the board.

Digestive mutualism in Nepenthes pitcher plants: role of the 'macrobiota' and its variation among plant species

Authors: Gaume Laurence[1], Bazile Vincent[2] and Le Moguédec Gilles[3], [1]Montpellier University, CNRS, France, [2]Montpellier University, France, [3]Montpellier University, INRA, France

Abstract: Carnivorous Nepenthes plants derive essential nutrients from arthropods captured in their pitcher-shaped leaves. The pitchers secrete a digestive fluid and house specific microbiota and 'macrobiota', mostly mosquito larvae, that aid in digestion, breaking the prey down into an easily assimilated form. We tested and measured the occurrence of such facilitation processes among Bornean Nepenthes. In a field experiment, prey items were introduced into the fluid of newly open pitchers of four Nepenthes species and their state was compared one month later between control pitchers and pitchers initially closed by insect screening mesh. The same experiment was performed in water-filled glasses. Metazoan diversity, tank dimensions and fluid pH were then measured in the 150 tanks.

Prey in macrobiota-deprived pitchers experienced lower degradation than in control pitchers in all Nepenthes species but not in water-filled glasses. Macrobiota exclusion impacted less species characterized by narrower pitchers and more acidic fluids. Rate of prey degradation increased significantly with abundance and diversity of inquilines. Therefore, Nepenthes pitcher plants are highly dependent on their 'macrobiota' to decompose prey. Such digestive mutualisms are even crucial in species whose pitchers have large aperture and less acidic fluids, housing a more diverse infauna and secreting presumably fewer digestive enzymes.

Museomics identifies genetic erosion in two butterfly species across the 20th century in Finland

Authors: GAUTHIER Jeremy[6], Kaila Lauri[3], Orlando Ludovic[4], Pajkovic Mila[2], Alvarez Nadir[5], Neuenschwander Samuel[7] and Schmid Sarah[1], [6]Switzerland, [3]Finnish Museum of Natural History, Zoology Unit, P.O.Box 17, FI-00014, University of Helsinki, Finland, [4]Laboratoire AMIS CNRS UMR 5288, Faculté de Médecine de Purpan-37 allées Jules Guesde, Bâtiment A, 31000 Toulouse, France Globe Institut, Lundbeck Foundation Geo, [2]Department of Ecology and Evolution, University of Lausanne, 1015, Lausanne, Switzerland, [5]Natural History Museum of Geneva, Switzerland, [7]Vital-IT, Swiss Institute of Bioinformatics, University of Lausanne, 1015, Lausanne, Switzerland, [1]Department of Ecology and Evolution, University of Lausanne, 1015, Lausanne, Switzerland Department of Computational Biology, University of Lausanne, 1015, Laus

Abstract: Erosion of biodiversity generated by anthropogenic activities has been studied for decades and in many areas at the species level, using taxa monitoring. In contrast, genetic erosion within species has rarely been tracked, and is often studied by inferring past population dynamics from contemporaneous estimators. An alternative to such inferences is the direct examination of past genes, by analyzing museum collection specimens. While providing direct access to genetic variation over time, historical DNA is usually not optimally preserved, in low quantities and degraded. It is necessary to apply genotyping methods based on hybridization-capture to unravel past genetic variation. We applied such a method, i.e., HyRAD, to large time series of two butterfly species in Finland: Erebia embla and Lycaena helle. We developed a new bioinformatic pipeline that standardizes and optimizes the analysis of HyRAD data. We show in the localities for which the data retrieved has sufficient power to accurately examine genetic dynamics through time, that genetic erosion has increased across the last hundred years, as revealed by signatures of allele extinctions and heterozygosity decreases, despite local variations. In one of the two butterflies, i.e., Erebia embla, isolation by distance also increased through time, revealing the effect of an increase in habitat fragmentation.

Main changes in the genus Plateumaris Thomson in the second edition (2022) of the Catalogue of Palaearctic Coleoptera: Chrysomelidae

Authors: Geiser Elisabeth, NHM Wien, Austria

Abstract: The members of the genus Plateumaris belong to the subfamily Donaciinae, whose larvae develop completely under water with a set of sophisticated morphological and physiological adaptions. They occur in the Nearctic region with 17 species and in the Palaearctic region with – that is the question!
The number of Palaearctic Plateumaris species considered as valid varies in the literature between 9 and 16. In my current update of the Catalogue of Palaearctic Chrysomelidae – Donaciinae I recognize 10 species as valid. However, there remain some doubts, especially in the highly variable Plateumaris sericea, which is also shown by at least 37 synonyms.

Traditionally, the Palaearctic Plateumaris were split into two subgenera: Plateumaris sensu stricto and Juliusina. But it figured out that the two "subgenera" didn't have even a single synapomorphy in common. Further molecular studies showed that the next relatives of many Palaearctic Plateumaris species are Nearctic species. Therefore, the subgenera had to be eliminated.

The Catalogue of Palaearctic Coleoptera also contains distribution information about each species. This will be updated, too. As the countries are only indicated with a short abbreviation in the Catalogue, further publications are edited now with detailed information and the source of it.

The Palaearctic species of the genus Plateumaris Author (Coleopterea, Chrysomelidae, Donaciinae): Who are they and if so how many?

Authors: Geiser Elisabeth, NHM Wien, Austria

Abstract: The number of Palaearctic Plateumaris species considered as valid varies in the literature to a remarkable extent. Askevold (1991) recognized nine species, but Silfverberg (2010) recognized 16. Other authors use other numbers in between. This is NOT due to new detected and new described species but results from the different opinions about species delimitation, subspecies status and synonyms. Some enigmatic species – described 100 years ago, never recorded again, type specimens missing – pop up in literature again and again like the undead.

In my current updating of the Catalogue of Palaearctic Chrysomelidae – Donaciinae I aim to declutter this situation. A very effective method is to compare museum specimens from different locations to study their morphological variety. The problematic species are very rare therefore it would be difficult to recapture them again at sites where they were found 100 years ago. Furthermore, the interesting biogeographical locations of the Caucasus and the countries south are dangerous regions to travel nowadays. Meticulous morphological study is an important step to better understanding of the species delimitation. This is prerequisite for the next step which is molecular analysis of museum specimens. These methods are rapidly developing now and they will be precise and affordable within the next years.

Metabarcoding Malaise trap plant components enables monitoring the diversity of plant-insect interactions

Authors: Gemeinholzer Birgit[1], Swenson Stephanie[2], [1]University Kasssel, [2]University of Kassel

Abstract: The declines in insect abundance and diversity over the past decades has also been observed in plants, and these events are most certainly linked. When insects are captured in Malaise traps, they carry traces of plants they have visited, either on the body surface or in the gut contents. DNA metabarcoding offers a promising method for identifying these plant traces, however, this method is not without its shortcomings and DNA metabarcoding of plant traces from Malaise samples types has not yet been tested. To examine the soundness of this method we analyzed 105 samples from sites across Germany with the ITS2 barcode. Here we report on the feasibility of sequencing these sample types, analysis of the resulting taxa, the usage of cultivated plants by insects near nature conservancy areas, and the detection of rare and neophyte species. We will additionally comment on the potential and pitfalls for plant metabarcoding from a variety of insect-mediated sources. DNA metabarcoding has advantages for rapid largescale biomonitoring inefficiency and resolution over microscopic identification of pollen, and we expect that it will have broad utility for future studies of plant-insect interactions when careful consideration is taken in study design and analysis.

Involvement of two secondary metabolites secreted by Serratia marcescens in mosquito-bacteria interactions

Authors: Gendrin Mathilde[2], Schönbeck Claes[3], Houël Emeline[1], Heu Katy[3], Romoli Ottavia[3], Kircher Verena[3] and Estevez Yannick[1], [2]Institut Pasteur de la Guyane, French Guiana, [3]Microbiota of Insect Vectors group, Institut Pasteur de la Guyane, Cayenne, France, French Guiana, [1]CNRS, UMR EcoFoG, AgroParisTech, Cirad, INRA, Université des Antilles, Université de Guyane, 97300 Cayenne, France, French Guiana

Abstract: Bacteria colonising the mosquito have positive impacts on their host, including protection against infection by pathogens, contribution to larval development and to blood digestion, but negative impacts have also been reported, they notably restrain lifespan and fecundity. We studied a strain Serratia marcescens isolated from our mosquito colony that has pathogenic effects on Aedes aegypti mosquitoes. S. marcescens produces several secondary metabolites in a strain-dependent manner, including prodigiosin, a red pigment known to have microbicidal and larvicidal activities, and serratamolide, a non-pigmented microbicidal and haemolytic metabolite. Our strain is a prodigiosin producer (red) that kills mosquitoes upon oral infection at high concentration and displays proteolytic and haemolytic activities. We produced two white mutants by non-targeted mutagenesis to investigate the role of prodigiosin in host-microbe interactions. We observed that mutant C1 is slightly less virulent than the wild type and that C3 is almost non-lethal. We also show that the culture supernatant of wt and C1 displays proteolytic and haemolytic activities, which are lost in C3. We hypothesized that C1 is deficient for prodigiosine synthesis only while C3 would produce neither prodigiosine nor serratamolide. We confirmed by whole-genome sequencing that C1 has a stop codon in prodigiosine-synthase while C3 has several mutations which are currently under investigation. Moreover, HPLC profiles suggest that serratamolide is present in C1 and absent in C3. Together, these data indicate that prodigiosine has a minor role in the virulence of S. marcescens in Ae aegypti while serratamolide may have strong implications on bacterial virulence and enzymatic activities.

Is biological control a solution for maize crop protection against maize leaf weevil (Tanymecus dilaticollis Gyll) attack in Romania?

Authors: Georgescu Emil[3], Lidia Cana[2] and Carmen Mincea[1], [3]National Agricultural Research Development Institute, Romania, Romania, [2]National Agricultural Research Development Institute, Romania, [1]Institute of Research-Development for Plant Protection, Romania

Abstract: Romania has more than 2.5 million hectares as maize cultivation which represents the highest area within the EU. Maize leaf weevil (Tanymecus dilaticollis Gyll) is the most dangerous pest of the maize crops. Favorable area of this pest is located in south and south-east of the Romania. The attack is dangerous when maize plants are in early vegetation stages (BBCH 10-BBCH 14). In case of high T. dilaticollis attack, the maize seedlings could not survive and the farmers have to sowing again their crops, that causing unexpected costs. Spring drought and higher air temperatures are even more favorable conditions for weevils attack. Also, maize monoculture has an increasing effect on pest density associate with higher impact of the attack. Recent studies from the last decades pointed out that chemical treatment of the maize seeds with systemic insecticides was the most effective control method of this pest at maize crops in Romania. However after European Commission Regulations 218/783, 218/784 and 218/785, no chemical alternatives remain available for maize seed treatment against T. dilaticollis in our country. In this paper there were presented results of a three years study, effectuated at NARDI Fundulea, in south-east of Romania, concerning the effectiveness in weevils control of the biological insecticides, used both, at seed treatment and foliar spraying (spinosad active ingredient and neem oil) comparative with chemical seed treatment with imidacloprid active ingredient. Attack intensity of the weevils at maize was evaluated when plants arrive in four leaf stage (BBCH 14), according a scale from 1 to 9 (1-plant not attacked; 9-plants complete destroyed, with stem chafed close to the soil level). Between 2016 and 2018, weather conditions from experimental location, during spring period were atypically for both, maize plants early stages development and weevils attack. The attack intensity of T. dilaticollis at maize untreated plants was 5.91 in 2016, 5.59 in 2017 and 4.61 in 2018. In case of variants treated with neem oil and spinosad active ingredient, the attack intensity of the weevils at maize plants ranged from 4.52 to 6.12. During this research, there weren't ascertained significant statistical differences ($p<0.05$) between weevils attack intensity registered at maize plants from untreated variant and attack intensity registered at maize plants from variants treated with neem oil and spinosad active ingredients, applied both, like seed and foliar treatments. In all years from this research, lowest attack intensity of the weevils at maize plants was registered in case of variant with maize seeds treatment with imidacloprid active ingredient. In this case attack intensity ranged from 3.45 to 3.70. Oil neem and spinosad active ingredients couldn't be an alternative for biological control of T. dilaticollis weevils in conditions of high pest pressure from south-east of the Romania.

Red Flour Beetle Oviposition and Development on Wheat Flour Alternatives

Authors: Gerken Alison[2] and Campbell James[1], [2]USDA ARS Manhattan, KS, United States, [1]USDA ARS Manhattan, KS, United States

Abstract: Many ancient and contemporary grains, seeds, nuts and other materials have been ground into flour and serve as alternatives or additions to traditional wheat flour in baking. Increased interest in using other types of flours has been driven by gluten allergies or sensitivities as well as an interest in a variety of texture, flavor and nutritional properties. Stored product insect pests such as the red flour beetle, Tribolium castaneum, can be major pests of wheat flour, but we know less about how susceptible these new flours are to infestation. Here we assess how readily red flour beetles will lay eggs in 17 alternative flour types when compared to wheat flour as a control. We find that there is a significant difference in the number of eggs laid across our tested flours, with wheat and teff having highest numbers of eggs laid and amaranth and cassava having the lowest. In addition, we find differential adult emergence, with teff and wheat having the highest number of progeny and almond, amaranth, cassava, and coconut having no progeny emergence. We find that the number of progeny negatively correlates with manufacturer labeled nutritional content such as total grams of fat and sodium but positively correlates with dietary fiber. Timing of adult emergence of the oviposited eggs was also different by flour with development quickest on wheat and teff with most adults emerging was highest 4 weeks after oviposition; followed by spelt, rye, quinoa, barley, and millet, with peak adult emergence on week 5; oat, corn, and buckwheat, with highest emergence on week 6; and sorghum and rice having the slowest developmental rate, with emergence peaking on week 7. We also evaluated egg to adult development over 4 weeks with a single egg placed in each of the flours. We found after 8 weeks on the flour, almond and amaranth have nearly 90% of eggs with no larval, pupal, or adult activity; cassava, coconut, and garbanzo have 30-40% of eggs that reach at least the larval stage, with some adults in garbanzo flour; potato had 20% of eggs emerge as larvae but no adults; and barley, buckwheat, corn, millet, rye, spelt, sorghum, wheat, and teff all have greater than 60% adult emergence. Together, these results suggest that female T. castaneum discriminate among different types of flour by laying different numbers of eggs. However, females laid high numbers of eggs on several flours, but adult emergence was low, suggesting these beetles may not be able to discriminate fine-scale nutritional profiles that restrict beetle development. In addition, immatures develop at different rates on the flours and have different probabilities of making it to the adult stage, suggesting some inhibiting factors such as a lack of key nutritional components. Future analyses will need to be done to pinpoint these components. The differences in oviposition and developmental rates suggests that some of these flours may not be as susceptible to insect infestations.

The Whitefly Bemisia tabaci is expanding its transmitted viruses to the aphid-transmitted genus polerovirus

Authors: Ghanim Murad[1], Ghosh Saptarshi[1], Lebedev Galina[1], Kontsedalov Svetlana[1] and Henrique Bello Vinicius[1], [1]Department of Entomology The Volcani Center Rishon LeZion, Israel

Abstract: The whitefly Bemisia tabaci, is a complex of cryptic species and considered one of the most invasive pests and a major worldwide threat to many agricultural crops. It feeds directly on plants causing weakening and honeydew secretion. The major damage inflicted by B. tabaci is the transmission of plant viruses from different genera, especially begomoviruses. The exceptional invasiveness of B. tabaci is a major factor that contributes to the spread and emergence of new plant viruses. During the last 20 years, new viruses belonging to genera that were not associated with whiteflies, were reported to be transmitted by B. tabaci, majorly the Middle East Asia Minor 1 (MEAM1) and the Mediterranean species (MED), also known as the B and Q biotypes, respectively. Poleroviruses (Luteoviridae) are phloem-restricted RNA plant viruses, which are exclusively transmitted by aphids. Multiple aphid-transmitted polerovirus species commonly infect pepper, causing vein yellowing, leaf rolling and fruit discoloration. Despite low aphid populations, a recent outbreak with such severe symptoms in many bell pepper farms in Israel led to reinvestigation of the disease and its insect vector. This outbreak was caused by a new whitefly (Bemisia tabaci)-transmitted polerovirus, which we coined Pepper whitefly borne vein yellows virus (PeWBVYV). PeWBVYV is highly homologous (>95%) to Pepper vein yellows virus (PeVYV) from Israel and Greece on its 5' end half, while it is homologous to African eggplant yellows virus (AeYV) on its 3' half. By constructing a PeWBVYV infectious clone causing the pepper disease, we were able to fulfill Koch's postulates and show that the B biotype of B. tabaci, but not the Q biotype or aphids, is able to transmit this new recombinant polerovirus. This is the first report of a whitefly-transmitted polerovirus which made a significant leap in its association with insect vectors and further demonstrates the ability of B. tabaci to expand the diversity of its transmitted viruses.

Role of endoplasmic reticulum-associated responses in Liberibacter transmission by psyllids

Authors: Ghanim Murad[2], Levy Amit[1], Lebedev Galina[2], Jassar Ola[2], Sarkar Poulami[2], Ghosh Saptarshi[2] and Kontsedalov Svetlana[2], [2]Department of Entomology The Volcani Center Rishon LeZion, Israel, [1]Citrus Research and Education Center University of Florida Lake Alfred, FL USA, United States

Abstract: We have recently identified a novel interaction between Candidatus Liberibacter asiaticus (CLas), the causative agent of the citrus greening disease and transmitted by the Asian Citrus Psyllid (ACP), and Candidatus L. solanacearum (CLso), which causes the carrot yellowing disease and transmitted by the carrot psyllid (CP). This interaction shows that the acquisition of CLso and CLas by CP and ACP, respectively, induced cellular morphological abnormalities in the adult guts of both vector species, but not in nymphs. Further transcriptomic and microscopic analyses from adults and dissected guts in both pathosystems showed similar and unique molecular immune and stress responses to the acquisition of the bacteria. Most importantly, the response of Endoplasmic reticulum (ER)-associated molecular pathways are induced, and ER-associated functions in the cell are recruited for the bacteria persistence and replication. Our hypothesis is that those closely-related bacteria evolved shared and unique mechanisms to establish their interactions with the vectors. Identifying such responses and insect factors that aid in the pathogen transmission is important for devising new control methods to prevent disease transmission.

Plant volatiles modulate immune responses of Spodoptera litura

Authors: Ghosh Enakshi, National Centre for Biological Sciences, India

Abstract: Plants emit a specific blend of volatiles in response to herbivory and these volatiles, which often attract predators and parasitoids function as an indirect plant defense. The impact of plant volatiles in shaping herbivore defenses is unclear. Here, we report that specific plant volatiles induce immune responses in the polyphagous herbivore, Spodoptera litura. We characterized the hemocyte profile and established their functional significance with respect to ontogeny and exposure to specific plant volatiles. Fifth instar larvae showed the highest number and hemocytes diversity. We characterized seven different types of hemocytes, of which granulocytes performed phagocytosis, oenocytoids showed melanization activity, and plasmatocytes along with granulocytes and oenocytoids were found to be involved in encapsulation. Among the six volatiles tested, exposure to (E)-ß-ocimene caused highest increase in total hemocytes number (THC) followed by linalool and (Z)-3-hexenyl acetate exposure. Although THC did not differ between these three volatile treatments, circulating hemocytes diversity varied significantly. (E)-ß-ocimene exposure showed higher number of plasmatocytes and phenol oxidase activity. The interaction of parasitic wasp Bracon brevicornis with (E)-ß-ocimene exposed larvae was poor in terms of delayed paralysis and lower egg deposition. In choice assay, the wasp showed clear preference towards control larvae indicating (E)-ß-ocimene treatment renders the host unattractive. Hemocyte profiles post-parasitoid exposure and (E)-ß-ocimene treatment were similar indicating cue-based priming. When challenged with Bacillus thuringiensis, linalool exposure caused highest survival as compared to other volatiles. Our results show that specific HIPVs can modulate cellular immunity of S. litura, revealing a new role for HIPVs in tri-trophic interactions.

A role for baculoviruses as vectors of horizontal transfer of transposable elements in lepidopterans?

Authors: Gilbert Clement, EGCE, Paris Saclay University - CNRS - IRD, France

Abstract: Horizontal transfer (HT) of genetic material is central to the architecture and evolution of prokaryote genomes. Within eukaryotes, the majority of HTs reported so far are transfers of transposable elements (TEs). Because of the lack of large-scale survey, the amount and impact of HT of TEs (HTT) in eukaryote evolution, as well as the mechanisms and vectors mediating these transfers, are poorly known. Here, I will report the results of our recent comprehensive analyses of HTT in 195 insect genomes. We developed a pipeline to detect and count HTT events which allowed us to infer a minimum of 2,248 independent HTT in insects. We show that DNA transposons transfer horizontally more often than retrotransposons, and unveil phylogenetic relatedness and geographical proximity as major factors facilitating HTT in insects. We also show that host taxa play an important role in shaping HTT by identifying Lepidoptera as a hotspot of transfers. I will also report the results of our search of TEs integrated in the genome of ten vertebrate and insect viruses using ultra-deep sequencing. While we found a large number and diversity of TEs integrated into the genomes of four baculoviruses replicated on six species of Lepidoptera, almost no TE were recovered from the other six viruses. Together, our results establish HTT as a major force shaping insect genome evolution and support the role of baculoviruses as vectors of HTT in Lepidoptera.

A targetted survey for the endemic and little-known bark beetles of the Hawaiian Islands

Authors: Gillett Conrad P.D.T., University of Hawaii at Mānoa, Honolulu, HI, United States

Abstract: The insect fauna of the Hawaiian Islands is over 95% endemic and at a heightened threat of endangerment, yet it remains largely understudied. One radiation of endemic Hawaiian insects is the xyleborine bark beetles, consisting of 21 described species of Xyleborus Eichhoff. They are the only indigenous scolytines in the islands, and many species have not been recorded for decades, or since their descriptions. In order to gain insights into the present diversity, distribution, relative abundance, and conservation concerns of these beetles, targeted sampling for bark beetles was undertaken across the Hawaiian Islands. We collected beetles using standardised lured Lindgren-funnel traps, deployed across numerous sites containing predominantly native vegetation, across six islands over the course of three years. We summarise the results of the survey, which confirm the persistence of native beetles at several sites containing well preserved native forest habitat. However, our results also indicate that native bark beetles now persist only as a numerical minority in local scolytine communities, occurring in low relative abundances, accounting for far less of the total trap catches across all sites than introduced exotic bark beetles. However, despite their comparative low abundances, locally, native bark beetles can represent the majority of species-level alpha diversity in native forest sites. The discovery during this survey of species not recorded since their descriptions, together with several new records that represent potentially undescribed species, suggest that much remains to be learned from the insect fauna of Hawaii's threatened forest biotopes.

Behavioral responses of invasive ambrosia beetles to fungal volatiles in mixed hardwood forests

Authors: Ginzel Matthew[1], Tobin Kelsey[1] and Ethington Matthew[1], [1]Purdue University

Abstract: Invasive ambrosia beetles (Coleoptera: Curculionidae: Scolytinae) are serious pests of landscape, nursery, orchard and forest trees worldwide, and are among the most commonly intercepted insects at ports-of-entry in the United States. Early detection of nascent invasive beetle populations is essential to initiate effective management efforts before incurring catastrophic losses. Current detection tactics for these pests utilize traps baited with ethanol lures placed at high-risk areas, such as ports and shipping hubs, but these are often ineffective at detecting incipient, low-level populations. There is a critical need for advanced methods to detect and manage these potentially destructive beetles. Recent studies have demonstrated that volatile compounds produced by symbiotic and co-occurring fungi of ambrosia beetles are behaviorally active and may enhance or reduce the response of beetles to other attractants. In this study, we conducted field-based experiments to determine the extent to which a suite of fungal volatiles influence the attraction of invasive ambrosia beetles to ethanol-baited traps. This information will be useful in establishing effective management programs for invasive ambrosia beetles to sustain the health, quality, and productivity of hardwood forests.

Competition within the parasitoid guild of Halyomorpha halys: Trissolcus japonicus and Trissolcus mitsukurii

Authors: Giovannini Lucrezia[1], Sabbatini Peverieri Giuseppino[1], Marianelli Leonardo[1], Hoelmer Kim[2], Roversi Pio Federico[1], [1]CREA - Research Center For Plant Protection and Certification, Italy, [2]USDA - ARS, United States

Abstract: The invasive stink bug Halyomorpha halys, originally from East Asia, is a serious agricultural pest of worldwide importance. Its economic impact and failures of chemical pest management led to consideration of biological control as the most effective long-term management approach. Two Asian egg parasitoids, Trissolcus japonicus and Trissolcus mitsukurii, are considered effective candidates as biological control agents. Because these two species can co-occur in the same habitats, interspecific competition could play an important role in the success of natural control. Interspecific competition can potentially disrupt biological control programs, or cause synergism, or it may have no influence at all. We investigated the foraging behavior and mechanisms displayed during interspecific competition between T. japonicus and T. mitsukurii and the way these species exploit common resources. In laboratory experiments using testing arenas, we simulated three different interspecific competition scenarios: i) indirect competition, where H. halys egg masses first parasitized by one species were subsequently offered to the second species after 0, 3, 5, or 7 days; ii) direct extrinsic competition, where both species were tested in arenas with simultaneous introductions, or iii) where half of the host egg mass had already been parasitized by the other species. Both Trissolcus species were able to parasitize H. halys eggs already parasitized by the other species. However, the female of the first-arriving species always produced more progeny. Nevertheless, when simultaneously releasing females in the arena, T. mitsukurii was the more aggressive competitor and spent more time defending host egg masses than T. japonicus. Based on our results, for biological control of H. halys a single-species release appears to be the best strategy. Indeed, the multiparasitism displayed by both species under laboratory conditions might also result in wasted searching time and energy and a reduced reproductive potential in the field.

Update on the fight against Halyomorpha halys with an adventive population of Trissolcus japonicus in New Jersey, USA

Authors: Girod Pierre[1], Hamilton George C.[1], [1]Rutgers University, The State University of New Jersey, United States

Abstract: Unintended border crossing events by insects raise major concerns, but in some rare cases could speed up the use of a biological control agent to manage invasive insect crop pests. In 2014, an adventive field population of Trissolcus japonicus (Ashmead), an Asian egg parasitoid of the invasive Asian brown marmorated stink bug (BMSB), Halyomorpha halys (Stål) appeared in the USA in Maryland. Populations of T. japonicus have been recorded across the USA, Canada, Switzerland and Italy. Prior to its first detection outside its native range T. japonicus was evaluated in quarantine facilities and extensive studies were conducted to evaluate potential non target effects.

Our work, focused on combining monitoring of BMSB and T. japonicus distribution in various crops across New Jersey for two years and conducting laboratory host range testing (choice/no-choice) on native Pentatomidae. Finally, we supported the national effort of redistribution of the adventive population of T. japonicus across the USA by conducting a propagule pressure experiment in a peach/apple orchard or soybean field.

As expected, the New Jersey T. Japonicus population appears to be more of an oligophagous egg parasitoid with a preference towards BMSB. Parasitism rate of BMSB is around 80% and can be achieved in 1 hour in laboratory conditions. Longer exposure periods do not result in higher parasitism rates. In the field, sentinel BMSB egg masses were exposed to parasitism for one day on various host plants. While low numbers of egg masses were parasitized, various parasitoids were collected and parasitism rates were acceptable. BMSB and T. japonicus field populations were also closely linked to the insect control strategy used at the site and the surrounding habitat.

Entomopathogenic Nematodes: Recent advances in genomic studies

Authors: Glazer Itamar, Agricultural Research Organization (ARO), Volcani Center, Israel, Israel

Abstract: Entomopathogenic Nematodes (EPN) have been used for biological control of insects in the past three decades. However, their expansion and intensification of use is still partial due to some limitation in their incompatibility with environmental conditions as well as relatively short shelf live in storage and transportation. One of the main avenues to enhance EPN performance as biocontrol agents is to use genetic approach for improvement their environmental tolerance, storage survival and efficacy.

Several research teams, worldwide, are utilizing advanced molecular and genetic techniques to explore the genetic foundation of key mechanisms in EPN. That includes transcriptomic and proteomic approaches to identify potential virulence factors produced by the EPN, genomics of longevity and storage survival of EPN infective juveniles, molecular basis of EPN host seeking behavior as well as identification of key survival genes among natural populations.

In the presentation, the recent studies related to these topics and some suggestions for future challenges will be given.

Genetic diversity of non-retroviral RNA virus integrations in the genome of Aedes aegypti mosquitoes

Authors: Gloria-Soria Andrea[1], Crawford Jacob[3] and Havill Jessen[2], [1]Center for Vector Biology & Zoonotic Diseases The Connecticut Agricultural Experiment Station, United States, [3]Verily, United States, [2]Denison University, United States

Abstract: The yellow fever mosquito, Aedes aegypti, is the primary vector of arboviruses, such as yellow fever, dengue, chikungunya, and Zika viruses, that have major impacts on human health. The intimate interactions among viruses and vectors lead to multiple levels of coevolution. Genomic integrations, complete copies or fragments of the virus genetic material that become incorporated into the vector genome, are one way in which viruses can influence their vector. Viral genome integrations are known to be widespread in insects and recent studies have shown that they are present in Ae. aegypti mosquitoes. Characterization of these non-retroviral integrations in a limited number of collections and cell lines indicates that they are predominantly related to insect-specific RNA viruses. We are conducting a screen of 230 Ae. aegypti genomes from across the species distribution to understand the extent and diversity of non-retroviral integrations in this mosquito and shed light into their biogenesis, function, and potential role in disease transmission. We present the results of this survey and discuss the implications of our findings for vector control

Using Selection Analysis to Investigate Gall Induction in Cynipid Wasps

Authors: Gobbo Erik, Swedish Museum of Natural History, Sweden

Abstract: Gall wasps (Hymenoptera: Cynipidae) induce complex galls on oaks, roses and other plants, but the mechanism of gall induction is still unknown. Here we take a comparative genomic approach to revealing the genetic basis of gall induction. We compared the genomes of gall wasps that are capable of different levels of host manipulation to identify genomic changes associated with the evolution of gall induction. We used a novel Bayesian selection analysis, which accounts for branch-specific and gene-specific selection effects, to search for signatures of selection in thousands of single-copy orthologous genes shared by Cynipid species. We then used gene set enrichment analysis to determine which biological process are more strongly associated with gall making.

Spectrum of pests associated with Oyster Mushroom (Pleurotus ostreatus) in Western Kenya and their management

Authors: Gohole Linnet[4], Kioko Esther[3], Musieba Fredrick[2] and Juma Selpha[1], [4]University of Eldoret, Eldoret, Kenya, [3]National Museums of Kenya, P.O BOX 40658-00100, Nairobi, Kenya, [2]Kenya Industrial Research and Development Institute, Nairobi, Kenya, [1]Department of Seed, Crop and Horticultural Sciences, University of Eldoret, Eldoret, Kenya

Abstract: Oyster mushroom is a major source of food and income in western Kenya. The production of oyster mushroom in this region has been hampered by arthropod pests that cause serious production losses in terms of quality and quantity. Development of an efficient pest control measure is based on the identification of pests infesting oyster mushroom in this region. This study aimed at identifying arthropod pests of oyster mushroom in western Kenya and developing an Integrated Pest Management (IPM) strategy to manage the pests. Oyster mushroom Pleurotus ostreatus was established at three sites: on-station, old and new mushroom farm sites. Pests were sampled weekly and identified using taxonomic keys at National Museums of Kenya. Various pest management options locally available to farmers were tested against the mushroom pests. Mites Pygmephorus spp. (Acaridae) and dipterans Megaselia scalaris (Phoridae), Bradysia spp. (Sciaridae), Culicoides spp. (Ceratopogonidae) and Anatrichus spp. (Chloropidae) were identified. All the other pests except Bradysia spp. were reported at the three sites through the three seasons. The incidences of all these pests were reported only during the incubation phase of oyster mushroom. Incidence of M. scalaris was 42% of the total count of the four pests that were sampled followed by Culicoides spp. at 33% with that of Pygmephorus spp. being 17% while that of Anatrichus spp. being 8%. Pygmephorus spp. was vectored by M. scalaris. These pests caused both direct and indirect damage on oyster mushroom. The old mushroom farm reported highest number of these pests. The integrated pest management method consisting of Nylon net + potted T. minuta + High spawn rate had a significantly lower mean number of pests compared to the individual methods. Therefore to effectively manage oyster mushroom pests, one would go the integrated way than using single methods.

In the front line against regulated pests: the work plan of the EURL for insects and mites (Montpellier) during the next two years

Authors: Goldarazena Arturo[1], Taddei Andrea[2], Reynaud Philippe[2], Mouttet Raphaelle[1] and Balmes Valerie[1], [1]EURL, France, [2]European Union Reference Laboratory for insects and mites, France

Abstract: National Reference Laboratories (NRLs) are specialist laboratories responsible for maintaining EU-wide standards for the routine testing of feed, food and plant and animal health. They provide advice and support on methods for official control testing, ensuring the delivery of risk-based and proportionate food enforcement to protect consumers. In the area of Plant Health, NRLs performed thousands of insects and mites identifications every year from samples coming from official interceptions at European ports and airports or from field surveys to confirm the absence of regulated or invasive arthropods on plant commodities. The results of these tests influence important decisions, i.e. refusal, destruction, return of commodities or onsite measures like crops destructions. This requires harmonization, validation, standardization of test methods and coordination of the network of NRLs to ensure accurate identification. In this poster, we describe the activities that will be developed at the European Reference Laboratory of insects and mites (EURL) (Montpellier - France) during the next two years. It will carry out a Proficiency Test on the identification of Spodoptera frugiperda J.E. Smith, based on morphological analysis of the male genitalia structure during December 2019-January 2020. In spring of 2020 it will carry out a proficiency test on the identification of Thrips palmi Karny based on morphological analysis of the adult female. The laboratory will organize a workshop for all the National Reference Laboratories with trainings about quarantine pests. Finally, at the end of 2020, we will organize a proficiency tests on the diagnosis of Popillia japonica Newman based on morphological analysis of the adult. At the same time, we are developing a project to improve NRLs diagnosis capacities of neotropical species of Epitrix that threaten European potato crops. Improving identification capacities of NRLs is a way for the European Union to better anticipate future insect and mite invasions. The EURL is now developing a website that will be for sure an important tool of communication in the next future for all the NRLs.

A new laboratory of entomology is born in Europe to defend us from the invasive plant pests

Authors: Goldarazena Arturo[2], Taddei Andrea[3], Reinzensein Helga[4], Marie Ramel Jean[3], Reynaud Philippe[3], Mouttet Raphaëlle[3], Gottsberger Richard[1] and Balmes Valerie[2], [2]EURL, France, [3]European Union Reference Laboratory for insects and mites 755 avenue du campus Agropolis CS 30016 FR-34988 Montferrier-sur-Lez Cedex, France, [4]European Union Reference Laboratory for insects and mites GmbH Spargeldeldstrase 191 1220 Vienna, Austria, [1]AGES, Institute for Sustainable Plant Production

Abstract: National Reference Laboratories (NRLs) performed thousands of insects and mites identifications every year from samples coming from official interceptions at European ports and airports or from field surveys to confirm the absence of regulated or invasive arthropods on plant commodities. The results of these tests influence important decisions, i.e. refusal, destruction, return of commodities or onsite measures like crops destructions. This requires harmonization, validation, standardization of test methods and coordination of the network of NRLs to ensure accurate identification. To fulfil this important task, a new European Reference Laboratory (EURL) for Insects and Mites was designated by the European Commission in 2019 (Regulation (EU) 2019/530 of 27 March 2019) as a consortium between the Entomology and Invasive Plants Unit at ANSES Plant Health Laboratory (Montpellier, France) and the Department for Molecular Diagnostics of Plant Diseases at AGES (Vienna, Austria). The EURL work program has the following tasks: (1) to ensure availability and use of high quality methods and to enable high quality performance by the NRL (providing reference methods and reference materials; organizing inter-laboratory comparative testing or proficiency tests; cooperating with NRLs and Commission in all subjects of detection of invasive plant pests); (2) to provide scientific and technical assistance to NRLs (coordinating practical arrangements necessary to apply new methods of laboratory analysis; conducting training courses for NRL staff; providing information on relevant national, Union and international research activities); (3) to provide scientific and technical assistance to the European Commission and other organizations; (4) Reinforce the reference collections and the molecular techniques of the NRLs to facilitate quick detection of quarantine pests. Through this new framework, testing results shall therefore become more reliable and comparable throughout the European Union.

The vagaries of biocontrol of exotic invasive species on exotic plant species in a non-evolved ecosystem; a study of the unexpected from New Zealand

Authors: Goldson Stephen, Bio-Proprotection Research Centre, Lincoln AgResearch, Lincoln, New Zealand

Abstract: New Zealand's intensive pastures, comprised almost entirely introduced Lolium L. and Trifolium L. species are arguably the most productive intensive grazing-lands in the world. However, these areas, because of their inherent lack of species diversity, present very little biotic resistance to destructive invasive pest species. There is a native natural enemy fauna in New Zealand that has evolved over millions of years of geographical isolation, but, it remains confined to indigenous ecosystem remnants. It therefore plays a minimal role in creating biotic resistance in the exotic pastures.

Of New Zealand's pasture pests, three of the most damaging are the Argentine stem weevil (Listronotus bonariensis), the clover root weevil (Sitona obsoletus) and the lucerne weevil (Sitona discoideus). These weevil species have been successfully suppressed by three different introduced koinobiontic parasitoids, Microctonus hyperodae, Microctonus aethiopoides (Irish strain) and Microctonus aethiopoides (Moroccan strain) respectively. Such a biological control result is rare with the chances of success being calculated at 1:1000 based on historical biological control records. Arguably the parasitoids themselves have been highly effective because they, like many of the exotic pest species, have benefited from enemy release in a simplified ecosystem. At the same time the absence of evolved complexity in New Zealand's sown-pastures has probably contributed to unimpeded parasitism of the host species.

Such parasitism has been so intense that, very unusually, the Argentine stem weevil has now evolved resistance to its parthenogenetic parasitoid Microctonus hyperodae. The high selection pressure has combined with the limited (if any) ability of the parasitoid to adapt compared to the sexually-reproducing weevil. Indications are now that the mechanism behind this Argentine stem weevil resistance is based on adaptation that results in enhanced evasion of the parasitoid. That the response is more strongly expressed in weevil populations collected from the warmer parts of New Zealand points to the parasitoid selection pressure being higher in these regions.

Olfactory signalling between flowers and bumblebees

Authors: Gomez Carolina[1], Muktar Iman[1], Schmitt Thomas[2] and Riabinina Olena[1], [1]Durham University, [2]University of Würzburg, Germany

Abstract: Plant-pollinator interactions are complex processes driven by diverse signals such as floral scent (Raguso, 2008). Bumblebees are important pollinators who are confronted with an enormous diversity of floral cues, which they use to make foraging choices (Mertes et al., 2021). Bumblebees are normally thought of as generalist pollinators (Goulson, 2003), although the specific floral and olfactory preferences across bumblebee species are not well known.

In this project we investigate whether bumblebees use smells of flowers to make their foraging decisions, and whether flower smell preferences are species-specific. We conducted collections of bumblebees in summer 2021 in Durham, UK, taking note of the flowers they were found on. Next, we collected floral volatiles using standard traps, and analysed them via gas chromatography-mass spectrometry. This approach allowed us to identify key volatiles of the flowers that were or were not visited by 10 sympatric bumblebee species. We also started to establish the patterns of floral preferences for our species of interest. The behavioural responses of the bumblebees to floral volatiles will be ascertained via dual- or multiple-choice assay with real or artificial flowers.

This work will contribute and expand the knowledge about sensory ecology of bumblebees and their important role as pollinators.

Carrion-feeding blowflies (Diptera, Calliphoridae, and Mesembrinellidae) as an indicator of the anthropogenic disturbance on the landscape in Colombia

Authors: Gomez-P. Luz M.[3], Amat Eduardo[2] and Altamiranda Mariano[1], [3]Grupo Bioforense, Tecnológico de Antioquia, Medellín, Colombia, [2]Grupo Bioforense, Tecnologico de Antioquia, Medellín Colombia, [1]Grupo Bioforense, Tecnologico de Antioquia, medellin Colombia

Abstract: Some insect taxa had been recognized as indicators of anthropogenic disturbance in tropical environments. However, studies at different disturbance levels, spatial and temporal scales are required for their practical usefulness. Carrion-feeding flies (Diptera, Calyptratae) were suggested as a restoration and conservation management bioindicator in the tropical rain forest, and also an indicator of the anthropic impact on the Andean landscape. Thirty localities were assessed, from a pristine tropical rain forest to a highly dense urban settlement within all Colombian natural regions. Each locality was categorized and ranked according to the values deducted on the Human Influence Index (HII) raster dataset. A data set (presence/absence) of the carrion feeding blowflies ensembles and the related blowfly fauna is offered as a critical supply to use this taxon as a practical parameter to assess the degree of anthropic disturbance of the landscape involved. Synanthropic preference and ecological category are documented. Finally, a checklist and a discussion of potential key species pointed to a particular landscape conservation status are treated. The study of carrion-feeding flies' ensembles at a low budget will quickly assess tropical landscape conservation status, monitoring, and restoration stage. We claim this taxon be included in Colombian environmental impacts assessments.

Bio-geography, species diversity, and host-specificity of the gall midge Mycodiplosis (Diptera, Cecidomyiidae) feeding on rust fungi (Basidiomycota, Pucciniales)

Authors: Gomez-Zapata Paula[2] and Aime M. Catherine[1], [2]Purdue University, United States, [1]Purdue University

Abstract: Rust fungi are plant pathogens that cause diseases on economically important crops and threaten native species with extinction in natural ecosystems. Although fungicides are the most common option to control rust fungi, their overuse causes severe damage to the environment and selects more aggressive rust strains. Biocontrol is an attractive alternative method for rust disease management. The gall midge, Mycodiplosis, is a promising biocontrol agent of rusts whose larval stage feeds on the spores of several rust species. However, phylogenetics, ecological information on Mycodiplosis and its relationship with rust fungi are scarce. In addition, the species identification of Mycodiplosis is based only on the morphology of adult males, which are rarely found on rusts. This study focuses on the biogeography, species diversity, and host-specificity of Mycodiplosis to rusts worldwide. We screened 6,000 rust collections from the Arthur Fungarium for the presence of Mycodiplosis, including major crops such as coffee, corn, wheat, willows, and species in the Myrtaceae family. Larval species were identified using morphological and molecular data and confirmed with live rearing of adults where possible. These data will provide baseline information to identify fly larvae feeding on rusts and their potential as a biocontrol agent for rust diseases

Bio-geography, species diversity, and host-specificity of the fungivorous insect Mycodiplosis (Diptera, Cecidomyiidae) as a natural enemy of rust fungi (Basidiomycota, Pucciniales)

Authors: Gomez-Zapata Paula[2] and Catherine Aime M.[1], [2]Purdue University, United States, [1]Purdue University Department of Botany and Plant Pathology, United States

Abstract: Rust fungi are plant pathogens that cause diseases on economically important crops worldwide. In addition, they threaten plant species with extinction and disrupt natural ecosystems. Fungicides are the most common option to control rust fungi when disease-resistant cultivars are unavailable. However, the overuse of fungicides is causing severe damage to the environment, and it is selecting new resistant rust strains to the fungicides. Biocontrol is an attractive alternative method for rust disease management. This method uses natural enemies to control the infection and prevent disease dispersion. The fungivorous insect, Mycodiplosis, is a natural enemy of rusts whose larval stage feeds on the spores of several rust species without causing any damage to the plant. Although this insect has potential as a biocontrol agent of rust fungi, we need to understand first how specific they are to the rust species and their distribution patterns before using them in open field essays. This study focuses on the biogeography, species diversity, and host-specificity of members of Mycodiplosis to rust fungi. We screened 6,000 rust-infected plant samples collected worldwide and looked for the presence of Mycodiplosis larvae. We identified larval species using morphological and molecular data. We also analyzed larval distribution patterns through heat maps and studied their preference for rust species through multi-locus phylogenetic analyses. This study covers the most representative sampling data of Mycodiplosis species feeding on rust fungi worldwide. It also provides the baseline for characterization studies of Mycodiplosis as a biocontrol agent of rust diseases.

Evolutionary history and species distribution of New Caledonian Taophila (Lapita) Gómez-Zurita et Cardoso (Coleoptera: Chrysomelidae) suggest their association with habitat transformations

Authors: Gómez-Zurita Jesús[1], Platania Leonardo[3] and Cardoso Anabela[2], [1]Institute of Evolutionary Biology (CSIC-UPF), Barcelona, Spain, [3]Institute of Evolutionary Biology (CSIC-UPF), Spain, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: New Caledonia is one of the most important biodiversity hotspots in the world, characterized by a high number of species often presenting a peculiar pattern of microendemicity possibly conditioned by the geological and the climatic history of the archipelago. The leaf beetle subfamily Eumolpinae is coherent with this scenario, showing a remarkable diversity, higher than previously suspected, and the species seem to have small ranges. Here, we put the focus on the diversity and evolutionary history of subgenus Lapita Gómez-Zurita et Cardoso belonging to the endemic genus Taophila Heller through a phylogenetic framework using the mitochondrial markers cox1 and rrnS. Only three species of the subgenus were known, but we increased the number up to eleven based on the analysis of morphological and genetic differences. Distribution data for these species is consistent with a pattern of microendemicity exclusively within the so-called New Caledonian rainforest ecoregion, with most species being allopatric, with the exception of some sympatric and parapatric species in the central part of Grande Terre. The mitochondrial phylogeny of Lapita shows that this linage evolved during the Miocene, originating in the northern part of the island about 30-17 Mya, and immediately separating in two northern and southern lineages possibly following a vicariant or a dispersal model. The expansion of the southern lineage some 15-6 Ma ago into an area with different geological origin and soil composition, and consequently with different plant communities, possibly triggered subsequent diversification. It is possible that climatic changes during the Pliocene and Pleistocene changed the distributions of biomes and evolutionary lineages, leading to secondary contacts of some of these lineages in the central region of the island. This scenario is consistent with hypotheses of the evolution of forest biomes in the major island in relation to the geological and environmental transformations occurred in the upper Cenozoic, which may have driven the evolutionary history of this group.

Stowaways in the Matahourua or the long transoceanic trip of the Eumolpini (Coleoptera: Chrysomelidae, Eumolpinae) to reach New Zealand

Authors: Gómez-Zurita Jesús[2], Cardoso Anabela[3], A. M. Reid Chris[1] and A. Trewick Steven[4], [2]Institute of Evolutionary Biology (CSIC-UPF), Barcelona, Spain, [3]Institute of Evolutionary Biology (CSIC-UPF), Spain, [1]Australian Museum, Sydney, Australia, [4]Massey University, Palmerston North, New Zealand

Abstract: The Eumolpinae are a species-rich group of leaf beetles in the tropics, well represented in Australia and SE Asia, that colonized most of the western Pacific archipelagos all the way through to Samoa. Eumolpinae are particularly diverse in old tropical archipelagos such New Caledonia (NC) and Fiji, where they radiated locally and, supposedly, from a reduced number of transoceanic arrivals of Eumolpini in the case of NC and Typophorini in Fiji. However, they are also present in temperate western Pacific islands, including New Zealand (NZ), where they have a reduced number of species, but of highly original groups, which were classified as five essentially endemic genera of Eumolpini. Here, we aim at shedding some light on the origins of this original fauna by investigating its phylogenetic relationships with representatives of neighbouring faunas, including Australia, NC and Lord Howe Island (LH). Several hypotheses have been proposed for the origin of the biota of NZ, including palaeoendemic and recent origins, and the latter from several different sources, typically from Australia because of geographic proximity, but also from other regions. In this respect, it is risky to make generalizations or predictions about the origins of specific NZ groups, and answering the question about these origins needs analyses on a taxon-by-taxon basis. For the study of NZ Eumolpini, we obtained sequences of two mtDNA markers (cox1, rrnS) and three protein-coding single-copy nuclear genes (Wnt, CPS, PABP1) for a representative sample of this tribe from the New World, SE Asia, Australia, LH, NC, and three out of five genera of Eumolpini from NZ. We investigated their phylogenetic relationships using maximum likelihood and their timing of separation using molecular clock approaches in a Bayesian framework. The most remarkable discoveries from these analyses, include: (1) a highly supported (NC+NZ+LH) clade corresponding to current emerged lands of the lost continent of Zealandia, and sister to the remaining Eumolpini; (2) polyphyly of NZ, with each genus nested within a different group of NC Eumolpini, thus representing unrelated origins for each NZ genus; and (3) independent origins of NZ genera occurring during the Oligocene, within a time interval between 15-30 Ma, after the separation of NC and NZ with the opening of the New Caledonian Basin, thus requiring separate transoceanic dispersal events for each genus. Eumolpinae in New Zealand enlarge the pool of recent endemic lineages that refute the Gondwanan hallmark of its original biota, strengthen the relevance of Zealandia as a biogeographic unit, and provide with interesting cases of long-distance dispersal in the Western Pacific. But at the same time, the study underlines the need to consolidate these ideas by expanding it to cover as much of the biodiversity of Eumolpini in NZ but also in Australia and other nearby islands, not sampled here, including Norfolk Island, Tasmania, Fiji or the Kermadec Islands.

Benefit and risk of combining an entomopathogenic virus with parasitoids to control Tuta absoluta

Authors: Gonthier Jérémy[2], Studer Janique[2], Sutter Louis[2], Collatz Jana[4], Arnó Judit[1] and Romeis Jörg[3], [2]Agroscope, [4]Agroscope, Switzerland, [1]3IRTA (Institute of Agrifood Research and Technology), Cabrils (Barcelona), Spain, [3]Agroscope, Research Division Agroecology and Environment, Reckenholzstrasse 191, 8046 Zurich, Switzerland

Abstract: The combination of different biocontrol agents, in particular of micro- and macro-organisms, can contribute to new and sustainable pest control approaches. Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) is one of the most destructive pests of solanaceous crops, and an emerging management strategy consists of biological control using the hymenopteran parasitoids Necremnus tutae (Reuter) (Eulophidae) or Dolichogenidea gelechiidivoris Marsch (Braconidae), however with limited efficacy. We evaluated the risks and benefits of combining the parasitoids with the Phthorimaea operculella granulovirus (PhopGV, Baculoviridae) infecting T. absoluta larvae. Due to their host specificity, potential non-target effects of baculoviruses on parasitoids should not result directly from infection. However, impacts can result from the viral infection killing the host before the parasitoid has completed its development, or from overlapping resource requirements of parasitoid immatures and the virus. Benefits arise in particular, if parasitoids discriminate between healthy and infected host, as they can minimize negative interference and control those hosts that have escaped the virus. We evaluated the interaction between the baculovirus and the koinobiont endoparasitoid D. gelichiidivoris and the idiobiont ectoparasitoid N. tutae in the laboratory. We assessed whether ovipositing females discriminate against virus-infected hosts and examined the outcome of within-host competition between parasitoids and virus. Then we evaluated the efficacy of the combined use of the baculovirus with the parasitoid N. tutae in greenhouse experiments. Female D. gelichiidivoris were able to discriminate against virus-infected hosts, whereas N. tutae were not. Depending on the species and the time after virus infection, we found reduced size, emergence, longevity and a longer development time, but in general, the virus had a low impact on parasitoid offspring. Finally, when compared to N. tutae and the baculovirus used solely, their combination improved significantly the control of the pest in the greenhouses. Therefore, both parasitoids seem to be compatible with the baculovirus to control T. absoluta.

Elucidating mechanisms that promote or deter conservation biological control

Authors: Gontijo Lessando[1], Saldanha Alan[1], Hiago Silva José[1], Carvalho Rayana[1] and Gandra Robert[1], [1]Federal University of Viçosa, Campus Florestal, Brazil

Abstract: Although it is widely understood that the dynamic interactions among natural enemies, pests and plants govern conservation biological control, the underpinning mechanisms of such interactions remain largely underexplored. Searching for the underlying mechanisms of such interactions is paramount to gain a new foothold in conservation biological control. Nonetheless, the outcome of these interactions may be context-specific, and their complexity will likely increase with the number of species involved. Thus, carrying out multiple manipulative field experiments and drawing on insightful connections among the variables assessed is essential. For biological control practitioners and researchers, it is specifically important to learn how habitat manipulations in agricultural settings can affect those trophic interactions, and ultimately the control of arthropod pests. In this context, in a series of field experiments we have been investigating the mechanisms that play out in companion planting settings, and how they impact biological control. Specifically, we have examined how companion plantings in a brassica system affect nocturnal vs. diurnal natural enemies, intraguild predation, the numerical response from natural enemies, the attraction of distant natural enemies, as well as their potential to favor key pests. We have found that bearing flowers is not a prerequisite for companion plants to promote conservation biological control. Additionally, companion plants will affect distinct groups of natural enemies in different manners, which may either promote or impair biological control. Lastly, the results suggest that companion plants may be more important for sheltering generalist natural enemies, which tend to arrive early in the growing season as well as to perform better in a more diversified agroecosystem.

The role of natural transposable element insertions in environmental adaptation

Authors: González Josefa, Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: Transposable elements are ubiquitous, abundant, and active components of genomes. Although most of the mutations caused by transposable elements are likely deleterious or neutral, adaptive mutations have also been repeatedly identified across species. Drosophila melanogaster is an excellent model species to quantify the role of transposable elements in environmental adaptation as it has recently colonized very distinct habitats. We have generated 32 Drosophila melanogaster reference genomes using long-read sequencing of flies collected in arid, cold and temperate environments. We have discovered and annotated transposable elements in these genomes using a combination of homology-based and de novo approaches. The in depth annotation of these genomes has allowed us to discover three new transposable element families in this well-studied species. We have also generated RNA-seq data for 25 of these genomes that will allow us to elucidate the role of transposable elements in expression quantitative trait loci variation. We are currently investigating the role that the identified transposable elements play in desiccation, oxidative and heavy-metal stress resistance. Our results will allow us to quantify the role of transposable elements in environmental adaptation and to generate testable hypothesis for follow-up functional validation studies.

A novel automated surveillance system which is capable to remote classify target mosquitoes by specie, sex and age.

Authors: González María Isabel[1], Faulhaber Bastian[3], Núria Busquets[4], Aranda Carles[4], Encarnação Joao[3], Brosa Josep[2], Williams Mark[3], Pujol Núria[2], Villalonga Pancraç[3] and Talavera Sandra[2], [1]CReSA-IRTA (Animal Health Research Institute- Agrifood Technology Research Institute) UAB (Autonomous University of Barcelona), Spain, [2]CResa-IRTA, Spain, [2]CReSA-IRTA, Spain, [3]IRIDEON, Spain, [4]IRTA, Centre de Recerca en Sanitat Animal (CReSA, IRTA-UAB), Spain

Abstract: Mosquitoes are considered one of the deadliest animals worldwide regarding their capacity to transmit several infectious diseases such as dengue, malaria, yellow fever, chikungunya, Zika, West Nile fever and Rift Valley Fever. Entomological surveillance of mosquito populations has been carried out, traditionally, through larval counting, ovitraps and sticky traps. Such methods, however, are notoriously costly, depend on entomology experts and are very time-consuming. These costs can significantly be reduced with remote sensing devices providing real time data effortless.

Here we present VECTRACK, a H2020 European project whose main output is the creation and continued development of an automated optoelectronic sensor which is already capable to distinguish between the specie, sex and age of mosquitoes with promising levels of accuracy.

A total of 5000 tests have been performed in order to train and validate the sensor through deep learning techniques. Three target species (Aedes aegypti, Aedes albopictus and Culex pipiens) have been tested for both sexes and three age categories. Major accuracy levels were obtained for genus and sex classification. Differentiation of species from the same genus was challenging but further samples will be tested to increase this accuracy. Age classification ranged between acceptable levels of accuracy, but it is improvable as well.

Currently, more species and biological conditions are being considered in laboratory experiments in order to increase the applicability of the system in field conditions. The overall final objective of VECTRACK is to provide the first transnational and automated surveillance system for mosquito control, a long-sought objective of public health agencies.

Hunting with catapults: the predatory strike of the dragonfly larva

Authors: Gorb Stanislav[2], Büsse Sebastian[1], [2]University of Kiel, Germany, [1]Department of Functional Morphology and Biomechanics, Institute of Zoology, Kiel University, Germany

Abstract: Odonata larvae are often key predators in their aquatic biotopes. They catch their prey with a unique and highly efficient apparatus, the so-called prehensile labial mask, a strongly modified and extensible mouthpart. However, the main driving mechanism and underpinning biomechanics of this movement remained questionable.

We used various techniques, such as micro computed tomography (µCT), scanning electron microscopy (SEM), confocal laser scanning microscopy (CLSM) and high-speed videography combined with manipulation experiments to gain insights into the biomechanics of the predatory strike of Odonata larvae.

Our results suggest a catapult system as the main driving mechanism for this prey-capturing process. We could identify two resilin-dominated sclerites (T-rod and premental sclerite) and two accessory muscles 0la5 and 0hy7 responsible for the mechanism of fast extension. Here the resilin-containing structure is strained by slow muscle action and thereby energy is stored. To allow for this energy storage in spring-loaded catapult systems, a complex latch mechanism and a trigger muscle (0la15) are present.

Furthermore, the hypothesis that hydraulic pressure is the driving force of the striking process, as suggested by former investigations, could be refuted by manipulation experiments. We suggest that hydraulic pressure is most likely used for recoil-preventing jet propulsion during the prey capturing process. Finally, we provide a proof of concept by a 3D-printed robotic system inspired by the odonate prehensile mask.

Sexual dimorphism in morphology of the raptorial forelegs and the dynamics of the predatory strike in Hierodula majuscula (Insecta: Mantodea)

Authors: Gorb Stanislav[2], Büsse Sebastian[1], Bäumler Fabian[1], [1]Department of Functional Morphology and Biomechanics, Institute of Zoology, Kiel University, Germany, [2]University of Kiel, Germany,

Abstract: Raptorial forelegs are prey capturing devices, which evolved convergently in different groups of insects. These predatory appendages are best known and investigated in praying mantises (Insecta: Mantodea), a group that shows strong morphological adaptations towards the lifestyle of an ambush predator. Sexual dimorphism occurs in many species of mantises, causing a difference in size and appearance between males and females. Although morphology and behaviour of adult Mantodea were investigated in the past, yet information about sexual dimorphism in internal and external morphology of the raptorial forelegs, as well as the dynamics of the predatory strike is scarce. We combined morphological methods (micro-computed tomography (µCT) and dissection) with force measurements, to compare male and female individuals throughout the postembryonic development until adulthood. Here, we show a detailed description of the extrinsic and intrinsic musculature of the raptorial forelegs, of male and female Hierodula majuscula (Mantidae) – a species showing noticeable sexual dimorphism only in adult stage. Using this data in combination with force measurements, we analyzed the scaling effect of muscle growth against force output throughout the postembryonic development. We supplemented our results with kinematic information, obtained from high-speed-video analysis, concerning duration, velocity and speed of the different phases of the predatory strike. By highlighting the musculature of the raptorial forelegs, in combination with kinetic and kinematic analyses, our work serves as a starting point for further investigations of the predatory strike, throughout different groups of mantises, differing in their lifestyle, prey preference and therefore eco-morphology.

Numerical flow simulations reveal the eco-morphological adaptations of the prehensile labial masks of dragonfly larvae (Insecta: Odonata)

Authors: Gorb Stanislav[3], Büsse Sebastian[1] and Brede Martin[2], [3]University of Kiel, Germany, [1]Department of Functional Morphology and Biomechanics, Institute of Zoology, Kiel University, Germany, [2]Lehrstuhl für Strömungsmechanik, University of Rostock, Germany

Abstract: The larvae of dragonflies and damselflies capture prey underwater using the prehensile labial mask, a fast-moving raptorial appendage. Within dragonflies (Anisoptera) two general shapes of the prehensile labial mask have evolved, differing in their distal segment, which is either flat and slender or concave. While the former (Anax) is a pure grasping device, the latter (Sympetrum) is also capable of scooping up smaller prey items, keeping them inside the cavity by arrays of setae. Fast motion in water usually causes substantial amounts of drag, yet the hydrodynamic properties of these structures have not been assessed previously. Based on high-speed footage and computer tomographic data (µCT), we use computational fluid dynamics (CFD) simulations of the prehensile labial mask to investigate how the different shape of the prehensile labial masks of two dragonfly groups (Anax and Sympetrum) impacts their function. The results suggest that both prehensile labial masks are highly streamlined and generate a low-pressure zone above the distal segment, which is even more pronounced in Sympetrum. We assume that this could be an effect analogous to compensatory suction feeding, as it is known for other aquatic predators. This may prevent the formation of a pressure wave in front of the grasping device, that could displace the prey. Our study provides first insights into the hydrodynamics of the predatory strike in dragonfly larvae and how the eco-morphology of the different shapes of prehensile labial masks impact their functionality.

Anchoring of whitefly eggs on plant leaves

Authors: Gorb Stanislav[3], Gorzolka Karin[1], P. W. Zebitz Claus[2], Kiefer Johannes[2] and Schrameyer Klaus[4], [1]Germany, [2]Institute of Phytomedicine, University of Hohenheim, Stuttgart, Germany, [3]University of Kiel, Germany, [4]Öhringen, Germany

Abstract: Whiteflies attach their eggs to plants by implanting the egg pedicel (hollow stem) into the fluid-filled epidermis cells of the underside of leaves. While the egg is kept in the gaseous leaf boundary layer, its pedicel slips into a secretion-filled hole, prepared by the ovipositor. During the insertion, the pedicel rotates and deforms, increasing frictional interactions and interlocking with the plant substrate. After implantation, the basal pedicel is clamped between tensile-loaded plant cell wall edges; the distal one is surrounded by the egg secretion released to the fluid plant intracellular matrix. Thus, it works like a wall plug embedded in sealing cement, presenting a smart and strong interconnection. How strong whitefly eggs adhere to plant leaves was comparatively studied with four cultivars of cut roses. To detach the egg from lower young rose leaves, a maximum pull-off force of 5.4 mN was measured, corresponding to maximum 941 times the egg mass and maximum adhesive strength of 12.2 MPa (Voigt et al. 2019). Leaf structural features had no significant impact on egg pull-off forces. A major effect of leaf turgor pressure and swelling of the probably proteinaceous, composite fluid-fibrous egg secretion surrounding the whitefly egg stem is assumed to facilitate the firm bond between egg and plant epidermis by a combination of form closure, friction locking, and adhesive bond by a composite material in the contact region.

Morphological, compositional and mechanical properties of the semi-lunar process (SLP) and their role in power amplification of locust locomotion

Authors: Gorb Stanislav[4], Wan Chao[1], Feng Xi-Qiao[2] and Hao Zhixiu[3], [4]University of Kiel, Germany, [1]Department of Mechanics, Beijing Institute of Technology, Beijing, China, [2]State Key Laboratory of Tribology, Tsinghua University, Beijing Institute of Biomechanics and Medical Engineering, Department of Engineering Mechanics, Tsinghua, [3]State Key Laboratory of Tribology, Tsinghua University, Beijing, China

Abstract: Power amplification is one of critical mechanisms for some insects to achieve rapid locomotion like jumping and kicking. As one of typical insects with power amplification, locusts have an impressive jumping and kicking performance that are suggested to be resulted from the storage and release of elastic strain energy in the semi-lunar processes (SLP) cuticle of their femorotibial joints. It is well-known that the amount of elastic strain energy depends on the mechanical properties of the materials. However, the power amplification mechanism of the SLP cuticles remains unclear. In this study adult locusts (Locusta migratoria manilensis) were investigated using some advanced micro-scale imaging techniques, mechanical tests and numerical simulations to reveal the microstructure, material composition and mechanical properties of the SLP cuticle, as well as the power amplification mechanism of the SLP for jumping and kicking. Following results were obtained. 1) The locust femur reveals pronounced stress relaxation behavior with evident displacement-force shift and weak fatigue resistance without cuticle healing. 2) The SLP cuticle consists of five main portions with di?erent microstructural features, material compositions, and mechanical properties. The mechanical properties of these five components are all transversely isotropic and strongly depend on their water contents. 3) The two parts of the core region of the SLP cuticle (i.e., dorsal-core and ventral-core parts) likely make significant contributions to its outstanding strain energy-storage ability. 4) Both of these two key portions exhibit strain rate-sensitive elastic modulus regardless of water content, meaning that the efficiency of elastic energy storage is only 51%-70% in the case of low strain rate. These findings deepen our understanding of the superior power amplification mechanism of locust locomotion and further provide valuable knowledge for design optimization of power amplification apparatus as well as bio-inspired jumping robots.

The stick insect attachment system: functional morphology and the evolution of attachment microstructures

Authors: Gorb Stanislav[6], Büscher Thies[3], Buckley Thomas[5], Bradler Sven[4], Kryuchkov Mikhail[1] and L. Katanaev Vladimir[2], [6]University of Kiel, Germany, [3]Department of Functional Morphology and Biomechanics, Zoological Institute, Kiel University, Kiel, Germany, [5]Manaaki Whenua - Landcare Research, New Zealand, [4]Johann-Friedrich-Blumenbach-Institute of Zoology and Anthropology, University of Göttingen, Göttingen, Germany, [1]Deepartment of Cell Physiology and Metabolism, University of Geneva, Geneva, Switzerland, [2]Department of Cell Physiology and Metabolism, University of Geneva, Geneva, Switzerland School of Biomedicine, Far Eastern Federal University, Vladivostok, Russ

Abstract: Insects have developed a broad array of specialized structures on their feet to properly attach to the vast diversity of natural surfaces. Stick and leaf insects (Phasmatodea) in particular achieve attachment to the substrate by using two different types of attachment pads: the tarsal euplantulae and pretarsal arolium. The euplantulae are cuticular structures capable of mechanical adaptation to the substrate profile and by this generation of the required attachment. The rapid adaptive radiation of stick and leaf insects caused various specializations to different environments including adaptations of the attachment system. This resulted in a wide range of microscopical functional surface microstructures on the attachment pads, especially on the euplantulae. Our investigation of 116 representative species, covering the major clades recognized in phasmids, their different ecological specializations and the entire distributional range of phasmids, yielded 12 different types of attachment microstructures (AMS) on their attachment pads. To access the phylogenetic context of the AMS distribution, we inferred the phylogeny of Phasmatodea based on molecular data and discussed the pattering of AMS in light of the phylogenetic relationships within Phasmatodea. The distribution of the AMS among phasmids suggests a high degree of independent origins of the same types of AMS, which can be explained by their high dependence of the ecological niche. An ancestral character state analysis yielded smooth AMS as the probable ancestral state. The AMS origin and their developmental background, however, remain largely unknown. To approach the mechanisms leading to different AMS, we applied the mathematical reaction-diffusion-model by Alan Turing. Using the model describing pattern formation in nature by self-organization of two chemical morphogens, we were able to simulate eight principal patterns of the phasmid AMS of phasmids and their transitions. The ease of the transitions between different AMS suggests their remarkable adaptive potential to different ecological contexts and furthermore explains the high degree of convergences between different AMS. We additionally discuss the functional morphology of different microstructures and their assumed advantages in the context of the ecological background of species studied.

Biomechanics of egg adhesion to artificial and natural substrates in Propylea quatuordecimpunctata and Harmonia axyridis (Coleoptera, Coccinellidae)

Authors: Gorb Stanislav[8], Büscher Thies[3], Salerno Gianandrea[6], Rebora Manuela[5], Kovalev Alexander[7], Gorb Elena[2], Austeri Lorenzo[1] and Piersanti Silvana[4], [8]University of Kiel, Germany, [3]Department of Functional Morphology and Biomechanics, Zoological Institute, Kiel University, Kiel, Germany, [6]Perugia University, Dipartimento di Scienze Agrarie, Alimentari e Ambientali, Italy, [5]Perugia University, Dipartimento di Chimica, Biologia e Biotecnologie, Italy, [7]University of Kiel, [2]Department of Functional Morphology and Biomechanics, Zoological Institute, Kiel University, Germany, [1]Department of Chemistry, Biology and Biotechnology, University of Perugia, Italy, [4]Perugia University, Dipartimento di Chimica, Biologia e Biotecnologie

Abstract: For predatory insects, such as Coccinellidae, the foraging habitat is predominantly one or several host plant species. The ability to attach firmly to different plant surfaces during all developmental stages is a fundamental prerequisite for these predators. For this reason, the physical and chemical features of plant surfaces can greatly affect egg adhesive performance of predatory insects that face all the mechanical barriers developed by plants against herbivore insects. In this regard, the aim of the present investigation is to clarify the biomechanics of egg adhesion in two common ladybird species, Propylea quatuordecimpunctata and Harmonia axyridis (Coleoptera, Coccinellidae) on substrates with different chemical and mechanical features. P. quatuordecimpunctata is typically mass reared and used as biological control agent, while H. axyridis is considered an invasive species. Using a traction force experiment set up, we tested the egg adhesion to artificial substrates having different wettability (hydrophilic, hydrophobic) and roughness as well as to natural surfaces (plant leaves) with different morphology (smooth, hairy, with cuticular folds, with 3D wax projections). We used characterized artificial and natural surfaces under cryo-SEM and measured their surface free energy. We studied the egg chorion and the glue in TEM and estimated the glue stiffness with indentation measurements. H. axyridis eggs adhere to the different natural and artificial surfaces strongler than P. quatuordecimpunctata . On artificial surfaces, the lower adhesion is shown on the higher roughness and on hydrophobic surfaces in both species. On natural surfaces, the egg glue has to cope with plant mechanical barriers such as trichomes and waxes, which heavily impair egg adhesion to the substrate in both species. The glue is very stiff, comparable with cuticle stiffness showing a Young's modulus of 0.82±0.23 GPa. The results of the present research (1) shed light on the mechanical ecology of evolutionary successfull group of coccinellids ; (2) may aid in development of suitable substrates for coccinellid egg laying, in order to improve the mass rearing technique of species used in biological control; (3) may aid in developing new biomimetic adhesive materials.

Genetic effects of global warming in populations of malaria mosquitoes in the taiga zone of Eurasia

Authors: Gordeev Mikhail[2] and Moskaev Anton[1], [2]Moscow Region State University, Russia, [1]Moscow Region State University, Russia

Abstract: Global warming has led to a change in the ranges of sibling species of Anopheles mosquitoes (Diptera, Culicidae): An. beklemishevi, An. daciae, An. maculipennis, An. messeae. Mosquito An. beklemishevi was driven out of a number of breeding sites in the southern taiga zone. The southern part of the area of this species is currently fragmented. Refugiums of An. beklemishevi are preserved in the subtaiga zone (in the Meshchera lowland, in the swampy territory of the Moscow and Ryazan regions). Mosquito An. daciae advanced north and entered the northern taiga zone in the south of the Komi Republic. This species is now dominant among the malaria mosquitoes of the steppe and forest-steppe zones. It has been shown that An. daciae replaces An. messeae at breeding sites in the south of Western Siberia (Tomsk region). Mosquito An. maculipennis significantly expanded its area in Europe; it spread to the northwest and northeast, to Karelia and to the Komi Republic. At the same time, this species moved east, from the Volga region to the Middle and Southern Urals, overcoming the Ural Mountains. Mosquito An. messeae became the dominant species of malaria mosquitoes in the northern taiga, along with An. beklemishevi. Chromosome composition of An. daciae / An. messeae has changed significantly over 45 years of observation. The first changes in the frequencies of chromosomal inversions were noted in the south of Western Siberia, beginning in 1985 (Gordeev, Ejov, 2004). Inversions XL0 and 2R0 first appeared in populations of the northern taiga, where they were not there before. The frequencies of these inversions increased everywhere in the southern and middle taiga. In our opinion, changes in the chromosome composition of populations are associated with an increase in average winter temperatures and with better survival of adults during diapause. We have shown that the chromosome compositions of populations of polymorphic species An. daciae / An. messeae correspond to certain landscape and climatic zones. Previously, the highest level of chromosomal polymorphism was noted in populations of the subtaiga zone. Currently, the chromosome composition of these populations has become more homogeneous, similar to the composition of steppe and forest-steppe populations. We predict further restructuring of the species composition and genetic structure of populations of malaria mosquitoes and the movement of sibling species to the north of the taiga zone, above the 65th parallel. Changes in the composition of malaria mosquitoes serve as a signal of the initial transformation of the ecosystems of the Eurasian boreal belt as a result of global warming. Global warming increases the risk of malaria recovery due to the spread of southern species of malaria mosquitoes and lengthening the season of transmission of Plasmodium parasites. The reported study was funded by Russian Science Foundation according to the research project 22-24-00183, https://rscf.ru/project/22-24-00183/.

Distribution of invasive species of mosquitoes Aedes albopictus (Skuse, 1895) and Aedes aegypti (Linnaeus, 1762) in the south of European part of Russia

Authors: Gordeev Mikhail[1], Bega Anna[1] and Moskaev Anton[1], [1]Moscow Region State University, Russia

Abstract: Populations of Aedes albopictus Skuse, 1895, the main vector of a number of arbovirus infections, were first detected in the Greater Sochi region, the Black Sea coast of the Caucasus, in 2011 (Ganushkina and other, 2012). This invasive species has captured a zone of humid subtropical climate on the Black Sea coast of the Caucasus for several years. The species has already crossed the Great Caucasus Range and began to develop the temperate zone in 2017. We have determined that by 2019 Ae. albopictus advanced north to the cities of Timashevsk, Korenovsk, Kropotkin. The northern border of the range corresponds to the isohist of 550 mm per year and air humidity of 60% in the summer. The eastern border of the area passes through the cities of Armavir and Labinsk. The western border of the area passes in the region of Anapa on the Black Sea coast of the Caucasus. Ae. albopictus has advanced 60 km into the Russian Plain over the past year.

Spread of Ae. albopictus was accompanied by a sharp decrease in the number of Aedes aegypti Linnaeus, 1762. This species was re-recorded on the territory of Russia in 2001 and captured the entire zone of humid subtropical climate by 2011. A sharp decrease in the number and habitat reduction of this mosquito was noted in 2012. Ae. aegypti was recorded by us only in the city of Sochi in 2019. This mosquito was found with Ae. albopictus, however, significantly inferior to him quantitatively.. We recorded 5-7 attacking Ae. aegypti females and about 200 Ae. albopictus females in 30 minutes during activity hours. Ae. albopictus is considered a semi-synanthropic species, in contrast to the synanthropic species Ae. aegypti. However, at the beginning of the invasion in Russia Ae. albopictus was recorded exclusively in urban areas with abundant vegetation and in rural settlements. The advancement of this species into the forest zone in the Greater Sochi region, with a rise to a height of 400 m, was noted by us only in 2019. Larvae were found in fallen large leaves and rocky depressions filled with rainwater. This territory is adjacent to the points where the number of the species was maximal (over 200 attacking females in 30 minutes, when counting during activity hours) and is close in climatic parameters to the natural range of this species.

We believe that air humidity is an important limiting factor for imago of Ae. albopictus. This species prefers moist habitats shaded by vegetation. Females of Ae. albopictus is active throughout the daylight hours, with a small pessimum for two hours in the afternoon. In our opinion, dry steppe zones are a natural obstacle to the further distribution of Ae. albopictus to the west and north. Promotion Ae. albopictus in the east will be easier and faster than in the north. The appearance of Ae. albopictus in the Stavropol province, as well as on the Crimean peninsula, is a matter of time.
The reported study was funded by RFBR, project number 19-34-90192.

Foothold matters in omnivorous mirid bugs Dicyphus errans, bridging gaps and contributing to the consolidation of multitrophic networks

Authors: Gorzolka Karin, Germany

Abstract: Omnivorous predatory mirid bugs Dicyphus errans Wolff and closely related species, belonging to the subfamily Bryocorinae (Heteroptera, Miridae), prefer to live on pubescent plant species, where other entomophagous insects struggle. Thus, the mirid bugs overcome structural hurdles and explore challenging niches, which let them seem to be promising predatory insects for biocontrol strategies. In context with their omnivorous mode of life, they are 'intermediate agents' of food chains, which implicates complex interactions at several trophic levels (Voigt 2005). Foothold matters in the highly complex life of omnivorous D. errans: mirid bugs' foothold increase significantly with plant trichome diameter and length (Voigt et al. 2007). Fecundity, hatching rate, and juvenile development relate significantly and positively with an increased foothold. Stronger attachment on the plant corresponds to a higher consumption rate (Voigt 2019). This study demonstrates that interfacial effects play a crucial role in insect-plant interactions. Insect settlement on plants depends on insect attachment ability (i.e., foothold), which is influenced by plant substrates. Hence, the impact of plant surface structures on mirid bug's, or even wider, on insect attachment ability and interfacial interactions should further be carefully considered when evaluating insect life history, prey consumption, and multitrophic plant-insect associations in the context of evolution, ecology, and sustainable pest management.

How Japanese pine sawyer beetles hold on arboreal substrates

Authors: Gorzolka Karin[3], Kuroda Katsushi[2], Tsuchihara Kazuko[1], Yazaki Kenichi[2], Hosoda Naoe[5], Tsubaki Remi[4] and Takanashi Takuma[2], [1]Department of Information Science, Tohoku Gakuin University, Sendai, 981-3193, Miyagi, Japan, [2]Forestry and Forest Products Research Institute, Tsukuba, Ibaraki 305-8687, Japan, [3]Germany, [4]Japan Agency for Marine-Earth Science and Technology, Yokosuka, Kanagawa, Japan, [5]Surface & Adhesion Science Group, Research Center for Structural Materials (RCSM), National Institute for Materials Science (NIMS), Namiki, Tsukuba, Ibarak

Abstract: Most longhorn beetles impress with their considerable body size, long antennae, long legs bearing expanded hairy tarsomeres and well developed paired claws. They have been observed to attach strongly to various surfaces. However, host substrates and attachment system were not considered in detailed studies so far. Exemplarily, host plant surfaces and tarsi of the Japanese pine sawyer beetle (Monochamus alternatus Hope) were visualized in order to shed light on longhorn beetle attachment.

Light microscopic observations, cryo-scanning electron microscopic studies and measurements of free surface energy of host substrates were carried out. Additionally, traction forces of male and female longhorn beetles on glass were measured and set into the context.

Monochamus alternatus may attach to a range of surfaces, including pine needles, twig and stem bark as well as female elytrae, which all vary in texture and free surface energy. Five tarsomeres are densely covered with in total about 23600 ribbon-shaped adhesive setae bearing oval spatula-shaped, tapered terminals. Terminals are dorsally equipped with 5 to 10 setulae. In contrast to numerous leaf beetles and ladybirds, no sexual dimorphism in shape of adhesive setae is observed. The 3rd tarsomere in both sexes appears clearly belobed. Adhesive setae occur anisotropically arranged. On flat glass, up to 102 mN pulling force is generated, whereas up to 206 mN are measured on glass rods (considerably stronger pulling forces compared to those of other insects). We suppose an adaptation of the tarsal attachment system of Monochamus alternatus to rod-shaped structures, such as present in the natural habitat of these longhorn beetles.

How tight are beetle hugs?

Authors: Gorzolka Karin[3], Tsipenyuk Alexey[1] and Varenberg Michael[2], [3]Germany, [1]Department of Mechanical Engineering, Technion—Israel Institute of Technology, Haifa, Israel, [2]George W. Woodruff School of Mechanical Engineering, Georgia Institute ofTechnology, Atlanta, Georgia, United States

Abstract: Sexual selection and mating behaviour in insects are fascinating phenomena, challenging experimental studies of the dynamic interactions. Similar to other leaf beetles, rosemary beetles Chrysolina americana exhibit a distinct sexual dimorphism in tarsal attachment setae. Setal discoid terminals occur only in males, and they have been previously associated with a long-term attachment to the female's back (elytra) during copulation and mate guarding. For the first time, we studied living males and females holding to female's elytra. Pull-off force measurements with a custom-made tribometer featuring a self-aligning sample holder confirmed stronger attachment to female elytra compared with glass in both males and females; corresponding to 45 and 30 times the body weight, respectively (Voigt et al. 2017).
In line with previous studies, males generated significantly higher forces than females on convex elytra and flat glass, 1.2 times and 6.8 times, respectively. Convex substrates like elytra seem to improve the attachment ability of rosemary beetles, because they can hold more strongly due to favourable shear angles of legs, tarsi and adhesive setae. A self-aligning sample holder is found to be suitable for running force measurement tests with living biological samples.

Associational resistance to exotic invasive pests in forests

Authors: Gossner Martin. M.[5], Jactel Herve[2], Brockerhoff Eckehard[4], Castagneyrol Bastien[1] and Feddern Nina[3], [1]Inra, France, [2]INRA, France, [3]Swiss Federal Research Institute WSL, Switzerland, [4]Swiss Federal Research Institute WSL, Switzerland, [5]WSL, Switzerland

Abstract: Invasive exotic pest species become increasingly important in forests worldwide. Theory and empirical studies suggest that mixed forests are more resistant against pest and pathogens than pure forests. This is generally referred to as associational resistance, summarising mechanisms leading to reduced likelihood of detection and vulnerability of a focal plant species with increasing plant diversity or changing plant species composition in its surrounding. Evidence comes mainly from studies on native insect species while the relationships between tree diversity/composition and exotic invasive species deserve to be better understood. We hypothesise that higher tree diversity and phylogenetic distinctiveness reduces the abundance of exotic pest species in forests. To test this, we compiled existing datasets of standardised assessments of insects in forests along a tree diversity/composition gradient in which exotic invasive insect species were sampled in sufficient numbers worldwide. We further identified key characteristics and functional traits of assessed exotic insect species. This study was conducted within the EU project HOMED. We found that the response of species abundances to tree diversity in terms of effect direction and shape depended on the traits of exotic species (e.g. the degree of host specialisation) as well as on characteristics of the forests (phylogenetic distance of trees) and regions (overall abundance of the exotic pest and regional environmental characteristics) included in a dataset. We discuss possible mechanisms underlying these diverse responses. Overall our study suggests that associational resistance can be important not only for native but also for exotic pest insect species and should be considered in future forest management strategies.

Photoperiodic regulation of insulin and juvenile hormone signalling pathways through the circadian clock in a bean bug

Authors: Goto Shin[2], Mano Genyu[1], [1]Osaka City University, [2]Osaka Metropolitan University, Japan

Abstract: Many temperate multivoltine insects assess photoperiods by a photoperiodic time measurement system, which is assumed to be a function of circadian clocks. Under short days, they activate or inactivate the endocrine organ or cell to enter diapause. However, the molecular elements involved in the axis from the circadian clock to the endocrine organs/cells are poorly understood. To approach this issue, we investigated the insulin-signalling and juvenile hormone (JH) pathways and their control under the circadian clock in the bean bug Riptortus pedestris. One of the insulins, ILP1, which is expressed in 12 cells in the pars intercerebralis in the brain, is upregulated under long days. RNAi targeted to Ilp1 reduced fecundity, but not affected ovarian development and yolk protein expression. A cytochrome P450 Cyp15, which catalyzes the epoxidation in the JH biosynthetic pathway, is also upregulated under long days. RNAi targeted to Cyp15 suppressed ovarian development even under diapause-averting long days. RNAi targeted to per, one of the circadian clock genes, induced Ilp1 and Cyp15 expression as well as ovarian development even under short days. This study clarified the photoperiodic regulation of insulin and juvenile hormone signalling pathways through the circadian clock.

Impact of constant versus fluctuating temperatures on the development and life history parameters of Tetranychus urticae (Acari: Tetranychidae)

Authors: Gotoh Tetsuo[1] and S. Y. I. Bayu Marida[2], [1]Faculty of Economics, Ryutsu Keizai University, Ryugasaki, Ibaraki, Japan, [2]Indonesian Legume and Tuber Crops Research Institute, Indonesia

Abstract: The impact of daily temperature fluctuations on arthropod life history parameters is inadequately studied compared with the ample amount of research that has been conducted on the effects of constant temperatures. Fluctuating temperatures are likely to be more realistic, as they are ecologically more similar to what these arthropods cope in nature. In this study, we compared the impact of 11 constant temperatures that ranged from 10 to 35°C with fluctuating temperatures with the same corresponding mean temperature and an amplitude of 10°C between high (12 h) and low (12 h) temperatures on the development and life history parameters of Tetranychus urticae under continuous light conditions. No eggs hatched at constant 10°C, whereas 81.5% of eggs successfully completed development at fluctuating 10°C (15/5°C). Egg-to-female adult development was faster under fluctuating temperatures from 12.5 to 27.5°C than under constant temperatures, whereas the opposite trend was observed at >30°C. The lower thermal thresholds (T) were 11.63 and 8.63°C, and thermal constants (K) were 127.81 and 150.69 degree-days for egg-to-female adults at constant and fluctuating temperatures, respectively. The data were analyzed based on age-stage, two-sex life table theory to take both sexes and different developmental stages in to consideration. The numbers of oviposition days were significantly higher at fluctuating 15°C than at the corresponding constant temperature, whereas the opposite trend was observed from 20 to 30°C. The intrinsic rate of increase (r) was higher at fluctuating than at constant 15°C. The r-values ranged from 0.063 day-1 (15°C) to 0.423 day-1 (30°C) at constant temperature, while they ranged from 0.104 day-1 (15°C) to 0.438 day-1 (30°C) at fluctuating temperature. The net reproductive rate (R0) was also higher at fluctuating than at constant 15 and 35°C, but showed an opposite trend at 20 and 25°C. We conclude that fluctuating temperatures should be considered to accurately predict the population dynamics of spider mite in nature.

Ontogenetic description of Proctolaelaps bickleyi (Bram) (Acari: Melicharidae), newly recorded in Japan from lepidopteran insect cultures

Authors: Gotoh Tetsuo[1], W. Negm Mohamed[2] and Kitashima Yasuki[2], [1]Faculty of Economics, Ryutsu Keizai University, Ryugasaki, Ibaraki, Japan, [2]Laboratory of Applied Entomology & Zoology, Faculty of Agriculture, Ibaraki University, Ami, Ibaraki, Japan

Abstract: Numerous species of Mesostigmata mites (Arachnida: Acari) have close association with insects. Proctolaelaps bickleyi (Bram) (Melicharidae) is redescribed from females, males, deutonymphs, protonymphs and larvae collected from laboratory cultures of Chilo suppressalis (Walker) and Cossus insularis (Staudinger) (Lepidoptera: Crambidae, Cossidae) in Japan. Mites were directly picked up from insect rearing cultures under stereomicroscope and mounted on glass slides using Hoyer's medium. The ontogenetic changes in idiosomal and leg chaetotaxy are discussed and a key to the Japanese species of Melicharidae is provided.

Local adaptation to seasonal cues in a range-expanding butterfly

Authors: Gotthard Karl[1], Ittonen Mats[1], [1]Department of Zoology and Bolin Centre for Climate Research, Stockholm University, Sweden

Abstract: Range-expanding populations need to adapt to new environments, but lack of genetic variation in marginal populations as well as maladaptive gene flow from the core range may hinder adaptation. Previous studies on adaptation in expanding populations have mainly focused on dispersal ability, while less is known about important life history traits such as seasonal timing in response to photoperiod. Using controlled laboratory experiments we show that populations of the range-expanding wall brown butterfly, Lasiommata megera, have, on a relatively small spatial scale, adapted locally to photoperiodic seasonal cues. In long day treatments, caterpillars from the northern range margin in central Sweden were more likely to enter diapause than caterpillars from southern Sweden. Although temperature also affected diapause induction, there were no signs of similar differentiation among populations in the response to temperature. Northern range margin populations seem to have rapidly evolved their response to photoperiod to match local season length and photoperiodic conditions. This is a crucial adaptation for correct life cycle timing and is in many insects likely to be important for successful colonization of novel areas during range expansions across latitudes

Convergence of nutritional symbioses in obligate blood-feeders

Authors: Gottlieb Yuval[2], Duron Olivier[1], [1]Centre National de la Recherche Scientifique (CNRS) - Institut pour la Recherche et le Développement (IRD) -Université de Montpellier (UM), France, [2]Hebrew University, Israel, Israel

Abstract: Symbiosis with intracellular or gut bacteria is essential for the nutrition of animals with an obligate blood feeding habit. Divergent bacterial lineages have independently evolved highly functional interactions with obligate blood feeders, but all have converged to an analogous biochemical feature: the provisioning of B vitamins. Although these symbionts and their hosts coevolve interdependence for millions of years, we emphasize here that their associations are not necessarily stable and permanent. Ancestral symbionts undergo massive genomic reduction that may lead to accumulation of maladaptation. Recently acquired bacteria with similar biochemical features are able to out-compete these ancestral symbionts, leading ultimately to their extinction. Additionally, a streamlined biotin (B7 vitamin) operon experiences extensive transfers across bacterial lineages, favouring the spontaneous emergence of novel nutritional symbioses with blood feeders.

Do Juvenile Hormone and ecdysteroids mediate aggressive behavior in a solitary parasitoid wasp?

Authors: Goubault Marlène[4], Lécureuil Charlotte[4], Liégeois Solène, G.E. Mathiron Anthony[3], Dixneuf Charly[3], Mondy Nathalie[2] and L. Earley Ryan[1], [1]Department of Biological Sciences, University of Alabama, Tuscaloosa, United States, [2]LEHNA, UMR 5023 CNRS - Université Lyon 1, Villeurbanne, France, [3]Research Institute on Insect Biology (IRBI), UMR 7261 CNRS - University of Tours, Tours France, France, [4]Research Institute on Insect Biology (IRBI), UMR 7261 CNRS - University of Tours, Tours France, France

Abstract: In vertebrates, titers of androgens such as testosterone are known to upregulate aggressive behaviors associated with reproduction. In insects, ecdysteroids (ESH) and juvenile hormone (JH) are good candidates to study the mediation of aggressiveness because they have important effects on both reproductive processes and behavior. Both ESH and JH have a gonadotropic effect across a broad range of insect species, increasing ovarian development in females and JH play a role in the regulation of aggressive behavior during competition in different species. To date, inconsistent results have been found with ESH, but only very few species have been studied. In Hymenoptera, the functions of ESH and JH have only been explored in social species. Surprisingly, no work has yet focused on the relationship between these hormones, reproduction and aggressiveness in a non-social Hymenoptera, although it may help understanding how hormone actions have evolved across taxa with different degrees of sociality. The question is also topical because the use of growth regulating insecticides, especially JH agonists, raises questions about their effects on non-target species. Here, we explored whether titers of ESH, JH and one of its agonist, the insecticide pyriproxyfen, influenced female reproductive status as well as aggressiveness and resolution of conflict in Eupelmus vuilleti (Hymenoptera: Eupelmidae). In this solitary ectoparasitoid wasp that can be used as biological control agent to regulate population of the pest Callosobruchus maculatus, females can indeed fight for hosts on which they lay their eggs. By quantifying hormone titers that naturally circulate in females after a contest, we first showed the ESH titers did not correlate with female aggressiveness, but winner wasps had higher titers than losers. Then, by injecting ESH or JHIII or by applying wasps externally with pyriproxyfen, (1) we confirmed that ESH, JH and pyriproxyfen favored egg maturation (i.e., gonadotropic effect) in E. vuilleti and (2) we showed that JH and pyriproxyfen increased female aggressiveness while ESH increased their probability of winning host access. Our results represent an important step in understanding how hormones mediate aggressive behavior during competition and highlights the importance of studying the diversity of possible unintended sublethal effects of pesticides on beneficial insects.

Impacts of a Warming World: Exposure to Simulated Heat Waves Decreases the Upper Thermal Tolerance of Buff-tailed Bumblebees

Authors: Goulson Dave[1], Sepúlveda Yanet[1], [1]University of Sussex, United Kingdom

Abstract: Climate change is one of the most significant challenges in the 21st century and among the main drivers of biodiversity loss. Recent distributional shifts and declines of pollinators seem to be associated with this phenomenon. However, few studies have assessed the upper thermal limits of temperate bumblebees. This study estimates the critical thermal maximum (CTmax) and heat coma temperature (HCT) of the British buff-tailed bumblebee, an important pollinator of wild and agricultural plants. CTmax occurred between 48.98-52.78 °C and was characterised by muscular spasms, disorganised movements, and inability to move forward, while HCT varied between 50.75-53.48 °C and occurred when the ability to move their body, legs, and/or antennae was lost. After measurements, around 23% of bees (n = 30) survived 24 hours or longer and coordination was never recovered, indicating that elevated temperatures may cause irreversible damage. There was no association between thermal tolerance and body mass, which highlights the need to integrate other factors to comprehend the mechanisms behind upper thermal limits. Individuals did not show acclimation capacity after heat wave exposure. In fact, the upper thermal limits of bumblebees decreased significantly after being exposed to a single heat wave of 34-36 ºC, while individuals exposed to a heat wave of 30-32 ºC showed no significant changes in their thermal tolerance. Our study provides novel insights into the upper thermal tolerance limits of Bombus terrestris audax and reveals that heat waves can have cumulative negative impacts on the fitness and survival of individual bumblebees, which is critical to predicting responses to future climate warming and increasing frequency of extreme weather events.

Aspirin-triggered anti-inflammatory eicosanoid-like mediators in Drosophila

Authors: Govind Shubha, The City College of New York and Graduate Center, City University of New York, United States

Abstract: Epidemiological reports have linked the use of aspirin to a drop in cancers and other chronic inflammation (CI)-based human diseases. Aspirin remains one the most effective pain-relieving and life-saving drugs. Its dual biochemical roles in reducing the levels of cyclooxygenase-mediated pro-inflammatory prostaglandins and increasing pro-resolution molecules in mammals are well known. But whether insects produce similar molecules and how these molecules affect their immune health has been an outstanding question in the field. Previous studies have shown that insects are sensitive to aspirin treatment, suggesting that its actions might be realized via anti-inflammatory lipid mediators acting through conserved mechanisms. In mammals, aspirin triggers the production of anti-inflammatory electrophilic mono-oxygenated (EFOX) lipid mediators. We therefore studied aspirin's effects in Drosophila models of CI. Ectopic immune (Toll/NF-kappaB and JAK/STAT) signaling in mutant D. melanogaster larvae leads to an expansion of the hematopoietic blood progenitor population and inflammatory granuloma-like blood tumors. Ectopic immune signaling also results in metabolic inflammation. Aspirin-treated mutant flies exhibit reduction in metabolic inflammation, mitosis, ectopic immune signaling, and macrophage infiltration into the fat body. Moreover, these flies synthesize 13-HODE (an oxygenated PUFA in mammals, associated with pain and inflammation) and aspirin triggers 13-oxoODE (13-EFOX-L2) production. Dietary supplementation of 13-HODE's precursor, C18 linoleic acid, or targeted knockdown of the transcription factor STAT in inflammatory blood cells (without aspirin), boosts 13-EFOX-L2 levels, while decreasing metabolic inflammation. Thus, hematopoietic cells appear to regulate CI in flies, and their effects can be reversed by pharmaceutical or dietary intervention. Aspirin's anti-inflammatory and anti-cancer effects in fruit flies suggest deep phylogenetic conservation in the processes required to resolve inflammation, repair tissue damage, and restore homeostasis. This model system brings the power of Drosophila genetics to bear on immuno-metabolic mechanisms that boost systemic health in humans, with the potential to identify conserved mechanisms across taxa.

Food is life - The effect of plant diet on the susceptibility of Agriotes obscurus towards the entomopathogenic fungus Metarhizium brunneum

Authors: Grabenweger Giselher[3], Reinbacher Lara[3], Praprotnik Eva[2], Razinger Jaka[1] and Bacher Sven[4], [1]Agricultural Institute of Slovenia, Ljubljana, Slovenia, [2]Agricultural Institute of Slovenia, Slovenia, [3]Agroscope, Zurich, Switzerland, [4]Department of Biology, University of Fribourg, Switzerland

Abstract: Entomopathogenic fungi (EPF) have been described as promising biological control agents against wireworms but success in field experiments is inconsistent. An array of abiotic and biotic factors may influence the efficacy of EPF. One of the latter is the fitness of the targeted insect and the ability of the potential host to withstand fungal infection. For the insects' immune defense, nutrition is among the most important determinants.

In this study, we investigated the effects of five plant diets on the development of the wireworm Agriotes obscurus in a greenhouse pot experiment. After living on a specific diet for eight weeks, wireworms were exposed to an environment inoculated with the EPF Metarhizium brunneum ART2825 and monitored for their susceptibility to fungal infection.

The results of this study may help to develop tools for an integrated pest management strategy against wireworms. Plant species which constitute unsuitable nutritional resources for wireworms and compromise their fitness, may be combined with application of EPF and ultimately enhance efficacy of the treatment in the field.

Identifying and integrating diverse datasets to understand insect decline: the EntoGEM project

Authors: Grames Eliza[3], Montgomery Graham[1], Elphick Chris[2], [1]University of California Los Angeles, [2]University of Connecticut, United States, [3]University of Nevada, Reno, United States,

Abstract: To fully understand insect population and community trends, it is necessary to identify, integrate, and synthesize datasets representing the diversity of insect taxa and their habitats globally. The literature documenting such datasets is vast and scattered across disciplines, from medical and forensic entomology, to agricultural pest management, to ecology and conservation biology, and more. The Entomological Global Evidence Map (EntoGEM) project is a systematic effort to broadly search for and catalog diverse studies with long-term data that can be used to understand changes in insect abundance and diversity. Though we have screened less than 10% of >130,000 studies that potentially contain long-term insect data, we have already identified more than 270 >10-year datasets and hundreds more shorter time series (2-9 years) documenting insect population and community trends. The datasets identified by the EntoGEM project can be used to estimate global trends more comprehensively, disentangle drivers of decline, and answer a myriad of questions about short- and long-term insect population dynamics.

Who is Knocking on Our Door? Meeting the Challenges of Invasive Species from a Southern Perspective (Tennessee, USA)

Authors: Grant Jerome, Department of Entomology and Plant Pathology The University of Tennessee Knoxville, Tennessee 37996, United States

Abstract: Invasive species pose tremendous threats to agricultural lands, forests, landscapes, natural areas, and urban areas. In Tennessee, some of these threats have been realized as millions of ash trees have died from emerald ash borer and millions of hemlock trees have died from hemlock woolly adelgid. Both of these species arrived unexpectedly and spread rapidly, mainly due to the abundance of hosts and suitability of climate for development and reproduction. The invasion of these species, as well as others (including kudzu bug, brown marmorated stink bug, and crapemyrtle bark scale), have posed challenges to our local municipalities and state government, land managers, federal agencies, etc. The eastern part of the state of Tennessee (USA) is located in the Southern Appalachian Mountain Range; other parts represent at least five other physiographic regions. The climate in these regions is conducive to establishment and reproduction of many invasive species, due to the warmer temperatures in the winters which reduce winter kill of invasive species. This climate, coupled with the diversity in geography, topography, etc. and the diversity of industries (e.g., nursery, agricultural, forestry, etc.), provide unique critical issues/challenges related to invasive species. Located in a southern climate, Tennessee has numerous high-traffic interstates and much international (and interstate) business is conducted. Thus, critical issues related to invasive species become obvious. This paper will address those critical issues and challenges from a southern perspective that relate to invasive species. This paper also will address the challenges faced by local and state governments, universities, and federal agencies in the state from funding issues to politics to natural enemy assessment to management. Because hemlock woolly adelgid, emerald ash borer, and kudzu bug have recently posed (and continue to pose) challenges in our state, this paper also will focus on lessons learned from these invasive species. Lessons learned will focus on importance of early monitoring, public involvement, education of legislators/government agencies, as well as the public, and communication. These experiences have provided insight into the spread, movement, and impact of invasive species and will prove to be extremely beneficial to our state as we face new invasive species ‘knocking at our door.’ These include gypsy moth, Asian longhorned beetle, and spotted lanternfly. Our previous experiences and lessons learned will enable us to better prepare for the establishment of these new invasive species.

Gut content analysis of preserved carabid specimens reveals past trophic interactions

Authors: Graux Yohann, Tours University

Abstract: Significant carabid collections have been built in many research institutes as part of studies focusing on biodiversity assessments or biological control in agricultural landscapes. Often, these specimens are preserved in ethanol. A metabarcoding analysis of these carabids’ gut contents would allow the determination of past trophic interactions and their evolution through time. The Zone Atelier Plaine & Val de Sèvre in Western France has carabid specimens collected yearly since 1995. Although, sample collection and specimen preservation were not conducted specifically for molecular analyses, this collection constitutes a repository of information about prey communities in agricultural landscapes in the past decades.

We analysed more than 200 specimens from two generalist predatory species (Nebria salina and Poecilus cupreus) collected between 2013 and 2021. Specimens were dissected and prey DNA was amplified from the insects’ crop using generalist PCR primers. The diet of carabids was then analysed using a metabarcoding approach.

By using existing collections of ethanol preserved carabids, our method has the potential to inform on the biocontrol services provided by carabids and its evolution through time. When applied to generalist predators, this method can highlight shifts in arthropod communities that may be related to global changes, agricultural practices or land management.

Recent advances on taxonomic status of pentatomid pests in the Neotropics (Heteroptera: Pentatomidae)

Authors: Grazia Jocelia[1] and Schwertner Cristiano[2], [1]Department of Zoology Federal University of Rio Grande do Sul, Brazil, [2]Federal University of São Paulo, Brazil

Abstract: Pentatomidae is the fourth most numerous families within Heteroptera including about 5,000 species in more than 940 genera. Pentatomids are represented in all zoogeographical regions although the tropical and subtropical faunas are the widest; they are commonly known as stink bugs. Nine or ten subfamilies are recognized, half of them with restricted distribution. In the Neotropical Region seven subfamilies are present: Asopinae, Cyrtocorinae, Discocephalinae, Edessinae, Pentatominae, Podopinae and Stirotarsinae. From the applied point of view the following four subfamilies should be highlighted. Pentatominae is the most diverse with 3,484 species in 660 genera in the world, and 886 species in 138 genera in the Neotropics. They are all phytophagous; many species are serious pests of crops. The classification within this subfamily has been considered chaotic including from eight to more than 40 tribes according to different authors. Asopinae have predacious habits and its importance as biological control agents is increasing. They are found in all zoogeographical regions with 303 species in 63 genera, and around 100 species in 23 genera in the Neotropics. Discocephalinae is exclusively Neotropical with 325 species in 81 genera. It includes two tribes, Discocephalini and Ochlerini, all phytophagous and some species are important vectors of Phytomonas spp. (Trypanosomatidae) in palms in South America. Edessinae includes the most colored and largest stink bugs, with great diversity in the Amazon region, with around 340 known species in 15 genera. They have in common the strong development of the metasternum. For more than a century the group was treated as a tribe of Pentatominae but studies in the last two decades raised the taxon to subfamily rank and increased the number of genera to fifteen. Recent studies in Pentatomidae have promoted a better understanding of the relationships among and within groups recognized as subfamilies whose impact on the current classification will be discussed, highlighting the pentatomid pests in the Neotropics.

A litmus test for harmonized mosquito monitoring across Europe and Africa

Authors: Graziosi Ignazio[10], Simoni Alekos[9], Ignjatovic-Cupina Aleksandra[11], Gaye Alioune[6], Crisanti Andrea[5], Núria Busquets[7], Aranda Carles[7], Diallo Diawo[6], Petric Dusan[11], Balestrino Fabrizio[2], Coulibaly Mammadou[8], Zgomba Marija[11], Diallo Mawlouth[6], Guelbeogo Moussa[1], Pollegioni Paola[4], Bellini Romeo[3], N'Falé Sagnon[1] and Napp Sebastian[7], [10]Polo GGB Genomics Genetics and Biology, Italy, [9]Polo d'Innovazione di Genomica Genetica e Biologia, Terni, Italy, [11]University of Novi Sad, Faculty of Agriculture, Serbia, [6]Institut Pasteur de Dakar, Senegal, [5]Imperial College London, United Kingdom, [7]IRTA, Centre de Recerca en Sanitat Animal (CReSA, IRTA-UAB), Spain, [2]Centro Agricoltura Ambiente "G. Nicoli", Bologna, Italy, [8]Malaria Research and Training Centre, Université de Bamako, Mali, [1]Centre National de Recherche et de Formation sur le Paludisme (CNRFP), Burkina Faso, [4]Consiglio Nazionale delle Ricerche, Istituto di Ricerca sugli Ecosistemi Terrestri, Italy, [3]Centro Agricoltura Ambiente, Department of Sanitary Entomology and Zoology (EZS), Italy

Abstract: The increasing incidence of mosquito borne diseases is urging the development of effective tools for monitoring insect populations and their larval habitats. The use of harmonized field protocols helps to build a comprehensive picture on species-specific vector ecology, and to implement coordinated mosquito surveillance programs across continents. We sought to test the efficiency and potential drawbacks of harmonized protocols proposed from earlier EU project VectorNet. We specifically aimed to capture the ecoregional variation of breeding site characteristics and population density of five mosquito vectors in Europe and Africa. As expected, the five species show different aquatic habitat preferences. Culex pipiens, Aedes albopictus in Europe and Ae. aegypti in Africa select breeding habitats within specific volume classes, while Anopheles gambiae and An. coluzzii select breeding habitats based on seasonal availability. Population densities in aquatic habitats greatly varied across species and countries, but larval production sites of Ae. albopictus generate populations with higher ratio of pupae compared to the other species. This result underlines the fundamental ecological difference between the selected vector species disregarding of the ecoregion. Mean water temperatures had limited variation across species and higher among countries. Understanding the ecology of native and non-native mosquito vectors is key in evaluating transmission risks for diseases such as West Nile, chikungunya and dengue fevers, zika and malaria. The proposed harmonized field protocols are a valuable tool for achieving homogeneous mosquito surveillance and support integrated vector management programs at various scale and across continents.

Risk-based surveillance of an imminent invader in the EU: the EFSA pest survey toolkit and the emerald ash borer Agrilus planipennis

Authors: Graziosi Ignazio[1], Delbianco Alice[1], Cortiñas Abrahantes Jose[1] and Vos Sybren[1], [1]European Food Safety Authority (EFSA)

Abstract: The emerald ash borer (EAB) Agrilus planipennis is approaching the European Union territory, where the beetle is subjected to mandatory surveillance. We developed three integrated tools for preparing and designing the surveys. The Pest Survey Card on Agrilus planipennis (https://arcg.is/09S94u) helps to define the target population of Fraxinus hosts and the methods for detecting the insect. The survey area is divided in epidemiological units (administrative boundaries and/or land use), risk locations are associated with higher probability of EAB presence, and risk areas identified based on the presence of ash resources. Trapping insects using green funnel traps is the recommended method early detection, and it can be combined with other techniques. The Guidelines for statistically sound and risk-based surveys of Agrilus planipennis (https://www.efsa.europa.eu/en/supporting/pub/en-1983) propose a step-wise approach for designing detection surveys to substantiate pest freedom and delimiting surveys for defining the boundaries of an infested zone. The method sensitivity, the confidence level and an appropriate design prevalence feed into the statistical tool RIBESS+ (https://arcg.is/0vWufj1), which calculates the sampling effort required to survey the target population. The proposed toolkit ensures harmonized survey conclusions that can be compared in time and space, thus providing robust evidence for pest freedom.

Strengthening the firewall against invasive insects: the EFSA plant pest survey toolkit

Authors: Graziosi Ignazio[1], Delbianco Alice[1], Mustapic Luka[1], Camilleri Melanie[1], Cortiñas Abrahantes Jose[1] and Vos Sybren[1], [1]European Food Safety Authority (EFSA)

Abstract: The European Union' Commission Implementing Regulation 2019/2072 lists Union quarantine plant pests (including over 400 insect taxa) for which EU member states are required to conduct surveys. We developed a Plant Pest Survey Toolkit (https://arcg.is/1v99CH) in line with the International Standards for Phytosanitary Measures to assist member states with surveillance activities. Detection (substantiating pest freedom of an area) or delimiting surveys (defining the boundaries of an infested zone) are completed through three-step process: preparation, design and implementation. 1) Pest Survey Cards help gathering relevant information for survey preparation. They are designed to characterize the target population (epidemiological units and risk areas are linked with environmental suitability, host range, and the pest' spread capacity), select an effective detection method, and appropriate inspection units. 2) Guidelines for statistically sound and risk-based surveys of plant pests are used to design the survey by defining the host population size, and setting method sensitivity, confidence level and design prevalence. The required sample effort is calculated through the RIBESS+ statistical tool. 3) Inspection units are allocated to the survey sites and surveys are implemented at member state level according to the design. This approach contributes to a cross-country harmonisation of surveillance activities.

Have residual chemical insecticides devalued urban entomology and can technology restore it?

Authors: Green Matt, Rentokil-Initial PLC, United Kingdom

Abstract: The last thirty years have seen a marked decline in the use of residual insecticide use in urban insect pest control. The role of residual insecticides has, in turn, degraded from: 'eradication solution' to; 'part of an integrated pest management programme' which places more emphasis on the ability of the operator to correctly understand and interpret observations on the biology of the insects they are looking to control. This re-emphasis has been industry driven, rather than through academic led best practice research and publishing.

New technology, particularly in the field of surveillance and remote monitoring can provide entomologists working in urban pest control with pertinent behavioural information that can and should inform the operator. This will necessarily require pest control operators to possess different skill sets than they would have had thirty years ago and will require a significant upskilling of those entering and continuing to work in the field.

This is a review of the discipline of urban entomology and pest control from a historic context, examining the reasons for its relative low status in the broader field of entomology and examines the potential role of technology in its future.

Mating signal evolution via sensory bias: lessons from the acoustic Lepidoptera

Authors: Greenfield Michael, Department of Ecology and Evolutionary Biology ; University of Kansas, United States

Abstract: Pair formation in moths typically involves pheromones, but some pyraloid and noctuoid species use sound in mating communication. The signals are generally ultrasound, broadcast by males, and function in courtship. Long-range advertisement songs also occur which exhibit high convergence with communication in other acoustic species such as orthopterans and anurans. Tympanal hearing with sensitivity to ultrasound in the context of bat avoidance behavior is widespread in the Lepidoptera, and phylogenetic inference indicates that such perception preceded the evolution of song. This sequence suggests that male song originated via the sensory bias mechanism, but the trajectory by which ancestral defensive behavior in females—negative responses to bat echolocation signals—may have evolved toward positive responses to male song remains unclear. Analyses of various species offer some insight to this improbable transition, and to the general process by which signals may evolve via the sensory bias mechanism.

Insulin signaling during overwintering in the alfalfa leafcutting bee, Megachile rotundata

Authors: Greenlee Kendra[3], Yocum George[2] and Cambron Lizzette[1], [3]North Dakota State University, United States, [2]Edward T. Schafer Agricultural Research Center USDA-ARS, United States, [1]Department of Biological Sciences North Dakota State University, United States

Abstract: Insects overwinter in a diapause state to survive unfavorable conditions, including low and fluctuating temperatures. For some species, commercial managers use storage at constant temperatures to mimic the overwintering period. The alfalfa leafcutting bee, Megachile rotundata, is often stored at 6°C during the winter months. Previous work showed that bees stored at constant temperatures had different gene expression profiles when compared to bees overwintered in naturally fluctuating temperatures from field conditions. The differences in genetic profiles included several metabolic pathways, but it remains unclear how the insulin signaling pathway varies during this time period or if it insulin signaling is affected by temperature fluctuations. Megachile rotundata overwinters as a prepupa for up to 9 months and does not feed during this time period, relying on energy stored from the previous summer to support metabolic processes. With fixed energy resources, overall metabolism and insulin signaling are maintained at low levels. Because insulin signaling is thought to regulate energy allocation, and insect metabolism is tightly linked to environmental temperatures, we expected to see differences in expression of genes in the insulin signaling pathway between bees overwintered in constant conditions and in the field. We used nCounter analysis (NanoString Technologies Inc.), a multiplex technique, to measure expression of genes in the insulin signaling pathway and cell cycle. We compared bees overwintered in the lab and field from November to June, spanning the entirety of overwintering stages. Expression of the insulin-like receptor differed by month depending on location, with lab bees having higher expression levels, suggesting the possibility of temperature regulating gene expression. Samui, a putative diapause termination signal, showed a similar pattern, potentially indicating that diapause is dysregulated in lab bees. Together these data suggest a possible connection between temperature and insulin signaling. During overwintering, expression profiles of genes in the insulin pathway did not all change, meaning only key players of the pathway, such as FOXO, PI3K, and MAPK, were being used. These targets connect to the cell cycle, which also showed significant differences in gene expression by location. The use of insulin pathway targets has been shown in other diapausing insects, but further studies are needed to determine how these targets are being regulated and interconnected.

The intestinal microbiota profile of Hermetia illucens larvae is modified by diet and genetic background and is linked to biomass accumulation

Authors: Greenwood Matthew[1], Rhode Clint[1], Hull Kelvin[1], Brink Marissa[1], [1]Stellenbosch University, South Africa

Abstract: Black soldier fly (Hermetia illucens) larvae are detritivores capable of converting large volumes of organic waste into high protein and fat content biomass. In recent years, industrial- and subsistence-level larval rearing systems have been developed to exploit this capability for the renewable production of protein-rich animal feeds, lipids and fertilizers. While much information regarding effective colony management and feed protocols are available in the literature, few studies have explored the relationship between black soldier fly gut microbiome dynamics, host genetics and larval performance traits. In this study, we focused on characterization of bacterial microbiome diversity and structure within late-instar larvae in light of different genetic backgrounds and multiple, industry-relevant diets. Microbiota composition and alpha diversity differed starkly by diet option, with moderate evidence for differentiation by genetic background. Furthermore, a core gut profile - consisting of 30 bacterial genera - was identified in line with what has been reported in prior studies of this species. Bacterial community structure, as inferred from correlation networks, was observed to be dynamic and altered by both feed and genetic background. Additionally, larval biomass metrics (dry mass, protein content, fat content) were found to be significantly linked to microbial community structure. In totality, the data highlights the importance of considering the larval gut microbiome in the development of alternative rearing protocols, as well as emphasizing the complexity which underlies the management of this gut ‘phenotype’.

The beetles bark but the caravan moves on. What do we really know about bark beetle control?

Authors: Grégoire Jean-Claude, Spatial Epidemiology lab Universite libre de Bruxelles, Belgium

Abstract: A few species among the 800+ conifer bark beetles in the world count among the major insect pests of forestry in Europe, North America and Asia. Their devastating outbreaks may, at best, be prevented but, in many cases, the foresters can just attempt to contain them at high costs and with heavy economic losses. The example of the European spruce bark beetle, Ips typographus, will be used to discuss how the management issues raised by these insects have been influenced by our improving knowledge of their biology and ecology, by changing priorities regarding the role of forests and, more recently, by increasing constraints brought by climate change. The species is still increasing its range in Eurasia, following the expansion of spruce plantations, and causes frequent outbreaks, generally after a storm or during a very hot and dry year. For a long time, sanitary thinning and clearfelling, and the peeling or fast removing of attacked stems were the only available options for the managers. About fifty years ago, the development of chemical ecology brought new possibilities for integrated pest management, with the prospect of easier monitoring and even preventive or curative mass-trapping or, possibly, push-pull behavioural manipulations. However, several factors should teach us to remain wary of reductionist solutions. On the one hand, the growing knowledge about bark-beetle dispersal, interactions with host- and non-host trees and with symbionts, competitors and natural enemies, gradually brings in more variables to take into account. On the other hand, the increasing emphasis on the multiple role of forests, beyond the production of wood, as well as a changing view of bark beetles, from simple pests to actors in ecosystem dynamics, also influence decision thresholds.

The role of landscape composition and heterogeneity on the conservation of coccinellid communities and their service

Authors: Grez Audrey[2], Tania Zaviezo[1], [1]Universidad Católica de Chile, [2]Universidad de Chile, Chile

Abstract: Coccinellids are important natural enemies of pests, with native species playing a crucial role in this important ecosystem service. Their abundance, diversity, and function may be affected by landscape composition and heterogeneity. Nevertheless, very few studies on this topic have been published so far, and fewer have separately analyzed the responses of native and exotic coccinellid species. In this presentation we show empirical evidence that native and exotic coccinellid species differentially respond to landscape characteristics. At local scale, we point out that edges are important structures for coccinellid colonization of crops. At the landscape scale, we provide evidence that i) native and exotic species differentially use cover types depending on their disturbance; ii) natives are favored by more heterogeneous landscapes whereas exotics seems to be less affected; iii) biological control of aphids in alfalfa fields is positively associated with the abundance of native coccinellids; iv) in more urbanized landscapes coccinellid richness and abundance in greenspaces decline, especially of native species; and v) the composition of coccinellid functional groups vary with landscape urbanization. These results highlight the importance of maintaining landscape heterogeneity at different spatial scales in order to conserve the composition and functionality of natural enemies in agroecosystems (Funding: FONDECYT 1180533).

Sow Wild! Citizen scientists find sown mini-meadows increase pollinator diversity in gardens

Authors: Griffiths-Lee Janine[1], Goulson Dave[1], Nicholls Elizabeth[1], [1]University of Sussex

Abstract: With increasing urbanisation there is growing potential to support insect populations in urban landscapes. Using citizen science, we investigated the effectiveness of a small 4m^2 mini-meadow in recruiting beneficial insects in UK gardens and allotments. Participants were allocated one of three treatment groups: Seed mix 1 (commercially available ‘meadow mix’); Seed mix 2 (formulated based on pollinator foraging preferences); or Control (no additional wildflower mixes). All participants conducted insect sampling over two years using standardised pan and sticky trap methods May-August. Samples were returned for identification by trained specialists. Mini-meadows provided resource-rich habitats, increasing wild bee richness and supporting on average 111% more bumblebees, 87% more solitary bees and 85% more solitary wasps in the year following seed-sowing, compared to Control. The wildflower mixes were also taxon-specific in their attractiveness, probably due to key plant species in the mix. We used citizen science as a novel and pragmatic approach to access private gardens to survey insects. Participant retention was good, and citizen scientists made an invaluable contribution. Domestic gardens and allotments provide huge potential habitat for pollinators. Small-scale floral enhancements can attract more beneficial insects in fragmented urban landscapes, supporting urban biodiversity, pollination services and biological control.

Immune response and alterations in midgut bacterial community of Galleria mellonella resistant to Bacillus thuringiensis

Authors: Grizanova Ekaterina[2], Kalmykova Galina [3] and Dubovskiy Ivan[1], [2]Novosibirsk State Agrarian University, Russia, [3]Siberian Federal Scientific Centre of Agro-Bio Technologies of the Russian Acade, [1]Novosibirsk State Agrarian University, Siberian Federal Scientific Centre of Agro-Bio Technologies of the Russian Academy of Sciences, Russia

Abstract: During selection of greater wax moth Galleria mellonella for resistance to Bacillus thuringiensis (Bt) (R line) the microevolutionary alterations in midgut bacterial community have been detected as compare with insects of susceptible line (S line). Uninfected R line insect had less percentage of genus Enterobacteriaceae than the S larvae, however, upon infection with Bt the percentage were significantly elevated up to 80 % in R line. Unlike the S insects, Bt infection significantly in 2-3 times reduced the percentage of the genus Enterococcus in the R insects but in 2-3 times elevated in S line. As compare with insects of S line we have detected less percentages of potentially pathogenic bacteria genus Serratia and Bacillus in midgut of R line larvae during Bt infection. This tendency has been detected in cadavers of the larvae from R line. In the uninfected state, resistant insects exhibited enhanced basal expression of antibacterial (AMP) genes in the midgut. Following oral infection with Bt, the expression of these genes was elevated in the midgut of S line larvae. RNA interference of Gloverin gene resulted in elevated susceptibility of insects of S line to Bt infection. These observations suggest that the R line not only has a more intact midgut but is secreting antimicrobial factors into the gut lumen which not only mitigate Bt activity but also affects the viability of other gut bacteria. The expresion of Bt genes in cadavers of R and S line insects were detected for the first time. The results will be discussed at conference. This work was supported RSF 19-16-00019, RSF 20-76-00025

Essentials of ecological knowledge that applied biological control urgently needs

Authors: Groot Tom[1] and Calvo Francisco Javier[2], [1]Koppert Biological Systems, Netherlands, [2]R&D Koppert Biological Systems, Spain

Abstract: The call to increase the contribution of biological control in IPM is louder than ever before, but current research efforts are often not geared towards meeting this demand. We argue that more focus on applied problems is needed in order to increase the efficiency of developing new biological control products. Selecting the right species to develop for augmentative biological control is hard and time consuming. There are several known selection criteria that are typically assessed in controlled laboratory and semi-field assays. Such assays typically quantify biological parameters in early phase of candidate screening. Besides these parameters, there is another group of applied criteria that a successful candidate biological control agent needs to pass. Such criteria examine versatile aspects of the candidate's suitability to be mass produced and shipped. Other criteria are related to the complexities of the agro-environmental conditions where the agents are released. We argue that applied problems are not high enough on the agenda of biocontrol research when the selection of candidates is concerned. In this presentation we review these. We discuss how reducing the gap between the current scientific efforts and the realistic field situation at growers' site may increase the efficiency of developing new biocontrol agents.

Phytoplasma infection of apple (Malus domestica) affects the behavior of its vector Cacopsylla picta

Authors: Gross Jürgen[2], Gallinger Jannicke[1] and Maria Görg Louisa[1], [2]Julius Kühn-Institut, Federal Research Centre for Cultivated Plants, Institute for Plant Protection in Fruit Crops and Viticulture, Germany, [1]Julius Kühn-Institut, Federal Research Centre for Cultivated Plants, Institute for Plant Protection in Fruit Crops and Viticulture, Germany

Abstract: The phloem feeding insect Cacopsylla picta Foerster (Hemiptera: Psyllidae) is vectoring 'Candidatus Phytoplasma mali', a small bacterium inducing apple proliferation disease (AP) in apple trees. In their migratory lifecycle, the young adults emigrate to conifers as overwintering sites, before they remigrate into fruit orchards the following spring where mating and reproduction takes place. The females oviposit on fresh green apple leaves. In previous no-choice studies, it was reported that higher numbers of eggs were placed on leaves of healthy apple plants [Mayer et al., 2011]. In dual choice tests, we assessed the behavior of C. picta females when given the chance to choose their oviposition site between a healthy or AP infected apple leave intruding from opposite sites into a small gauze tube. Location and number of eggs were recorded after 96 h. We found that females preferred healthy leaves over AP infected leaves for oviposition. Furthermore, the influence of host plants infection status onto the feeding behavior of the vectoring insect C. picta was assessed. Analysis of 12 hour lasting electrical penetration graph recordings (EPG) from distinct developmental stages of the vector showed changes in feeding behavior influenced by developmental stage as well as by phytoplasma infection of their host plants. In order to link behavioral changes in vectoring insect to alterations in their host plant caused by phytoplasma infection, we studied phloem metabolite composition by collecting phloem sap using the centrifugation technique [modified after Hijaz & Killiny, 2014], derivatization and GC-MS analysis followed by AMDIS analysis according to [Gallinger & Gross, 2018]. Phytoplasma infection resulted in significant physiological changes especially regarding the sugar composition of the phloem.

Integrative taxonomy of some West Palearctic Trichogramma species

Authors: Groussier Géraldine[2], Marchand Anael[1], Cruaud Astrid[1], Rasplus Jean-Yves[1], Ris Nicolas[3] and Warot Sylvie[1], [2]INRA, France, [1]INRA, France, [3]National Research Institut for the Agronomy, France

Abstract: Trichogramma are minute chalcid wasps that are, altogether, egg parasitoids of various insect orders (mainly Lepidoptera). The genus is extremely diverse with more than 200 described species worldwide and 40 in Europe.
This diversity, their small size as well as the possible presence of species complexes make difficult their identification, in particular by non-specialists. This situation is detrimental not only for basic research but also (and maybe more importantly) for the use of some Trichogramma strains as biological control agents.
Using (i) intensive DNA Barcoding using part of the mitochondrial marker Cytochrome Oxidase I (COI), (ii) multi-locus phylogeny including COI but also other mitochondrial (CytB) and nuclear markers (Wingless, EF1alpha, RpL27a et RpS4), (iii) crossing experiments as well as (iv) additional sources of information (e.g. previous identifications based on morphological characters or GENBANK accessions), we investigated the diversity of Trichogramma strains collected by ourselves or provided by various international colleagues in the Western Palaearctic.
Taken as a whole, we hence identified about 20 Molecular Operational Taxonomic Units (MOTUs), most of them being cross-validated by other sources of information. Among this diversity, some MOTUs were nevertheless not associated with a species' name and required further investigations. Moreover, two species complexes were observed, the first one encompassing T. cacoeciae and T. embryophagum as well as putative new species and the second one encompassing some strains previously identified as T. brassicae and T. euproctidis.
Based on this first dataset, our perspective is to widen our collaborative network not only to have access to new strains/information but also to unite disseminated specialists of this genus. This objective is also supported by the creation and certification (ISO9001:2015) of a Biological Resource Center in France devoted to Egg Parasitoids (BRC EP-Coll – https://www6.inra.fr/crb-eggparasitoids-coll/Presentation).

Invasion theory and natural enemy introductions

Authors: Gruner Daniel, University of Maryland, United States

Abstract: Biological invasions are major drivers of the global biodiversity crisis, causing economic losses and profound impacts to recipient communities and ecosystems. Invasive species successfully colonize novel ecosystems, establish populations, spread geographically, and overcome antagonistic species interactions to impact native communities and ecosystems. Classical or introduction biological control seeks to reproduce these phases, in service towards reduced population growth and spatial spread of invasive species. The defining life history, behavioral and population traits that contribute to invasiveness are also traits we seek in identifying candidate biological controls to arrest their spread. Testing hypotheses for failure or success of biological invasions has been problematic and controversial, however, in part because information is incomplete and research is reactive. Arguably, few advances from ecological theory have advanced the success of biological control, whereas biological control introductions can provide hypotheses testing for invasion theory because variables such as propagule pressure, residence time, climate-matching, and phenological synchrony can be controlled and monitored in experimental approaches.

Using invasion theory to guide natural enemy introductions

Authors: Gruner Daniel, University of Maryland, United States

Abstract: Biological invasions are major drivers of the global biodiversity crisis, causing economic losses and profound impacts to recipient communities and ecosystems. Invasive species successfully colonize novel ecosystems, establish populations, spread geographically, and overcome antagonistic species interactions to impact native communities and ecosystems. Classical or introduction biological control seeks to reproduce these phases, in service towards reduced population growth and spatial spread of invasive species. The defining life history, behavioral and population traits that contribute to invasiveness are also traits we seek in identifying candidate biological controls to arrest their spread. Testing hypotheses for failure or success of biological invasions has been problematic and controversial, however, in part because information is incomplete and research is reactive. Arguably, few advances from ecological theory have advanced the success of biological control, whereas biological control introductions can provide hypotheses testing for invasion theory because variables such as propagule pressure, residence time, climate-matching, and phenological synchrony can be controlled and monitored in experimental approaches.

A root-feeding herbivore uses chemical cues to avoid competition and elevated predation risk

Authors: Grunseich John[2], Hay Allison[1], Grunseich John[1] and Thompson Morgan[1], [2]Texas A&M University, United States, [1]Texas A&M University, United States

Abstract: Plant-produced volatile compounds play essential roles in foraging by both herbivores and their natural enemies. It has been well documented that herbivore feeding damage on plants triggers the production of herbivore-induced plant volatiles (HIPVs) and that these volatiles can protect plants directly by repelling herbivores or indirectly by recruiting natural enemies that kill herbivores. Although the majority of studies have focused on aboveground systems, recent research has demonstrated that herbivore-damaged plant roots also emit HIPVs. Despite growing recognition that plant cues are important for below-ground ecological interactions, however, our understanding of root-produced HIPVs and their ecological functions in soil environments remains limited. In this study, we investigated the role of volatile compounds from roots of cucumber plants (Cucumis sativus) in mediating foraging decisions by specialist cucumber beetle larvae (Acalymma vittatum) and entomopathogenic nematode natural enemies Heterohabditis bacteriophora (EPNs).

Improved monitoring of thrips by the combined use of attractive visual and olfactory cues?

Authors: Grupe Björn[2] and Meyhöfer Rainer[1], [2]Leibniz-Universität Hannover, Inst. f. Geobotanik, Angew. Entomologie, Germany, [1]Leibniz University of Hannover, Institute of Geobotany, WG Entomology

Abstract: Coloured sticky traps are used worldwide for the monitoring of thrips (Frankliniella occidentalis) in greenhouses. Especially blue sticky traps are used for the monitoring of thrips and can sometimes be used to get informations about the thrips population density on crops. In the last two decades, LED-traps have been tested for attractivity toward thrips in mostly small scale experiments under controlled conditions. Additionally, different semiochemicals that were found to be attractive toward thrips, are nowadays used for an enhanced thrips monitoring. However, the combination of those semiochemicals together with attractive LED-traps has been studied very few. To understand the behavioural ecology of thrips in more detail, it is necessary to proof the promising results from small experiments under more complex conditions. Within a BMEL project, the attractivity of the combination of the olfactory together with a visual cue is studied under greenhouse conditions. It will be investigated if those monitoring tools can improve the detection of thrips in crop stands by an earlier detection of the pest. Besides this, it will be investigated if one can get more informations about the thrips population density on the crop and if it is possible to pull the insect to the trap.

Forensically relevant developmental data for Necrodes littoralis (Coleoptera: Silphidae)

Authors: Gruszka Joanna, Matuszewski Szymon[1], [1]1/ Laboratory of Criminalistics, Adam Mickiewicz University, Poznan, Poland. 2/ Wielkopolska Centre for Advanced Technologies, Adam Mickiewicz University, Pozna, Poland

Abstract: Necrodes littoralis is a necrophagous beetle, that may be useful for postmortem interval estimation. It is frequently found on human cadavers. Unfortunately there are no forensically useful developmental models for this species. Here, we present first full developmental dataset for N. littoralis from ten constant temperatures (14-30°C).
To establish a colony, adult beetles were collected from pig carcasses. Larvae were reared in aggregations (50 larvae per container, eight containers per temperature) at constant temperature and humidity, with photoperiod 12:12. They were fed with pork ad libitum and had constant access to water. Six randomly chosen larvae from four containers were measured at intervals representing no more than 10% of the stage duration. Larvae in all containers were monitored for developmental landmarks. Postfeeding larvae were transferred into smaller containers for pupation. At emergence we measured length and weight of adult beetles and determined their sex. Thermal summation models, isomorphen and isomegalen diagrams and growth curves were derived using the data.
Depending on the temperature, development lasted between about 23 and 89 days. Mortality was high at the extremes of the temperature range. The thermal summation constant for the total development was 434.7 ± 28.86 accumulated degree-days above a developmental threshold of 9.04 ± 0.55°C.

Effect of fungicide on pollen foraging by honeybees differs by fungicide type

Authors: Guedot Christelle[2], Lois Abby[1] and Jaffe Benjamin[1], [2]University of Wisconsin Madison, United States, [1]University of Wisconsin Madison, United States

Abstract: Honeybees (Apis mellifera Linnaeus) (Hymenoptera: Apidae) play a major role in the pollination of cranberry (Vaccinium macrocarpon; Ericaceae). However, fungicide applications during cranberry bloom may affect bees foraging behavior. This research reports the amount of cranberry and noncranberry pollen brought back to hives immediately before and after two types of fungicide applications. The amount of cranberry pollen decreased while the amount of noncranberry pollen increased following a fungicide application. However, this relationship differed depending on the type of fungicide applied. Understanding how different fungicides specifically impact bee behavior is essential to minimizing bee exposure to potentially harmful chemicals.

Functional genomic approaches in the cruciferous pest Plutella xylostella

Authors: Guest Marcus[2] and Gonzalez Izquierdo Patricia[1], [2]Syngenta, United Kingdom, [1]Syngenta

Abstract: Forward genetic methodologies provide a non-hypothesis led route to pesticide mode of action and mode of resistance elucidation. Linkage mapping, of either field isolated or lab generated resistance, provides a genetic link between active ingredient and candidate resistance mutation / potential target sites. Reverse genetic studies can be used to validate candidate resistance mutations. Whole genome resequencing and genome editing make such approaches feasible in pest species.

We have been utilising genome editing and linkage mapping techniques in Plutella xylostella to study a range of insecticide mechanisms of resistance / mechanisms of action, as well as to generate strains to assist in developing crop protection products. Plutella is a particularly useful model for lepidopteran pests due to its small size, relatively short life cycle and relative ease of genetic manipulation. In this poster, we discuss some of the methodologies developed and results obtained.

Comparative anatomy of venom glands suggests a role of maternal secretions in gall induction by cynipid wasps

Authors: Guiguet Antoine[2], Tooker John[1], Deans Andrew[1] and Hines Heather[1], [2]Penn State, United States, [1]Penn State

Abstract: Many herbivorous insects are capable of hijacking plant development to induce novel plant organs called galls. In most groups of galling insects, the insect organs and molecular signals involved in gall induction are poorly understood. We focus on gall-wasps (Cynipidae), the second largest clade of gall inducers, for which the developmental stage and organs responsible for gall development are unclear. We investigated female abdomen anatomy in gall-inducing and non-gall-inducing species across each of the major lineages of the Cynipoideae super-family to test the correlation between this lifestyle and the relative size of secretory organs. We confirmed the massive expansion of the venom apparatus size in gall-inducing species. Among these gallers we measured the largest venom gland apparatus relative to body size ever recorded in insects. Non-galling inquiline species are accompanied by reduction of this apparatus. Altogether, the massive expansion of secretory organs specifically in gall-inducing species strongly suggests a role of these secretions in the process of gall formation, and the variance in size of venom glands, accessory glands, and the contents of these glands among gallers, suggests that gall formation across this clade is likely to employ a diversity of molecular strategies.

Advances in Ixodes scapularis Genetics and Genomics

Authors: Gulia-Nuss Monika[4], Nuss Andrew[3], Sharma Arvind[3], Rasgon Jason[1], Pham Michael[3], Harrell 2nd Robert[2] and Yim Won-Choel[3], [4]The University of Nevada, Reno, United States, [3]The University of Nevada, Reno, United States, [1]Penn State University, United States, [2]The University of Maryland, United States

Abstract: Ticks are obligate hematophagous parasites and are important vectors of a wide variety of pathogens. Lyme disease (LD) caused by the spirochete Borrelia burgdorferi and vectored by the black-legged tick, Ixodes scapularis, is the most prevalent vector-borne disease in the United States. Despite their importance, our knowledge of the biology of the ticks on a molecular level is limited. Advances in tick genomics and genetics have mainly been stymied by a lack of molecular tools to carry out forward and reverse genetics. Similarly, genome sequencing has been challenging due to a large (2.1 Gb) genome with long repetitive sequences. The currently available I. scapularis genome comprises of 369,495 scaffolds representing 57% of the genome. The fragmented genome further poses challenges in identifying gene sequences and therefore a high-quality genome sequence is needed for advance genomics and genetics work in this vector.

To fill these gaps, we have developed methods for targeted gene disruption using CRISPR-Cas9 and have utilized both embryo injections and a newly developed ReMOT Control (Receptor-mediated Ovary Transduction of Cargo) strategy for delivery of gene-editing reagents. In addition, we used the 10X sequencing along with chromatin capture Hi C technique to achieve chromosomal level assembly of the tick genome. We successfully assembled the genome in 28 >100Mb sequences that correspond to 28 chromosomes in I. scapularis. The availability of near-complete I. scapularis genome along with gene-editing tools that we developed will advance our knowledge of the biology of this and related tick species.

Cryopreservation effects on drone sperm Apis mellifera L. morphometric parameters and ultrastructure

Authors: Gulov Alexey[2], Bragina Yelizaveta[1], [2]Federal state budgetary scientific institution “Federal beekeeping research cent, [1]A.N. Belozersky Research Institute of Physico-Chemical Biology, M.V. Lomonosov M

Abstract: Long-term cryopreservation is detrimental to sperm function and drone fertility, killing more than 50% of the sperm during the process. Prediction of cryopreservation damage from freezing drone semen remains elusive. The purpose of this study was to assess the impact of long-term cryopreservation in “Kakpakov diluents” (C46) on morphometric measurements of sperm head of the Apis mellifera L. and ultrastructure. For the experiment, sperm samples from the cryobank of the Federal Beekeeping Research Centre (Russia), frozen since 1993, 2011 and 2013 were used. In the present study, it was found out that cryopreservation had a considerable impact on the drone sperm head morphometry. Sperm head measurements of cryopreserved samples were significantly lower compared with the extended sample for morphometric measurements of the nucleus area 3.55±0.12, 4.07±0.1, 4.31±0.04 (5.57±0.03, respectively); nucleus perimeter 10.57±0.11, 11.11±0.13, 11.59±0.05 (11.72±0.06, respectively); nucleus length 4.66±0.05, 4.82±0.06, 5.07±0.02 (5.22±0.03, respectively); nucleus acrosome length 3.72±0.08, 3.65±0.08, 3.96±0.05 (4.24±0.04, respectively). Cryopreserved and thawed spermatozoa revealed changes in ultrastructure such as vacuolation of the axoneme, intranuclear vacuoles, and loss of the derivative’s mitochondria. These details provide valuable data for further experiments on modification of the composition of cryomedium to minimize cryodamage in the semen of honey bee drones.

Environmental sensing, xenobiotic detoxification and digestive capabilities of Halyomorpha halys (Stål), the brown marmorated stink bug

Authors: Gundersen-Rindal Dawn, USDA-ARS European Biological Control Laboratory, Montpellier, France

Abstract: Halyomorpha halys (Stål), the brown marmorated stink bug, exhibits high levels of polyphagy and is a remarkably invasive insect species, having emerged as a top pest in North America and Europe. In addition to causing significant economic losses in agricultural contexts, its overwintering in human habitats makes it a considerable nuisance. To better learn of the genetic elements responsible for some of its behaviors, which in turn may serve as gene targets for use in biopesticide formulations, a genome sequencing and community annotation project was undertaken, led by USDA-ARS. These efforts have generated considerable knowledge about this insect's biology in general and the genic underpinnings of its highly polyphagous feeding behavior in particular. In this presentation, we will emphasize some of the gene families arguably most promising for biological control of this species, including chemosensory, vision-related, defensome constituents (i.e., cytochrome P450s, carboxylesterases and glutathione S-transferases), cathepsins and salivary effectors, among others. We will also discuss challenges encountered and propose means to overcome them in future genomics projects.

Evolution in Isolation: insights on evolution of dung beetles from the atypical Australasian fauna

Authors: Gunter Nicole, The Cleveland Museum of Natural History, United States

Abstract: The evolution of dung beetles (Coleoptera: Scarabaeinae) is contentious, especially the origin of the dung feeding that has been attributed to their ecological success. Today, most of the 6,600 species feed exclusively on mammal dung and the diversity of scarabaeines across biogeographic realms broadly correlates with the diversity and density of mammals in these regions. Australian native dung beetles are unique having evolved in under an entirely different set of selective pressures that the rest of the global fauna, most significantly the absence of placental mammals, and their dung, through most of their evolutionary history. Their feeding biology provide insights into ancestral traits of dung beetles and how they adapted in isolation on the Australian continent. Furthermore, most species from the Australasian endemic clade have restricted geographic ranges, we explore phylogeographic trends to provide evidence in support of a Gondwanan origin that predates colonization of marsupials to Australia.

Increased density of endosymbiotic Buchnera related to pesticide resistance in yellow morph of melon aphid

Authors: GUO SHAOKUN[2] and WEI SHU-JUN[1], [2]Beijing Academy of Agricultural and Forestry Sciences, China, [1]Beijing Academy of Agricultural and Forestry Sciences, China

Abstract: Many invertebrates develop into different color morphs in response to changes in environmental conditions. Color morphs can differ in their biology and stress tolerance including pesticide resistance, but underlying mechanisms are unclear. In this study, we found that yellow morphs (predominant in hot summer conditions) of an agricultural pest, the melon aphid Aphis gossypii, have higher levels of resistance to the commonly-used pesticides imidacloprid and sulfoxaflor compared to the green morphs (predominant in cooler spring and autumn conditions), while no difference was found in morph resistance to the antibiotic/pesticide avermectin. Transcriptome analysis and biochemical assays of enzyme activities revealed no differences in metabolic processes between the two color morphs except for differentially-expressed genes related to wing development. Microbiome analysis revealed that the endosymbiont Buchnera aphidicola is the dominant bacterium in both morphs, representing 86.76%-99.88% of the microbiome. The yellow morph had a higher density of Buchnera compared to the green morph. When yellow morphs were treated with avermectin and antibiotics, the density of Buchnera was reduced to levels similar to the green morph, and their susceptibility to imidacloprid was simultaneously increased. These results indicate an association between resistance in the yellow morph of A. gossypii and symbiotic bacteria, providing novel insights into pesticide resistance mechanisms and the plasticity of stress adaptation.

Are ecological communities the seat of endosymbiont horizontal transfer and diversification? A case study with soil arthropod community

Authors: Gupta Manisha, Indian Institute of Science Education and Research, Mohali (IISER-Mohali), Knowledge city, Sector 81, SAS Nagar, Manauli, PO 140306, Punjab, India, India

Abstract: Maternally inherited endosymbionts are one of the most abundant bacteria infecting arthropods and show extensive horizontal transfer. Such widespread distribution and extensive recombination among these endosymbionts could be an outcome of horizontal transfer as for such genetic exchanges to occur their hosts should come in contact. One such level of biological organization where different hosts can do that is the ecological community. Despite various studies focusing on known model species and specific ecological interactions among hosts, reports on community wide endosymbiont data are rare. To better understand endosymbiont spread, we investigated the incidence, diversity, extent of horizontal transfer and recombination of three such endosymbionts (Wolbachia, Cardinium and Arsenophonus) in a specific soil arthropod community. Wolbachia strain characterization was done using multiple genes whereas single 16S rRNA gene was used for Cardinium and Arsenophonus. Amongst 3509 individual host arthropods belonging to 390 morphospecies, 12.05% were infected with Wolbachia, 2.82% with Cardinium and 2.05% with Arsenophonus. Phylogenetic incongruence between host and endosymbiont indicated extensive horizontal transfer of endosymbionts within this community. Three cases of recombination between Wolbachia supergroups and eight incidences of within supergroup genetic exchange were also found. Statistical tests of similarity indicated supergroup A Wolbachia and Cardinium to show a pattern consistent with rapid horizontal transfer within the community. However same tests done for super group B Wolbachia and Arsenophonus did not show similar patterns. We highlight the importance of extensive community wide studies for a better understanding of the spread of endosymbionts across global arthropod communities.

Assemblage structure, functional diversity and predation patterns of spiders (Araneae) across landscape complexity gradients in brassica production systems

Authors: Gurr Geoff[3], Sohaib Ahmed Saqib Hafiz[4], Chen Junhui[1], You Minsheng[2] and Chen Wei[1], [3]School of Agricultural and Wine Sciences, Charles Sturt University, Orange, NSW 2800, Australia, [4]State Key Laboratory of Ecological Pest Control of Fujian and Taiwan Crops, College of Plant Protection, Fujian Agriculture and Forestry University, Fuzhou, 350, [1]1 State Key Laboratory of Ecological Pest Control of Fujian and Taiwan Crops, College of Plant Protection, Fujian Agriculture and Forestry University, Fuzhou, 3, [2]Fujian Agriculture and Forest University, China

Abstract: The accelerating loss of farmland natural enemy diversity due to agricultural intensification and anthropogenic activities can impair the viability and functioning of the agro-ecosystem. To prevent the loss of natural enemies in an agroecosystem, it is necessary to precisely understand the multiple factors involved in shaping the assemblage of species and their foraging patterns. However, there is a scarcity of information on the response of predator assemblages and their predation patterns in highly dynamic agroecosystem such as those that are common in smallholder production systems, especially in response to local management and surrounding landscape composition. Focusing on spiders, essential providers of biological control, we tested the influence of local and landscape factors as the filters of taxa, functional assemblages and prey items in brassica vegetable fields. At the local scale, the crop identity showed a significant influence on all taxonomic and functional diversity measures. In contrast, pesticide regime had a significant influence only on the taxonomic measures of spiders but not on functional diversity. Local and landscape-scale factors interacted such that high proportions of cauliflower crops (a complex plant structure and longer duration crop than Chinese cabbage) and neighboring forest fragments positively influenced the assemblage of both taxonomically and functionally diverse spider assemblages including many web and non-web builders. In contrast, pesticide-treated Chinese cabbage (a simple plant structure and shorter duration crop than Chinese cauliflower) fields surrounded with simple landscape had impoverished assemblages of spiders and were dominated by active hunters (such as ground runners). Next-generation sequencing-based food web analyses confirmed that resource partitioning occurred in terms of abundance and diversity of prey taxa in the gut of spiders. Prey of Araneidae, Lycosidae, Pisauridae, Salticidae and Thomisidae spiders were enriched with dipterans, coleopterans, hemipterans, lepidopterans and orthopterans along with a wide range of other prey groups. These results suggested that in a highly dynamic agroecosystem, the existence of structurally complex crop species and conservation of neighboring forest patches can play a potent role in protecting the loss of farmland biodiversity and lessen the damaging effects of conventional management schemes, which in turn can offer an improved level of pest suppression and decrease the crop damage. The dietary patterns correspond well with the generalist foraging behavior of spiders and making them important taxa in encouraging and strengthening the biological control efforts in agroecosystems.

Working with smallholder farmers in Papua New Guinea to protect sweetpotato crops using habitat manipulation, organic mulches, and Entomopathogens.

Authors: Gurr Geoff[5], Agiwa Alex[2], Komolong Birte[4], Wilson Bree[1], Ash Gavin[1], Liu Jian[3], Pitiki Melanie[8], Brown Philip[7], Culas Richard[6], Geno Robert[4], Dotaona Ronnie[9] and Wau Wilfred[4], [5]School of Agricultural and Wine Sciences, Charles Sturt University, Orange, NSW 2800, Australia, [2]Fresh Produce Development Agency, Papua New Guinea, Papua New Guinea, [4]National Agricultural Research Institute, Papua New Guinea, Papua New Guinea, [1]Centre for Crop Health, University of Southern Queensland, Toowoomba, 4350, Queensland, Australia, [3]Graham Centre for Agricultural Innovation (Charles Sturt University and NSW Department of Primary Industries), Charles Sturt University, PO Box 883, Orange, NSW, [8]University of Technology, Papua New Guinea, Papua New Guinea, [7]School of Health, Medical and Applied Sciences, Central Queensland University, Queensland, Australia, [6]School of Agricultural and Wine Sciences, Charles Sturt University, PO Box 883, Orange, NSW 2800, Australia, [9]University of Technology, Papua New Guinea;, Papua New Guinea

Abstract: Sweetpotato is the major food staple in Papua New Guinea, integral to the culture of its peoples, and key to economic development. The crop is heavily attacked by a complex of arthropod pests yet farmers currently have little knowledge of management options and commonly plant new crops immediately adjacent to older (infested) crops, contributing to large yield gaps. Current efforts to transition sweetpotato production to more intensive production as a cash crop demand the development of effective pest management tactics that are suitable for use in remote areas with poor access to inputs and extension support. Here we report on a project in which a package of low-tech and biologically-based methods is being developed and tested on farms in the Highlands of Papua New Guinea. Habitat manipulation approaches include planting of new crops several meters from other crops, into beds that are free of weeds and residue from the preceding crop, and surrounded by a row of barrier plants to repel adult sweetpotato weevils and potentially provide floral resources to natural enemies of pests. Mulches of locally-available plant materials are being screened in laboratory and on-farm studies to identify those that protect sweetpotato storage roots from attack by weevils, and some of these treatments promote natural enemies. Entomopathogenic fungi, that could be produced in 'cottage industry' enterprises, have been screened in the laboratory and optimal isolates are now being tested on farms in conjunction with mulches that provide protection of the fungus from desiccation and ultraviolet light, and may even constitute a substrate for fungal growth. Together with the use of clean planting material and sex pheromone trapping of sweetpotato weevil adults, these biologically-based strategies have doubled marketable yields in the first year of on-farm trials.

Not just more plants, but the right ones: species richness and traits supporting ecosystem services on East African smallholder farms.

Authors: Gurr Geoff[6], Arnold Sarah[1], Elisante Filemon[8], Darbyshire Iain[5], Ndakidemi Patrick[4], Stevenson Philip[9], Mkenda Prisila[7], Belmain Steven[3] and Tembo Yolice[2], [6]School of Agricultural and Wine Sciences, Charles Sturt University, Orange, NSW 2800, Australia, [1]1. Natural Resources Institute, University of Greenwich 2. The Nelson Mandela African Institution of Science and Technology, United Kingdom, [8]The Nelson Mandela African Institution of Science and Technology, Tanzania, [5]Royal Botanic Gardens, Kew, United Kingdom, [4]Nelson Mandela African Institution of Science and Technology, [9]University of Greenwich Royal Botanic Gardens, Kew, United Kingdom, [7]Sokoine University of Agriculture, [3]Natural Resources Institute, University of Greenwich, [2]Lilongwe University of Agriculture and Natural Resources

Abstract: Because smallholder farmers typically do not use expensive agricultural inputs such as pesticides, they are highly reliant on ecosystem services such as natural pest regulation. However, evidence suggests many smallholders do not fully appreciate the benefits they receive from such ecosystem services. Consequently, there is a need to ensure strong evidence-based guidelines on optimal management of field margins and non-crop vegetation, to support beneficial insects like pollinators and natural enemies. We studied 32 smallholder fields of common bean (Phaseolus vulgaris) across Tanzania and Malawi, as beans are an important protein source for communities in these regions. By combining botanical surveys with insect trapping and observational transect walks we were able to build interaction networks and analyse associations between plant species and insect functional groups. We discovered that plant species richness positively predicts beneficial insect abundance and activity overall, and several aspects of network structure (e.g. robustness). Natural enemies of pests such as aphids were significantly associated with fields where herbaceous plant richness was high, but the importance of native species was less clear-cut. Farms with higher tree species richness also had higher levels of carpenter bee visitation on the crop, and trees were overrepresented among those plant species predictive of beneficial insect abundance. Several plant species associated with beneficial insects, such as Bidens pilosa, Ageratum conyzoides and Tithonia diversifolia, also have pesticidal properties when processed by farmers into a spray or drench, and so are promising candidate plants to support multiple ecosystem services on smallholder farms. As fields with plant-rich field margins benefited from more pollinator activity and lower pest damages at the crop edges, establishment of field margins is recommended. However, many of the plant species associated with beneficial insects were non-native to the regions, and the implications of promoting such species should be considered carefully.

Field and landscape management to support beneficial arthropods for IPM on vegetable farms

Authors: Gurr Geoff[7], Sandoval Vivian[10], Rizvi Syed[2], Haque Ahsanul[2], Johnson Annie[3], Mo Jianhua[6], Melo Maria[9], Furlong Michael[8], Reynolds Olivia[1], Munro Scott[5] and Osborne Terry[4], [7]School of Agricultural and Wine Sciences, Charles Sturt University, Orange, NSW 2800, Australia, [10]University of Queensland, Brisbane, QLD, Australia, [2]Charles Sturt University, Orange, NSW, Australia. Graham Centre for Agricultural Innovation, Wagga Wagga, NSW, Australia. International Joint Research Laboratory on E, [5]New South Wales Department of Primary Industries, Yanco, NSW, Australia, [4]New South Wales Department of Primary Industries, Menangle, NSW, Australia

Abstract: The colonization of arthropods in an agricultural field depends on the arrangement of land-cover types (landscape complexity) and its effects on the factors that control the exchange of species between the habitats. Landscape complexity almost always increases the abundance and diversity of natural enemies by providing resource subsidies such as shelter, nectar, alternative food sources, and pollen. Many natural enemies are influenced by the non-crop habitats surrounding the agricultural fields. We surveyed 492 focal crops including sweet corn, brassica, carrot, lettuce, capsicum, and beans field, across Australia, to determine if, and at what scale, adjacent land-use types influence the abundance and diversity of pests and natural enemies. We identified and measured the pest and natural enemy populations in the edges of focal crops adjacent to different habitats. We found that the diversity and density of both pests and natural enemies are significantly influenced by the adjacent land-use types. Non-crop vegetation such as riparian strips and shelterbelts tended to be associated with higher numbers of natural enemies and lower numbers of pests in the nearby edges of vegetable crop fields. Field centres, in contrast, had more pests and fewer natural enemies, suggesting that (i) riparian vegetation and shelterbelts are donor habitats for beneficial arthropods and that could be associated with pest suppression and (ii) the spatial scale at which vegetation patterns on farmlands affect in-crop pest and beneficial densities is small, at least for many key taxa. Crops of a given vegetable species planted contiguously tended to have fewer beneficial arthropods and more pests but separating crops by areas of other land uses, including crops of other species, improved the composition of arthropod communities. Notably, pests were similar in number across both organic and conventionally managed crops, whereas natural enemies were significantly higher in organic fields. This suggests that synthetic insecticides may not be essential; natural enemies can adequately check pest outbreaks in the absence of synthetic insecticide use.

Microbial influence in the niche shift of an insect pest: Drosophila suzukii

Authors: Gurung Kiran[3], Wertheim Bregje[4], Falcão Salles Joana[2] and g kiran[1], [3]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [4]University of Groningen, Netherlands, [2]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands, [1]Groningen Institute for Evolutionary Life Sciences, University of Groningen, Netherlands

Abstract: Insect-microbe interactions provide insights about how the microbes might act as resources for the insects, be it beneficial or non-beneficial. Hence, it is essential to understand whether microbes associated with an insect influence its life history traits. Drosophila suzukii is an invasive insect pest of soft fruits with its origin in South Asia. It infests ripening fruits, unlike the other members of its family Drosophilidae that infest rotten fruits. The fundamentals of D. suzukii in the Netherlands are backed by a limited study of its microbiome. We have characterized the bacterial and fungal communities in D. suzukii in order to address the question of whether its pest status is contributed by its associated microbes.

Demography of the Filbert Aphid, Myzocallis coryli (Goeze) (Hemiptera: Aphididae) on three different hazelnut species

Authors: Güncan Ali[2] and Dizdar Elif[1], [2]Ordu University, Turkey, [1]Department of Plant Protection, Faculty of Agriculture, Ordu University, Turkey

Abstract: The filbert aphid Myzocallis coryli (Goeze) is a serious aphid pest of hazelnut in North America, Italy, Spain, and Turkey. M. coryli were reared on three hazelnut species including Corylus avellana (L.), Corylus colurna L. and Corylus maxima Mill. under laboratory conditions to assess the resistance of hazelnut species to the aphid. Prolonged developmental times result in longer exposure of the more vulnerable, immature stages of the pest to natural enemies. In addition, the use of host-plant resistance together with biological control has been proposed as a sustainable alternative to chemical control. The developmental times of preadult and adult stages, total longevity, reproduction, and life table parameters were analyzed according to age-stage, two-sex life table theory, in which the stage differentiation and variable developmental rates among individuals could be described. The intrinsic rate of increase (r) and finite rate of increase (λ) varied among the species. The highest values were found for aphids reared on C. maxima (r= 0.2330 d-1, λ=1.2624 d-1), which differed significantly from C. colurna (r= 0.1944 d-1, λ=1.2146 d-1), whereas these parameters were lowest for C. avellana (r= 0.1838 d-1, λ=1.2018 d-1). Based on longer nymphal and preadult development periods, adult longevity together with the demographic parameters, C. avellana provide an unfavorable environment for the filbert aphid than the other species. The results obtained from demographic data together with estimates of pest growth potential generated by computer projection based on age-stage, two-sex life table theory, demonstrate that C. maxima is the most susceptible species to M. coryli among the tested hazelnut species.

Local and landscape effects of bioenergy cropping on arthropod traits and pest suppression

Authors: Haan Nathan[1] and Landis Douglas[1], [1]Michigan State University

Abstract: Bioenergy cropping could transform landscapes in coming decades and have sweeping impacts on biodiversity and associated ecosystem services like pest suppression. The nature of these changes will depend on which crops are adopted, how they are managed, and which ecosystem types they replace. We censused several taxonomic groups and measured pest suppression rates in a long-term experimental array containing ten bioenergy cropping systems including three intensive annual crops, four simple perennial grass systems, and three complex perennial polycultures. Species richness of most groups varied strongly across cropping system types and was usually low in annual systems, somewhat higher in simple perennial systems, and highest in complex perennial polycultures. Functional group composition of ground beetles and ants, which can be important predators of crop pests, also varied among crop types with predatory species often being more well-represented in perennial crops. Predation potential, which we measured by quantifying attack rates on plasticine caterpillars, also varied strongly among cropping systems and usually mirrored biodiversity trends. Expansion of arable bioenergy crops is likely to reduce biodiversity and erode biocontrol services, while replacing marginal annual crops with complex perennial bioenergy habitats could enhance them.

Time-series to study insect decline

Authors: Habel Jan Christian, University of Salzburg

Abstract: Historical data sets show a rapid and continuous decline in insect diversity. Large data sets collected over long time periods and across large spatial scales show a dramatic decline in insect diversity as well as abundance and thus biomass during the past decades. In addition, species communities are changing significantly, proving that numerous species are suffering from agricultural intensification. Here, in particular specialist species are vanishing rapidly acorss landscapes. An assessment of the current situation and an estimation of future trends is only possible by considering historical data sets collected over several decades.

Toward reference quality assemblies of agricultural pest insects, updates from the Ag100Pest Initiative

Authors: Hackett Kevin[1], Geib Scott[2], Childers Anna[3], Coates Brad[3], Scheffler Brian[3], Childers Chris[3] and Poelchau Monica[3], [1]United States Department of Agriculture, Agricultural Research Service, United States, [2]USDA-ARS Daniel K. Inouye U.S. Pacific Basin Agricultural Research Center:, United States, [3]USDA-ARS, United States

Abstract: The Ag100Pest goal is to produce annotated, reference quality genome assemblies for the top arthropod agricultural pests in the United States. The Ag100Pest prioritization team is considering approximately 400 species nominations and establishing selection criteria for arthropod pests of US field crops, livestock, bees, trees, and stored products as well as foreign pest species considered potential invasive threats to US agriculture. The foundation for these genome assemblies will be PacBio single molecule data, from a single insect when possible. This data is further combined with Illumina, 10X Genomics, and HiC data to generate chromosome-scale assemblies to serve as a foundation for these pest species.

Beyond genomes, Ag100Pest teams are developing best practices that will benefit the entire arthropod genomics community. Examples of high quality assemblies created from single insects will be presented, using CLR long reads and compared to HiFi reads. Additionally, standard, low, and ultra-low input methods will be demonstrated, towards creating routine methodologies for high-throughput whole genome assemblies.

A Universal Food Immunomarking Technique (UFIT) for Studying Arthropod Feeding Activities

Authors: Hagler James, USDA-ARS Arid-Land Agricultural Research Center, United States

Abstract: The molecular identification of predator feeding activity relies almost exclusively on the use of species-specific polymerase chain reaction (PCR) assays. However, there is viable alternative to the PCR assay approach. The method consists of tagging potential food items with exogenous protein(s). In turn, the guts of foraging arthropods can be examined for the presence of protein-marked food items by a suite of standardized protein-specific sandwich ELISAs. I will discuss how this universal food immunomarking technique (UFIT) can be adapted to pinpoint life stage-specific predation events, cannibalism, and scavenging.

Does the source matter for SIT? No effects of x-ray vs gamma irradiation on sterilization or sterile male performance in the mosquito Aedes aegypti.

Authors: Hahn Daniel[1] and Chen Chao[1], [1]University of Florida, United States

Abstract: Sterile insect technique (SIT) can be effective as a component in area-wide integrative pest management for multiple insect pests. SIT may be particularly useful for vector mosquitoes like Aedes aegypti that live in close proximity to humans, occupy cryptic larval breeding sites with adults resting in places difficult to reach with insecticide sprays, and that have populations showing resistance to common chemicals. For SIT, males are typically sterilized by exposing them to gamma radiation. However, gamma irradiators are not always available of easily accessible due to restrictions on the radio-isotopes used. One solution to this problem is to irradiate male mosquitoes using x-rays rather than gamma sources because x-ray irradiators are readily available, relatively affordable, and do not require the stringent safety and security restrictions necessary for gamma irradiators. Here we compare an established gamma irradiator heavily used for an operational Ae. aegypti SIT pilot program with that of a new x-ray irradiator for sterilizing male pupae and adults while maintaining male performance after irradiation. Our results show Aedes aegypti SIT programs can successfully transition from gamma to x-ray sources, and new programs can begin using x-ray irradiation sources to avoid regulatory and cost hurdles associated with gamma sources.

Invasion Dynamics, Prediction and Spread of Accidental Introductions of Natural Enemies

Authors: Hajek Ann[1], Liebhold Andrew[2], [1]Cornell University, United States, [2]USDA Forest Service Northern Research Station, Czech Republic

Abstract: In nearly all global regions, various natural enemy species have been accidentally transported with cargo and passengers outside of their natural ranges. In regions where they encounter hosts, several species have established. The ability of accidentally introduced natural enemies to become established and spread depends in part on the biologies of the natural enemy and host. We propose theories to help explain and predict which natural enemies are more likely to be transported and easily established after introduction. For example, entomopathogens and insect-parasitic nematodes causing more chronic infections could be introduced easily along with invasive hosts. More virulent natural enemies, such as parasitoids would have a better chance of becoming established if host populations are already present in invaded areas. Examples of different scenarios will be provided as well as data on interceptions of natural enemies that document their transport.

Large-scale multi-year trends using benthic arthropod COI metabarcodes as bioindicators

Authors: Hajiababaei Mehrdad[2], Robinson Chloe[2], Baird Donald[1], Wright Michael[2] and Porter Teresita[2], [2]University of Guelph, Canada, [1]Environment and Climate Change Canada And University of New Brunswick, Canada

Abstract: Canada holds 20% of the world's total freshwater resources consisting of a large number of river systems, lakes and wetlands. In order to reinforce biomonitoring capabilities of the Canadian Aquatic Biomonitoring Network (CABIN) we began piloting the use of benthic DNA metabarcoding in key areas such as the Peace-Athabasca delta in northern Alberta. Climate change is causing an increase of freshwater evaporation and reduction in the frequency of ice-jam flooding in this region. Through analyzing layers of richness data across 6 years of biomonitoring in the delta, we detected similar biodiversity trends which correlated with recent flooding events in 2011 and 2014. At a local scale, annual differences in benthic arthropod community composition compared to our baseline was driven largely by turnover, whereas at a broader scale, differences were largest when measured over time. Assessing biodiversity change through investigating different levels of richness and function at different spatial and temporal scales is essential for better understanding the effects of global ecosystem perturbations on benthic macroinvertebrates. Since 2018, we began a Canada wide project, STREAM (Sequencing the Rivers for Environmental Assessment and Monitoring) by merging the sampling capacity of community-based monitoring with benthic DNA metabarcoding. This effort will set the stage for routine application of DNA-based biomonitoring across all Canadian watersheds.

Hazard assessment of oak processionary moth (Thaumetopoea processionea L.)

Authors: Halbig Paula[2], Delb Horst[1], Stelzer Anne-Sophie[3], Schopf Axel[4], Pennerstorfer Josef[4] and Baier Peter[4], [2]Forest Research Institute Baden-Württemberg (FVA), Dept. of Forest Health, Germany, [1]Dept. of Forest Protection, Forest Research Inst. of Baden-Württemberg, Germany, [3]Forest Research Institute of Baden-Württemberg (FVA), Dept. of Biometry and Computer Science, Wonnhaldestr. 4, 79100 Freiburg, Germany, [4]University of Natural Resources and Life Sciences (BOKU), Vienna, Dept. of Forest- and Soil Sciences, Institute of Forest Entomology, Forest Pathology and Fores

Abstract: The growing presence of oak processionary moth (OPM), Thaumetopoea processionea L. (Lep., Thaumetopoeinae), in Central Europe since the 1990s and the concomitant consequences for the vitality of the host trees and human/animal health urgently require hazard assessment and control strategies. Regarding climate change, increased intensities of oak tree defoliation and human/animal infections with the urticating hairs (setae) released by the larvae are expected.

For hazard assessment, the online early warning system “PHENTHAUproc“ was generated. This tool comprises six different models, i. a. newly developed, temperature-based phenology models for bud swelling of oak (Quercus robur L.) and for the non-overwintering OPM stages. The prototype of PHENTHAUproc which was created and validated for Germany gives local predictions (for the sites of meteorological stations) and regional predictions (map service). The early warning system provides information on OPM-related hazards for the public and decision support of planning and implementation of appropriate and effective integrated pest management for professionals to protect oak tree vitality and human/animal health in forest, urban and rural areas.

Best management plans for rose rosette disease: A threat to roses worldwide

Authors: Hale Frank[3], Windham Alan[2], England Brent[2], Byrne David[1], Solo Katherine[2], Windham Mark[2], Collins Sara[2] and Hitch Walt[4], [3]The University of Tennessee, United States, [2]The University of Tennessee, United States, [1]Texas A&M University, United States, [4]University of Tennessee, United States

Abstract: Rose rosette disease (RRD) is a fatal viral disease of roses. Most infected plants die within 2-3 years. Symptoms include a profusion of thorns, thin elongated leaves, thickened stems and dense witches’-broom growth. The only known vector is an eriophyid mite, Phyllocoptes fructiphilus. These tiny mites spread to other plants by floating in the wind. The populations of P. fructiphilus are forty times higher on tissues collected from rose shoots symptomatic for RRD than asymptomatic foliage on the same plant. The use of miticides has had mixed results in protecting roses from infection. Two other eriophyid mite species have been found on roses infected with Rose Rosette Virus (RRV): Eriophyes eremus and Callyntrotus schlechtendali. It is not known if these mites can vector RRD. The search for host plant resistance is ongoing with rose trials in Tennessee, Delaware, Oklahoma and a few in Texas.

Elevated CO2 alters the effect of plant silicon on aphids and their parasitoids

Authors: Hall Casey[3], Rowe Rhiannon[1], Johnson Scott[2] and Hartley Susan[4], [3]Hawkesbury Institute for the Environment, Western Sydney University, Locked Bag 1797, Penrith, NSW 2751, Australia, [1]Hawkesbury Institute for the Environment Western Sydney University 2753 Richmond, Australia, [2]Hawkesbury Institute for the Environment, Western Sydney University, Locked Bag 1797, Penrith, NSW 2751, Australia, [4]York Environment and Sustainability Institute, Department of Biology, University of York, York YO10 5DD, United Kingdom

Abstract: Many grasses take up large amounts of silicon (Si) which acts as a potent physical defence against insect herbivores. Silicon supplementation has also been linked to the jasmonic acid (JA) signalling pathway, which underpins a wider array of anti-herbivore defences. We recently found that elevated CO2 (eCO2) decreases silicon uptake through the suppression of the JA pathway. Despite this decrease, we found that silicon remained an effective defence against herbivory by a pest caterpillar (Helicoverpa armigera) under eCO2. Aphids, however, are thought to be less susceptible to physical Si defences and in some cases respond positively to eCO2. Si and eCO2 induced changes in phytohormone signalling, and subsequent changes in plant quality may not only affect herbivores but also their natural enemies. To date, only a few studies have investigated the effect of Si uptake on tritrophic interactions and none have linked this to changes in defensive phytohormonal pathways under eCO2. We investigated the effect of Si on a plant-aphid-parasitoid system, using a common pasture grass, Phalaris aquatica, which is known to produce a range of toxic alkaloids. The aphid, Rhopalosiphum padi, and its hymenopteran parasitoid (Aphidius colemani) were reared on plants grown with and without Si under both ambient and elevated CO2. Alkaloid and phytohormone concentrations were quantified in response to Si supplementation, CO2 and aphid infestation. We found that aphids significantly reduced Si uptake due to lower endogenous JA. Host aphid (mummy) size was significantly larger on non-Si plants but only under ambient CO2. While the reverse was true on eCO2 plants, i.e. mummy size was larger on Si plants. Parasitoid size however, was only larger on non-Si plants under ambient CO2. Fewer parasitoids emerged from aphids reared on Si supplemented plants under ambient CO2 while those on eCO2 plants emerged on average two days earlier. The difference in plant quality due to Si supplementation reduced host aphid quality and subsequent parasitoid development but only under ambient CO2. We found that the effects of Si on higher trophic levels depend on CO2-related changes in both host plant and aphid quality.

Laboratory and field studies on leptotriene, a component of the male-produced aggregation pheromone of the western conifer seed bug, Leptoglossus occidentalis, an invasive pest of pine trees in Europe

Authors: Hall David[2], Ponce-Herrero Laura [3], Pajares Juan[3], Millar Jocelyn[1] and Zou Yunfan[1], [2]Natural Resources Institute, University of Greenwich, [3]Sustainable Forest Management Research Institute, University of Valladolid-INIA, [1]Departments of Entomology and Chemistry, University of California, Riverside, CA

Abstract: The western conifer seed bug, Leptoglossus occidentalis Heidemann (Heteroptera: Coreidae) is native to North America but was introduced into Europe in the 1990s, and has since spread rapidly throughout the continent. This species is a specialist feeder on conifer seeds. In both its native and invasive ranges it can be a major pest in conifer seed orchards, and in Europe it is of particular concern to growers of edible pine nuts.

One male-specific component of the volatiles collected from virgin male L. occidentalis elicited a strong electroantennogram response from both male and female bugs in coupled gas chromatography-electroantennography analyses. This was isolated, and identified as a unique sesquiterpene which was synthesised and given the trivial name "leptotriene".

Trapping studies in Spain showed that synthetic leptotriene was highly attractive to both female and male L. occidentalis. Addition of possible minor components did not consistently affect this attractiveness.

In laboratory studies over three years, male L. occidentalis typically produced leptotriene in two periods during February-March and July-August, whereas trap catches in the field were highest in September-October. The reasons for this will be discussed along with the possible roles of potential minor components of the sex/aggregation pheromone.

Friend or foe? Drosophila suzukii interactions with fungi

Authors: Hamby Kelly[3], Lewis Margaret[1] and Schöneberg Torsten[2], [3]University of Maryland, College Park, United States, [1]Ph.D. Candidate Department of Entomology University of Maryland, United States, [2]Postdoctoral Scholar Department of Entomology University of Maryland, United States

Abstract: Interactions between Drosophila and fungi range from mutualistic, such as the "farming" and dispersal of yeasts, to antagonistic competition and parasitism. While most drosophilids rely upon yeast rich fermenting substrates such as overripe fruit, the invasive pest Drosophila suzukii attacks ripe, unspoiled fruit. Despite this unique niche, fungi significantly impact D. suzukii's life history. D. suzukii feed upon a variety of yeast species; in particular, Hanseniaspora uvarum has been recovered from 93% of field collected larvae (n = 56 across 4 sites and 2 states) and 100% of adults (n = 11 across 2 sites and 1 state). Yeasts are critical for D. suzukii larval survival, impacting adult and larval behavior. In addition to yeasts, D. suzukii co-occurs with fruit rot fungi. We are characterizing adult and larval D. suzukii fungal communities, as well as evaluating the nature of their relationship with fruit rot fungi. Understanding how D. suzukii interacts with fungi may lead to the development of novel sustainable pest management strategies for this fruit pest. If D. suzukii influence fruit rot epidemiology, improved insect and pathogen management programs may also be developed.

Managing Natural and Constructed Agricultural Wetlands for Athropod Biodiversity

Authors: Hambäck Peter[2], Åhlén David[1], [2]Stockholm University, Sweden, [1]Department of Ecology, Environment and Plant Sciences, Stockholm University, Sweden

Abstract: Wetlands in the agricultural landscape has been the focus of numerous studies where emphasis on arthropod diversity in the light of wetland construction and re-construction is key. However, when considering agricultural wetlands as highly productive ecosystems, where successional transition is incredibly rapid; one must also consider the way in which such a habitat is managed. Its structure will soon change if left to its own accord, and with it, the arthropod community within. Therefore, the aim of this project is to understand what mechanisms drive arthropod diversity in agricultural wetlands, how these mechanisms affect arthropod interactions, and what effect management has on them. This will be achieved by studying what effect microhabitat, flood zones, hydrology and primary production has on the arthropod community; and also what beneficial effects wetland arthropods can have on the surrounding agricultural landscape. Arthropod collection will be performed by malaise-, and emergence trapping, aspiration collection and hand collecting; and gut-content analyses will be done using metabarcoding techniques and subsequent sequence comparisons to the Barcode of Life database. By looking at the effect of management on these variables, regimes for how an agricultural wetland should be managed in order to maximize arthropod diversity can be created. At the same time an understanding on how management can affect the interactions in the community is gained, which is also important when considering how management should be performed.

The power of next-generation sequencing to resolve the population structure of an invasive insect pest, Anoplophora glabripennis

Authors: HAMELIN Richard[1], Cui Mingming[2], Roe Amanda[5], Porth Ilga[4] and Giguère Isabelle[3], [1]Department of Forest Sciences University of British Columbia Vancouver, Canada, [2]Department of Wood and Forest Sciences, Laval University, Canada, [5]Natural Resources Canada, Canadian Forest Service, Great Lakes Forestry Centre, Canada, [4]Laval University, Canada, [3]Institute of Integrative Biology and Systems, Laval University, Canada

Abstract: Asian longhorned beetle (Anoplophora glabripennis – ALB), is a native forest pest in mainland China and the Korean peninsula. This species has successfully invaded and spread to hardwood forests in North America and particularly in Europe. ALB mines the heartwood of a range of tree species and poses a significant threat to all newly invaded forest ecosystems. The key to reducing this risk is via early detection and intervention. We are working on developing biosurveillance tools that allow the end-users in plant protection agencies and at the border control with a single test to identify simultaneously species, source of the intercepted specimen and adaptive traits that suggest risk for establishment. In this study, we generated genome-wide molecular markers using high-throughput sequencing technology (Genotyping-by-Sequencing) to characterize genetic variation within and among native ALB populations. Our results show clear population differences between ALB populations in China and South Korea, as well as pronounced population structure within China. These genomics-based results provide much greater clarity on ALBs native population structure than earlier work on mitochondrial DNA and microsatellites was able to. The new results also provide important insights from a genomics perspective into the history of human-mediated dispersal of ALB and the substantial potential for local adaptation within its native range. These data lay the foundation for the development of target-enriched biosurveillance tools that will help us increase preparedness and facilitate early action against ALB.

Bacterial Communities Associated with Two Parthenogenetic Aphid Species Cocolonizing Pomegranate across Morocco

Authors: Hance Thierry[2], Fakhour Samir[1], Renoz François[3], Gala Jean-Luc[3], Ambroise Jérôme[3], [2]UCLouvain, Belgium, [1]National Institute of Agronomic Research, Morocco, [3]Université catholique de Louvain, Belgium

Abstract: Like many insects, aphids (Hemiptera: Aphididae) can harbor a wide diversity of inherited symbiotic bacteria that can be important drivers of their evolutionary ecology. In addition to the obligate nutritional symbiont Buchnera aphidicola, these phloem-sap feeding insects can host various facultative symbionts whose functional diversity depends on complex interactions between the genotype of the host and that of the bacterial partners, and on the other hand, between the genotype of the partners and environmental factors. In this study, we examined the distribution of two parthenogenetic aphid species (the melon aphid, Aphis gossypii, and the pomegranate aphid, A. punicae) cocolonizing pomegranate trees (Punica granatum) across Morocco. We also determined the diversity of symbionts associated with these two aphid species to compare the bacterial communities sheltered by aphid species feeding on the same host plant species, but displaying different lifecycles and a very different feeding ecology, and to test the hypothesis that environmental factors contribute to shaping the bacterial communities associated with insects. We found that A. punicae was mainly distributed in coastal areas, while A. gossypii was more widely distributed in inland areas. Deep 16S rRNA sequencing and species-specific diagnostic screening enable us to establish that the overall symbiotic diversity sheltered by these two aphid species is low compared to that found in the pea aphid Acyrthosiphon pisum. We found that the symbiont communities differed significantly between the two species: the highly polyphagous species A. gossypii harbored a more diverse bacterial community than the oligophagous species A. punicae. Prevalence of Arsenophonus infections was particularly high in A. gossypii populations. The symbiont communities also differ across aphid populations sampled from the different bioclimatic zones, suggesting that environmental factors contribute to shaping the bacterial communities associated with aphids.

Phenotypic plasticity explains violation of Dollo’s law of irreversibility

Authors: Hance Thierry[3], Visser Bertanne[3], M. Nieberding Caroline[2], Rebar Darren[1], Weissing Franjo[4], T. Alborn Hans[5], M. Riederer Jana[4], Haillot Manon[2], Tiso Stefano[4], Rondeaux Suzon[2] and J. B. van Eldijk Timo[4], [3]UCLouvain, Belgium, [2]UCLouvain, Belgium, [1]Emporia State University, United States, [4]University of Groningen, Netherlands, [5]USDA-ARS CMAVE, Gainesville, FL, United States

Abstract: Dollo’s law states that traits once lost during the course of evolution will not re-appear, but recently several violations of this law have been described. Using both an experimental and theoretical approach, we show that an archetypal violation of Dollo’s law, the loss and regain of fat synthesis in parasitic wasps, actually concerns the evolution of plasticity. First, using replicated experiments, we showed that fat synthesis can be switched on or off depending on the developmental environment (fat content of the host). Second, a comparative protein domain analysis revealed that key enzymes involved in fat synthesis have remained functional over extended evolutionary times (~350 my). Third, computer simulations showed that a regulatory switch can remain functional within the genome for millions of generations, even when only sporadically used. The evolution of plasticity could explain other presumable violations of Dollo’s law. Our results can further explain how adaptations to rare and extreme environmental events can be maintained over long evolutionary times.

Cerambycid beetle pheromones: a cornucopia of new compounds and monitoring tools for invasive, endemic, and endangered species

Authors: Hanks Lawrence M., Department of Entomology University of Illinois at Urbana-Champaign, United States

Abstract: The chemical ecology of the large beetle family Cerambycidae remained almost unexplored until early this century, despite the growing importance of cerambycids as invasive species as a result of ever-increasing global commerce. It had even been suggested that cerambycids made very limited use of pheromones. In fact, the reverse appears to be true; over the past 15 years, there has been a veritable explosion in the number of sex and aggregation pheromones identified from this family, with attractant pheromones now identified from several hundred species in the 5 major subfamilies, and many more in progress. Initial screening studies with known pheromones and analogs suggested that the structures might be highly conserved within related taxa. However, more recent studies targeting pheromone identifications from individual species have shown that the bioactive compounds vary from being apparently unique, species-specific compounds, through to compounds which are shared by species on all six habitable continents. Thus, the latter types of chemical signals must have persisted unchanged for millions of years as speciation occurred and the continents separated. An increasing variety of chemical structures also are being identified, including compounds containing nitrogen and sulfur. In parallel with the identification of novel pheromones, optimization of traps and lures has greatly improved the efficiency of pheromone-based trapping. In sum, this has resulted in increasing recognition of the value of this technology, and increasing uptake into monitoring and surveillance protocols, particularly for invasive species. Pheromone-based monitoring is also proving to be a valuable tool for sampling the ranges and population sizes of endangered cerambycid species. This presentation will summarize the rapid progress in elucidating the chemical ecology of cerambycids since the turn of the century. It will also emphasize some of the more basic and still unanswered ecological questions with regard to patterns of pheromone use within this large and diverse insect family.

The importance of regulatory small RNAs in small symbiont genomes

Authors: Hansen Allison, University of California, Riverside Department of Entomology, United States

Abstract: Organelles and host-restricted bacterial symbionts are characterized by having highly reduced genomes that lack many key regulatory genes and elements. Thus, it has been hypothesized that the eukaryotic nuclear genome is primarily responsible for regulating these symbioses. However, with the discovery of organelle and symbiont expressed small RNAs (sRNAs) there is emerging evidence that these sRNAs may play a role in gene regulation. Here, we reveal that a conserved antisense sRNA in the model mutualistic aphid endosymbiont genome, Buchnera, is important in post-transcriptional expression of an important protein involved in Arginine biosynthesis; an important symbiont product of the ~200 million-year obligate symbiosis with its insect host. We further demonstrate that conserved Buchnera sRNAs are differentially expressed under different developmental and nutritional environments and are present in other Hemipteran-symbiont systems as well. These conserved sRNAs are potentially important in regulating essential amino acid biosynthesis with its insect host.

Pheromones and neural circuitry underlying sexual isolation in Drosophila

Authors: Hansson Bill[1] Knaden Markus[1], Khallaf Mohammed[1], [1]Max Planck Institute for Chemical Ecology, Germany

Abstract: Insects use distinct sex pheromones as a reproductive isolating mechanism to attract only conspecific mating partners. Genetic and neural variations that contribute to the evolution of pheromone signaling systems remain unclear. Here, we identify various male-specific compounds in the four subspecies of Drosophila mojavensis, an established model for incipient speciation. One of these compounds, is detected by olfaction in all subspecies, is exclusively present in two of them and induces their female receptivity. This female receptivity is governed by OR65a ortholog whose neural circuit innervation and underlying behavior differ from the Or65a circuit of D. melanogaster. Mutational analysis and behavioral experiments indicate that the novel compound and the novel Or65a circuitry are major drivers of the sexual isolation among the closely-related subspecies. Together, these results advance our understanding of nervous system alterations underlying sex pheromone evolution and provides novel evidences for an ongoing speciation process in D. mojavensis subspecies.

Evolution of sex pheromones across the genus Drosophila

Authors: Hansson Bill[1] Knaden Markus[1], Khallaf Mohammed[1], [1]Max Planck Institute for Chemical Ecology, Germany

Abstract: Most insects use sex pheromones as a reproductive isolating mechanism to attract only conspecific mating partners. Despite the profound knowledge of Drosophila melanogaster sex pheromones, little is known how other drosophilids regulate their social and sexual behaviors. Here we analyze the chemical profiles of 101 species within the genus Drosophila to elucidate how species-specific signals can contribute to form premating isolation barriers. Chemical and genetic analyses indicate a correlation of the chemometric profiles and the phylogenetic relation of drosophilid flies. Through a series of chemical synthesis, we identify 46 novel male-specific compounds, many of them are transferred to females during copulation. Electrophysiological recordings of pheromone sensory neurons in all species to all male-transferred compounds revealed the specificity of the pheromone detection system in Drosophila. Finally, we test all these compounds in courtship assays for their behavioral role in female receptivity and male courtship inhibition. Our results increase the understanding of the evolution of Drosophila pheromones and show how sexual isolation barriers between species can be created by species-specific olfactory signals.

Drosophila attractiveness boosted by alcohol -

Authors: Hansson Bill[3], Sachse Silke[1], Knaden Markus[3] and W Keesey Ian[2], [3]MaxPlanck Institute for Chemical Ecology, Germany, [1]Dept Evol Neuroethol Max Planck Inst Chem Ecol Jena, Germany, [2]Dept of Evol Neuroethol Max Planck Inst Chem Ecol Jena, Germany

Abstract: Drosophila has in earlier studies been shown to be attracted to ethanol. Different, sometimes quite anthropomorphic explanations have been discussed. In the present study we revisit vinegar fly alcohol attraction in the context of sexual attraction. We show that access to alcohol, especially methanol, has a boosting effect on male attractiveness to females. We proceed to investigate the olfactory pathways underlying attraction to alcohol and present a possible scenario for how attraction to certain types of fruit allows access to alcohols and thereby interacts with the fly's pheromone production. We propose that this interaction is the true background to alcohol "addiction" in vinegar flies.

Neuroethology of feeding and oviposition behavior in the hawkmoth Manduca sexta

Authors: Hansson Bill[4], Sachse Silke[1], Knaden Markus[4], Bisch-Knaden Sonja[3] and Treesa Tom Megha[2], [4]MaxPlanck Institute for Chemical Ecology, Germany, [1]Dept Evol Neuroethol Max Planck Inst Chem Ecol Jena, Germany, [3]Max Planck Institute for Chemical Ecology Department of Evolutionary Neuroethology Hans-Knoell-Strasse 8 D-07745 Jena, Germany, [2]Max Planck Institute for Chemical Ecology Department of Evolutionary Neuroethology Hans-Knoell-Strasse 8 D-07745 Jena, Germany

Abstract: Female hawkmoths, Manduca sexta, use olfactory cues to locate nectar sources and oviposition sites. We investigated how a large set of ecologically important and chemically diverse odors is coded in the antennal lobe (in vivo calcium imaging), which behavioral relevance the same odors have (wind tunnel experiments), and if there is a correlation between the activity level of single olfactory glomeruli and the observed feeding and oviposition behavior. Next, we aimed at identifying odorant receptors that target these behaviorally relevant glomeruli, and therefore expressed individual odorant receptors of the moth heterologously in the antennae of the vinegar fly Drosophila melanogaster. Using the same odors as before, we were able to correlate the response profiles of odorant receptors and olfactory glomeruli. Our results are a step forward towards unraveling the neuronal circuits underlying odor-guided behaviors in the hawkmoth.

Subpopulation of lateral horn output neurons is required for odor avoidance and aggression behavior

Authors: Hansson Bill[4], Sachse Silke[3], Knaden Markus[4], Mohamed Ahmed A. M.[2], A. Khalaf Mohamed[1] and Das Chakraborty Sudeshna[1], [4]MaxPlanck Institute for Chemical Ecology, Germany, [3]Dept Evol Neuroethol Max Planck Inst Chem Ecol Jena, Germany, [2]Department of Evolutionary Neuroethology, Max-Planck institute for Chemical Ecology, Jena, Germany, [1]Department of Evolutionary Neuroethology, Max-Planck institute for Chemical Ecology, Jena, Germany

Abstract: Animals exhibit innate attraction or aversion behaviors in response to olfactory cues. In Drosophila, a higher-order olfactory center called the lateral horn (LH) is believed to be involved in coding olfactory-induced innate behaviors. Unlike the early olfactory processing centers, our knowledge of odor processing in the LH is still scant. Here, we identify a subset of LH output neurons that encodes and mediates odor aversion. Using 2-photon calcium imaging, we show that 3-4 neurons of this cluster respond strongly to aversive odors with no or weak responses to attractive odors. Moreover, this cluster contains, at least, one neuron that is activated exclusively by the sex pheromone cVA. Interestingly, our results show that odor representations are different between the input and the output site of these third-order neurons, which implies that odor responses are modulated along their processing pathway. Finally, silencing this cluster of third order neurons abolishes avoidance behavior while attraction is not affected. In summary, our data shows that the olfactory information from distinct input channels converges in these higher order neurons to mediate the same behavioral output.

Developmental and sexual divergence in the olfactory system of the marine insect Clunio marinus

Authors: Hansson Bill[6], Vogel Heiko[1], S Kaiser Tobias[5], Vilcinskas Andreas[3], Große-Wilde Ewald[2], Christine Missbach[4], [6]MaxPlanck Institute for Chemical Ecology, Germany, [1]Department of Insect Symbiosis, MPI for Chemical Ecology, Jena, Germany, [5]Max Planck Institute for Evolutionary Biology, Germany, [3]Institute of Insect Biotechnology, Justus-Liebig University, Germany, [2]Dept Evol. Neuroethol, Max Planck Inst. Chem. Ecol, Jena, Germany, and EXTEMIT-K, ETM, FFWS, CULS, Prague, Czech Republic, Czech Republic, [4]Max Planck Institute for Chemical Ecology, Germany

Abstract: An animal's fitness strongly depends on successful feeding, avoidance of predators and reproduction. All of these behaviours commonly involve chemosensation. As a consequence, when species' ecological niches and life histories differ, their chemosensory abilities need to be adapted accordingly.

The intertidal insect Clunio marinus (Diptera: Chironomidae) has tuned its olfactory system to two highly divergent niches. The long-lived larvae forage in a marine environment. During the few hours of terrestrial adult life, males have to find the female pupae floating on the water surface, free the cryptic females from their pupal skin, copulate and carry the females to the oviposition sites. In order to explore the possibility for divergent olfactory adaptations within the same species, we investigated the chemosensory system of C. marinus larvae, adult males and adult females at the morphological and molecular level.

The larvae have a well-developed olfactory system, but olfactory gene expression only partially overlaps with that of adults, likely reflecting their marine vs. terrestrial life styles. The olfactory system of the short-lived adults is simple, displaying no glomeruli in the antennal lobes. There is strong sexual dimorphism, the female olfactory system being particularly reduced in terms of number of antennal annuli and sensilla, olfactory brain centre size and gene expression. We found hints for a pheromone detection system in males, including large trichoid sensilla and expression of specific olfactory receptors and odorant binding proteins.

Taken together, this makes C. marinus an excellent model to study within-species evolution and adaptation of chemosensory systems.

Chemical and reverse chemical ecology of a moth: what can we learn from the deorphanization of Spodoptera littoralis odorant receptors?

Authors: Hansson Bill[9], Walker William[11], Caballero Vidal Gabriela[8], Jacquin-Joly Emmanuelle[4], Montagné Nicolas[3], Koutroumpa Fotini[5], de Fouchier Arthur[6], Meslin Camille[7], Larsson Mattias[2], Binyameen Muhammad[1] and Sun Xiao[10], [9]MaxPlanck Institute for Chemical Ecology, Germany, [11]USDA-ARS, United States, [8]INRAE, Sorbonne Université, Institute of Ecology & Environmental Sciences of Paris, Versailles and Paris, France, [4]INRA, Institute of Ecology and Environmental Sciences (iEES) - Paris, France, [3]iEES-Paris, INRAE, Sorbonne Université, Versailles, France, [5]INRAE, iEES-Paris Institute, Versailles, France, [6]INRAE, Institute of Ecology and Environmental Sciences of Paris, France, [7]INRAE, Sorbonne Université, Institute of Ecology & Environmental Sciences of Paris, Versailles and Paris, France, [2]Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Alnarp, Sweden, [1]Bahauddin Zakariya University, Pakistan, [10]School of Life Sciences, Henan University, Kaifeng, Henan province, China

Abstract: In the recent years, the development of high-throughput sequencing technologies has highlighted the diversity of insect odorant receptors (ORs). These ORs are transmembrane proteins expressed in olfactory sensory neurons, and they are at the core of odorant detection. Each species has evolved a unique repertoire of ORs whose functional properties are expected to meet its ecological needs, though little is known about the molecular basis of olfaction outside Diptera. Using transcriptomics and genomics, we have identified the whole set of larval and adult ORs in the cotton leafworm Spodoptera littoralis, a herbivorous Lepidoptera model in chemical ecology. A large part of the OR repertoire has been functionally characterized using heterologous expression in Drosophila antennae coupled to electrophysiology, a premiere in a Lepidoptera. Noteworthy, we found basic conservation of function within the receptor repertoire of Lepidoptera, across the different major OR clades. Focusing on caterpillar-expressed ORs, we used these data to conduct an OR-guided approach and identified new caterpillar attractants, whereas caterpillar-enriched and caterpillar-specific ORs appeared to be tuned to repellent ligands. This reverse chemical ecology approach led us to acquire knowledge on ORs that not only helps to identify key stage-specific behavioural cues, but also open new perspectives in pest control, since such ORs may be used as targets for the design of new behavioural disruptors.

The role of farm floral diversity in Tasmania

Authors: Hanusch Yolanda[1], Gloag Ros[1], Latty Tanya[1], [1]The University of Sydney, Australia,

Abstract: Just like humans, many pollinators benefit from a diverse nutritional diet. Recent studies in Europe and North America show that the biodiversity of flower-feeding insects in modified agroecosystems can remain high provided there are varied floral resources. We are assessing whether this effect is also observed in an Australian context, by investigating the insect pollinator communities of Tasmanian orchards (apple and blueberry) and mixed fruit and vegetable market-gardens. The pollinator communities in Tasmania includes two common introduced bees (Apis mellifera, Bombus terrestris) along with solitary native bees, and other floral visiting insects. Floral-visitation networks are used to assess the role of both crop and non-crop floral resources in the diet of each insect species. To do this the diversity of plants found within and adjacent to production areas are monitored and bees are tracked using florescent dust. When looking at floristic diversity at sites the overall pollinator-plant interactions were inter-webbed, with a range overlapping food-sources, yet also preference towards particular plants. Native and introduced pollinators visited both native and introduced plants, yet there was a strong differentiation of preferences for crop and non-crop flowers. Here it was found that the two introduced bees were the dominate visitors to flowering fruit trees (with Bombus mainly on blueberry not apple) and also diverse crops in market-gardens. In some orchards solitary reed bees (Exoneura) were frequently observed visiting flowering fruit trees, yet in general native insects contributed very little to visitation of particular crops grown. Importantly, a diverse range of non-crop plants, both native plants and introduced plants (i.e. weeds, herbs) were found to play a substantial role the diet of native and introduced flower-feeding insects, consistent with a key role for floral variety in sustaining insect biodiversity in Tasmanian agroecosystems.

Selective effect of fish farming on freshwater communities

Authors: Harabiš Filip[1], Poskocilová Anna-Marie[1], Šípková Hana[1], Hronková Jana[1] and Holer Tomáš[1], [1]Department of Ecology, Faculty of Environmental Sciences, Czech University of Life Sciences Prague, Czech Republic

Abstract: Fish ponds provide vital ecological services and serve as irreplaceable breading sites and key habitats for many rare and endangered species of plants, invertebrates and vertebrates, and can be considered by many as biodiversity hotspots. Nevertheless, the ecological value of ponds is decreasing due to human activities including intensive fish farming involving predation pressure of fish, reduction of macrophyte vegetation, high nutrient loads and turbidity. Although many studies indicate a strong correlation between the abundances macrophyte vegetation, predation pressure of fish and the diversity of aquatic communities, information about the functioning of the individual mechanisms is still missing. Our goal is to focus on the mechanisms behind the formation of aquatic communities. We assume that fishpond management acts as a filter of regional species pool. In other words, that the fishpond management selecting species with certain characteristics. Understanding of these mechanisms may be the key to maintaining a high ß diversity of fishpond areas.

Our research was funded by the Grant Agency of the Czech Republic - GACR no. 18-24425S

Parasitism, lack of parasitism and disruption: native and imported egg parasitoids and their potential to control pomegranate pest butterflies

Authors: Hardy Ian[1] and Al-Riyami Abdulhamid[2], [1]Uni. Helsinki, Finland, [2]Univ. Nottingham

Abstract: Here we consider the relative performance of, and interactions between, imported and indigenous species of natural enemies in biological pest control. Attempts to control the pomegranate butterfly, Deudorix livia, in Oman using two imported and mass-reared species of egg parasitoids, Trichogramma brassicae and Trichogramma evanescens, have not met with great success. From field surveys and laboratory rearings, we show that almost no pest eggs become parasitized by these imported species. However, a naturally occurring parasitoid, Telenomus nizwaensis, attacks around 40% of pest eggs in the field. At present, this native pest cannot be cultured and thus mass-reared for release. Laboratory experiments based on enforced competition indicate that the Trichogramma species can disrupt reproduction by Telenomus nizwaensis. Further, Telenomus nizwaensis typically achieves parasitism too late in the fruiting season to prevent economic damage. A recent field study identified biotic and abiotic factors that affect the seasonal dynamics of butterfly attack on pomegranates and the parasitism of pest eggs by T. nizwaensis, with the ultimate goal of developing methods for improving the native parasitoid’s contribution to conservation biological control.

Quasi-social parasitoid sex ratios under multi-foundress local mate competition with reproductive dominance

Authors: Hardy Ian[2], Lehtonen Jussi[3], Guo Xiaomeng[1], Malabusini Serena[4], Li Baoping[1] and Lupi Daniela[4], [1]Nanjing Agric. Univ, [2]Uni. Helsinki, Finland, [3]Univ. Jyvaskyla, [4]University of Milan, Italy

Abstract: Social Sclerodermus parasitoids in the aculeate family Bethylidae form female multi-foundress groups on large, paralysed hosts and then cooperatively care for large broods of offspring throughout their development. The sex ratios of offspring produced by multi-foundress groups are more female biased than predicted by standard Local Mate Competition (LMC) theory. Using microsatellite markers to identify maternity shows that nearly every foundress produces offspring and overall reproductive skew is mild. However, males are more often the progeny of the largest or earliest-ovipositing foundress, and many foundresses do not produce any male offspring at all. Skew in male production suggests that larger females are able to dominate the production, or the survival, of males. We incorporate reproductive dominance and/or the infanticide of developing males into LMC theory, predicting both the sex ratios of individual foundresses and those of foundress groups. The predicited group sex ratios broadly match empirical observations and thus provide feasible explanation for the extremely female-biased sex ratios produced by multi-foundress groups and more generally expand the scope of LMC theory to consider reproductive dominance.

Dampen or Amplify? The role of soils in modulating threats experienced by bees

Authors: Harmon-Threatt Alexandra, Assistant Professor Entomology, The University of Illinois at Urbana-Champaign, United States

Abstract: Disturbances like climate change, parasites, pathogens, and habitat change are among the greatest threats to bees. Despite bees spending the majority of their life cycle in the nest or in contact with nesting materials, little work has examined how nesting traits of bees (i.e. where they nest) or the environmental characteristics of nest sites may dampen or amplify the threats experienced by bees. Ground-nesting bees are particularly understudied due to the difficulty locating and accessing nest. This lack of work on bee nesting has resulted in a poor understanding of the full effects of disturbances on bees. Combining a review of the literature and recent empirical work, I will discuss how these common disturbances may affect bees and where research is needed to better predict responses of bees to environmental threats.

Evidence of long-distance hoverfly (Diptera: Syrphidae) migration through the Midwestern United States: a stable isotope study (d2H)

Authors: Harmon-Threatt Alexandra[1], Clem Scott[2], [1]Assistant Professor Entomology, The University of Illinois at Urbana-Champaign, United States, [2]University of Illinois at Urbana-Champaign, United States

Abstract: Understanding the winter biology of beneficial insects such as hoverflies (Diptera: Syrphidae) is an understudied, yet vastly important area of research. The adult stages of most hoverfly species are important pollinators of a variety of crops, while the larvae occupy a wide array of niches from detritivores to aphidophagous predators. Several European species exhibit a unique winter survival behavior in which certain individuals migrate hundreds of miles in response to seasonal changes. Few studies to date, however, have directly investigated these behaviors in North American species. The overall purpose of this project is to investigate the migratory strategies of hoverflies through the Midwestern United States using stable deuterium isotopes (d2H) from wing and leg tissues in Urbana, Illinois. Through multiple years of study, we uncover evidence of partial migration in three aphidophagous species: Eupeodes americanus, Syrphus ribesii, and Syrphus rectus. Implications of this behaviour in pollination, biological control, and other ecological phenomena will be discussed.

Pesticide drift into pollinator habitat and its implications for ground-nesting bees

Authors: Harmon-Threatt Alexandra[1], Leonard Ryan[2], Yannerall Anthony[2], [1]Assistant Professor Entomology, The University of Illinois at Urbana-Champaign, United States, [2]University of Illinois at Urbana-Champaign, United States

Abstract: Pesticide drift into natural and semi-natural areas from neighbouring cropland may represent a significant ecotoxicological risk to wild bees including ground-nesting species. The extent of this risk, however, is largely unknown. We quantified the concentration and identity of pesticide contaminants drifting into pollinator conservation areas in prairies bordering cropland in Illinois, United States. Within each prairie, we also quantified the diversity and abundance of wild bees using a combination of active and passive trapping methods and related differences in these variables to pesticide drift concentration and identity, floral resource availability and surrounding land cover type. Our results highlight the need to consider pesticide drift when choosing conservation areas.

New insights into best practices for management of tick vectors

Authors: Harrington Laura[2], Burtis James[2], Stafford III, Kirby[5], A. Diuk-Wasser Maria[1], Cucura Moses[4], Nadolny Robyn[6] and Daniels Thomas[3], [2]Cornell University, United States, [5]The Connecticut Agricultural Experiment Station, United States, [1]Columbia University, United States, [4]Suffolk County Department of Public Works, United States, [6]Tick-Borne Disease Laboratory, Army Public Health Center, United States, [3]Fordham University, United States

Abstract: Tick-borne diseases constitute 77% of all vector-borne disease reported to US CDC. While Lyme disease (B. burgdorferi ss) is the most prevalent vector-borne zoonotic disease, the increasing suite of human pathogens transmitted by the blacklegged tick, lone star tick and the recent introduction/establishment of the Asian longhorned tick in the Western Hemisphere, increases occupational health risk for soldiers training in the field, for military. Here, we present our work in progress, on testing efficacy and integrated approaches to tick control that will reduce tick density. We will focus on three important tick vectors: Ixodes scapularis, Amblyomma americanum and the invasive Haemaphysalis longicornis.

Social and anti-social cockroaches

Authors: Harrison Mark[3], Korb Judith[7], Schal Coby[1], Bornberg-Bauer Erich[9], Jongepier Evelien[5], M Robertson Hugh[8], PM Kremer Lukas[2], Arning Nicolas[10], Richards Stephen[6] and Belles Xavier[4], [3]Institute for evolution and biodiversity University of Muenster, Germany, [7]University of Freiburg, Germany, [1]Department of Entomology and Plant Pathology, North Carolina State University, Raleigh, NC, United States, United States, [9]University of Muenster, Germany, [5]University of Amsterdam, Netherlands, [8]University of Illinois at Urbana-Champaign, United States, [2]German cancer research centre Heidelberg, Germany, [10]University of Oxford, United Kingdom, [6]University of California, Davis, United States, [4]Institute of Evolutionary Biology (CSIC-UPF), Spain

Abstract: Blattodea is an enormously diverse clade, including over 4000 cockroach species that occupy a broad range of habitats across the globe. Several major innovations have occurred within this order, including vivipary (e.g. Diploptera punctata), wood feeding (several taxa) and different levels of sociality, including the eusocial termites. Cockroach genomes belong to the largest known among insects, ranging from 2 - 5 Gb (termites: 0.5 - 2 Gb), including a high level of transposable elements. With comparative genomic and transcriptomic analyses, we aim to better understand the molecular basis of the large diversity and success of this group. We have so far found massive expansions in several gene families but no contractions in the large genome of the omnivorous pest species, B. germanica. Many of these expansions help explain their success in harsh, unsanitary conditions, allowing them, for instance, to develop multiple insecticide and pathogen resistance. Many of these gene families are contracted again within the termites, related to their much more specialist and less septic lifestyles. We have also found evidence for transposable element assisted gene family expansions along with the evolution of termites. A rewiring of important developmental pathways, strong changes in expression patterns and adaptive evolution of genes involved in chemical communication assisted this major transition to eusociality.

The Janzen-Connell Hypothesis; Do insects or microbes drive overcompensating negative density dependent mortality in a Papua New Guinean forest?

Authors: Harrison Stefan[2] and Vojtech Novotny[1], [2]Lab of Tropical Ecology, Institute of Entomology, Czech Academy of Science, Czech Republic, [1]Lab of Tropical Ecology Institute of Entomology Czech Academy of Science, Czech Republic

Abstract: We designed a series of manipulative in-situ experiments to be carried out in the 50Ha CTFS plot in a lowland tropical forest at Wanang Conservation Area in Papua New Guinea. Using an integrative approach, we combined experimental findings with plant trait measurements, and data from a long-term forest dynamics plot. 4000 seedlings of two canopy tree species were transplanted into 96 X 1m2 experimental plots that were treated with either insecticides, fungicides or water (as a control). Plots were placed close to, or far from conspecific mature “parent” trees. Individual tagging of 3840 seedlings within experimental plots allowed seedling survival and RGR to be followed over the course of a year.

In a parallel experiment, the densities of seedlings of one of these tree species were mapped at the 1m2 scale in 21 forest areas where they occurred in naturally high densities. Seedlings were removed in a controlled manner to artificially manipulate densities. Again, replicated plots, where treated with either insecticides, fungicides or water, allowing the fate of 2520 individually tagged seedlings to be tracked over the course of 18 months.

A series of complementary shade-house experiments were also established on the edge of a nearby forest clearing. Seedlings of the same tree species, as well as others, were planted into shade-houses so that within each shade-house there existed an area of seedlings at high and low densities. Insect herbivores that were known to be generalists (from pilot feeding tests) were introduced into shade houses at artificially high densities to test if they were attracted to higher seedling densities. Leaf damage, RGR and survival were recorded over the course of 6 months. Here we present the results after having tracked the survival of 2400 seedlings of two species contained within shade-houses.

These three related experiments show how the expected survival patterns produced by overcompensating negative density dependent mortality - driven by insect and microbial mortality agents - are not clearly observed in these species. Instead, seedling survival seems independent from the effect of insect herbivores and appears to be most clearly linked to mid-densities - where microorganisms are not excluded. From these results, we can hypothesise that, in the case of these tree species, mutualistic fungi are more important to their survival, allowing seedlings to escape the confines of JCH.

We now seek to explore this hypothesis by comparing how the communities of pathogenic and mutualistic soil microorganisms change using from samples taken from the experimental plots prior to the beginning - and following the harvest - of these experiments.

These findings highlight the difficulty in making simple predictions of density-dependent survival when plant-microbe-insect interactions are so complex, interactive, and species dependent.

Investigation of the aggregation pheromone of the Guam haplotype of coconut rhinoceros beetle, Oryctes rhinoceros, CRB-G

Authors: Harte Steven[2], Dewhurst Charles[1], Hall David[4] and Ero Mark[3], [2]NRI, University of Greenwich, United Kingdom, [1]Natural Resources Institute, University of Greenwich, United Kingdom, [4]University of Greenwich - Natural Resources Institute, United Kingdom, [3]Papa New Guinea Oil Palm Research Association (PNGOPRA), Papua New Guinea

Abstract: The coconut rhinoceros beetle, Oryctes rhinoceros (CRB), is a major pest of coconut and oil palm that has been effectively controlled by the Oryctes rhinoceros nudivirus for over 30 years. A new haplotype, CRB-G, that is not controlled by the virus appeared in Guam in 2007 and has since spread to other countries in the Region. There has been much research on alternative methods to control CRB-G, and there have been reports that it does not respond to the well-established aggregation pheromone of CRB.

We found that the male CRB-G beetles produce ethyl 4-methyloctanoate and 4-methyloctanoic acid in 4:1 ratio, essentially as reported for CRB previously by Hallett et al. (1995). The enantiomers of these compounds were synthesised by enzymatic resolution and both the male-produced compounds were shown to be (R)-enantiomers. Hallet et al. (1995) reported that CRB produced the (S)-enantiomers on the basis of field studies, but re-examination of the pheromone produced by CRB beetles confirmed that they also produced the (R)-enantiomers.

Electroantennogram (EAG) responses to natural volatile collections from Oryctes and to the synthetic compounds indicated that both male and female beetles respond to the ester but not to the acid. EAG responses were recorded to both enantiomers, but responses to the ethyl (R)-4-methyloctanoate were consistently greater than those to the (S)-enantiomer.

In field testing in Papua New Guinea, ethyl (R)-4-methyloctanoate was attractive to both male and female CRB-G beetles and significantly more attractive than the (S)-enantiomer. The racemic ester was as attractive as the (R)-enantiomer, and addition of (R)-4-methyloctanoic acid gave a marginal increase in attractiveness of the lure.

Thus CRB-G beetles produce the same pheromone as CRB, although the enantiomeric composition of this was previously wrongly assigned. Both male and female CRB-G are attracted by racemic ethyl 4-methyloctanoate in the field, so that the same lures can be used for monitoring and control of CRB-G as for CRB.

Hallett RH, Perez AL, Gries G, Gries R, Pierce HD, Yue J (1995). Aggregation pheromone of coconut rhinoceros beetle, Oryctes rhinoceros (L.) (Coleoptera: Scarabaeidae). J Chem Ecol 21:1549-1570

Identification of the sex pheromone of the newly described canola flower midge Contarinia brassicola

Authors: Harte Steven[5], Mori Boyd[3], Bray Daniel[2], Hall David[6], Farman Dudley[4] and Vankosky Meghan[1], [5]NRI, University of Greenwich, United Kingdom, [3]Department of Agricultural, Food and Nutritional Science, University of Alberta, Edmonton, Canada, Canada, [2]Chemical Ecology and Plant Biochemistry Group, Natural Resources Institute, University of Greenwich, United Kingdom, [6]University of Greenwich - Natural Resources Institute, United Kingdom, [4]NRI, University of Greenwich, United Kingdom, [1]Agriculture and Agri-Food Canada, Saskatoon, Canada

Abstract: The canola flower midge Contarinia brassicola Sinclair (Diptera: Cecidomyiidae) is a newly-described species that induces galls on canola, Brassica napus Linnaeus and Brassica rapa Linnaeus (Brassicaceae). Identification of the sex pheromone of C. brassicola is essential to develop monitoring tools to elucidate the geographic range and hosts of this new pest, and the extent to which it threatens the $26.7 billion Canadian canola industry. The aim of this study was to identify and synthesise the female-produced sex pheromone of C. brassicola and demonstrate its effectiveness in attracting males to traps in the field. Two peaks were identified through GC-EADanalysis of female-produced volatiles which elicited electrophysiological responses in male antennae. These peaks were initially characterised through GC-MS and synthesis as 2,7-diacetoxynonane (major component) and 2-acetoxynonane (minor component), with the racemic compounds also eliciting EAG responses in male antennae. All four stereoisomers of 2,7-diacetoxynonane were synthesised and the naturally-produced compound was shown to be primarily the R,S-isomer by analysis on an enantioselective GC column. The configuration of the minor component could not be determined because of the small amount present, but was assumed to be R. In field trapping trials conducted in Canada during 2018, the individual stereoisomers of 2,7-diacetoxynonane were unattractive to C. brassicola males. Re-examination of the analytical data suggested that a small amount of (R,R)-2,7-diacetoxynonane was also present in volatiles from female midges. During field trials in 2019, lures loaded with a 10µg:1 µg blend of (R,S)- and (R,R)-2,7-diacetoxynonane caught large numbers of male C. brassicola and significantly more than other blends tested. Addition of 0.5 µg of (R)-2-acetoxynonane to this blend further increased the number of males caught. Planned future work will seek to identify the optimum trapping protocol for use with the pheromone lure, prior to its application in agricultural monitoring and surveillance.

How automation, machine learning, and DNA barcoding can accelerate species discovery in "dark taxa": Integration with Morphology

Authors: Hartop Emily[1], Srivathsan Amrita[1], Ronquist Fredrik[3] and Meier Rudolf[2], [1]Leibniz Institute for Evolution and Biodiversity Science Berlin, [3]Swedish Museum of Natural History, Sweden, [2]Leibniz Institute for Evolution and Biodiversity Science, Germany

Abstract: Tackling poorly known, species rich groups requires innovations in all steps of the discovery process. In this talk, we focus on species delimitation with LIT: Largescale Integrative Taxonomy. The goal of LIT is to achieve the conflicting goals of (1) basing species concepts on multiple data sources while (2) increasing the speed at which we can delimit species in complex, species rich taxa. To achieve this we first determine putative species based on data that are obtained for large numbers of specimens efficiently and at low cost. We then evaluate these preliminary species concepts using a more expensive type of data that we collect for a targeted subset of specimens based on objective criteria. We developed and tested LIT using a dataset of 18 000 phorid flies. We obtained NGS barcodes (our inexpensive primary data source) for all specimens and used them to group specimens into 315 putative species. We then validated these with morphology (secondary data source) using just 5.8% of the total specimens. To do this systematically and objectively, we tested for quantitative indicators that can predict when barcode clusters are likely to be incorrectly aligned with species boundaries. This revealed that maximum p-distance within clusters and stability across different clustering thresholds are both strong indicators of whether an initial delimitation will hold once examined using a secondary data source. We identified these indicators by thoroughly evaluating the first 100 putative species and then tested them with the remaining 215 clusters. This revealed that they correctly identify all problematic clusters, allowing us to target these clusters with greater scrutiny (more specimens examined). Formal LIT protocol requires examination of approximately 5% of the total specimens with a second data source, and further reveals that a third data source is rarely necessary because "incongruent" morphospecies were, in all cases, subsets of initial delimitations, allowing us to rectify species concepts through alteration of clustering thresholds. We evaluate our results across different barcode clustering techniques to show that levels of incongruence are similar across methods, conclusively demonstrating that "barcode only" species delimitations are problematic. In this talk, we include examples from our dataset of practical cluster evaluation to demonstrate how LIT can aide taxonomists in making objective delimitations based on multiple data sources. LIT is part of a larger workflow: an overview talk is being presented separately, and another talk focuses on robotics sorting and photography in preparation for barcoding.

Effects of prescribed fire during drought on bark beetle damage

Authors: Hartshorn Jessica[2] and Palmer Forest[1], [2]Clemson University, United States, [1]Clemson University, United States

Abstract: Prescribed fire has been used to prevent or mitigate southern pine beetle infestations and outbreaks, however, anecdotal evidence suggests that this method during drought conditions may allow for damage by other bark beetles, namely Ips. Little empirical evidence exists to show how extended drought as a result of climate change affects the use of prescribed fire in managed pine in terms of susceptibility or resistance to bark beetle and spb attack. We seek to answer these questions with field observations in burned and unburned stands through the use of prescribed fire across various levels of drought in the southeastern United States. We will trap bark beetles and measure damage, mortality, and brood production across these different treatments to elucidate the effects of drought on host susceptibility to bark beetles. Our overarching goal is to predict the effects of climate change on host resistance and susceptibility and use this information to better manage for native and invasive forest pests.

Quantitative analysis of citizen science data on Heteroptera: example of the invasive heteropteran Halyomorpha halys distribution

Authors: Hartung Viktor[1] and Schneider Alexander[2], [1]Senckenberg Gesellschaft für Naturforschung, Germany, [2]Senckenberg Research Institute and Museum Frankfurt, Germany

Abstract: Citizen science platforms such as iNaturalist.org are getting more and more popular, with tens of thousands of nature aficionados worldwide contributing new photos day by day. Although the users of such platforms often lack taxonomic expertise, the sheer number of their contributions provide a valuable resource for research, since thousands of "amateurs" can access so many regions and habitats with such a regularity that few hundreds taxonomists cannot match. Many professionals already employ citizen science data in their research – however, this research is still mostly qualitative, pertaining to new records of species and distribution shift ranges. Here, we demonstrate that the immense amount of data collected by citizen scientists also has much potential for quantitative approaches. Citizen science data on Halyomorpha halys distribution allows us e. g. to test the hypothesis of this subtropical species' spread in Germany via cities – the so-called "warmth island hopping". We compare its distribution with that of the local pentatomids Palomena prasina and Rhaphigaster nebulosa, the results supporting the city-mediated distribution of H. halys. We hope that this and some additional examples will inspire entomologists to approach more sophisticated questions using citizen-science data.

30 years of arthropod monitoring in German beech forests: outcome and outlook

Authors: Hartung Viktor[1], Schneider Alexander[2], Pauls Steffen[2], Dorow Wolfgang[2], Blick Theo, Köhler Frank, Römbke Jörg and Zub Petra[2], [1]Senckenberg Gesellschaft für Naturforschung, Germany, [2]Senckenberg Research Institute and Museum Frankfurt, Germany

Abstract: Arthropod monitoring program in Hessian forest reserves started at Senckenberg Museum in 1990 and was among the earliest initiatives of that kind in Germany. Its unique feature is concentrating not on few indicator groups, but on species-level data of many diverse taxa, i. a. Coleoptera, Aculeata, Heteroptera (ATBI-approach). 30 years of study uncovered the immense species richness in middle-European beech forest: estimated at several thousand species, 3-4 times more than the numbers accepted before. With taxa pooled and analysed together, their diversity patterns correlated i. a. with forest type, deadwood amount or forestry tradition. Diversity patterns of individual taxa mostly did not show clear environmental correlations, but high variation depending on the reserve and the group, demonstrating the analytical strength of ATBI-approach. The results of the monitoring helped to establish a list of forest affinities for taxa, enabling deeper ecological research in the future. The new monitoring concept that is being developed now will have enhanced statistical power and temporal resolution; a modular structure would make the monitoring expandable on less common forest types or habitats. It is also to integrate modern approaches such as DNA-metabarcoding with the classical morphology-based methods.

Habitat management to enhance insect adaptation to climate change and climatic extremes

Authors: Harvey Jeffrey, Netherlands Institute of Ecology, Netherlands

Abstract: Climate change is one of the greatest threats to biodiversity at all levels of organization. The biosphere has not only been warming over the past several decades, but short-term climatic extremes – in particular heatwaves – are increasing in frequency, intensity and duration. Warming over variable temporal scales poses different kinds of threats to ectotherms like insects. Over longer timescales, insects need to adjust their life-cycles over the course of a growing season, or else alter their distributions pole-wards or to higher elevations to track increasing temperatures to which they are best adapted. This poses a challenge of ensuring that they are also able to find and exploit resources (i.e. food plants, prey, hosts) that are essential for their survival. Heatwaves pose a more immediate threat to their survival, because they can push insects above thermal limits for survival and reproduction. Here, I discuss habitat management strategies to enhance insect resilience to both incipient, longer-term warming and climatic extremes.

The hidden inhabitants: unraveling the seed microbial endophytes of wild cabbage

Authors: Harvey Jeffrey[1], Garbeva Paolina[3], Tyc Olaf[2] and Putra R.[2], [1]Netherlands Institute of Ecology, Netherlands, [3]The Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [2]NIOO-KNAW, Netherlands

Abstract: Endophytic bacteria are known for their ability in promoting plant growth and defense against biotic and abiotic stress. However, very little is known about the microbial endophytes living in the spermosphere.
We isolated bacteria from the seeds of five different populations of wild cabbage (Brassica oleracea L) that grow within 15 km of each other along the Dorset coast in the UK. The seeds of each plant population contained a unique microbiome. Sequencing of the 16S rRNA genes revealed that these bacteria belong to three different phyla (Actinobacteria, Firmicutes, and Proteobacteria). Isolated endophytic bacteria were grown in monocultures or mixtures and the effects of bacterial volatile organic compounds (VOCs) on the growth and development on B. oleracea and on resistance against an insect herbivore was evaluated.
Our results reveal that the VOCs emitted by the endophytic bacteria had a profound effect on plant development but only a minor effect on resistance against an herbivore of B. oleracea. Plants exposed to bacterial VOCs showed faster seed germination and seedling development. Furthermore, seed endophytic bacteria exhibited activity via volatiles against the plant pathogen F. culmorum.
Hence, our results illustrate the ecological importance of the bacterial seed microbiome for host plant health and development.

Molecular tools reveal temporal prey selection by coccinellids in apple and peach orchards

Authors: Harwood James[2], Xu Qingxuan[1], Su Wang[1] and Da Xiao[1], [2]Beijing Academy of Agricultural and Forestry Sciences, China, [1]Beijing Academy of Agricultural and Forestry Sciences, China

Abstract: Molecular tools have revolutionized our understanding of predator-prey food webs. This research examines the structure of coccinellid food webs in apple and peach agroecosystems, documenting how prey selection occurs as prey abundance fluctuates throughout the year.

Abstract to be updated pending season 2019 results.

Low temperature induced diapause in Trichogramma evanescens and T. chilonis reared on Plodia interpunctella: Implications to biological control

Authors: Hasan Md. Mahbub[2], G. Athanassiou Christos[3] and Parveen Nishat[1], [2]Department of Zoology Rajshahi University Rajshahi 6205, Bangladesh, Bangladesh, [3]Laboratory of Entomology and Agricultural Zoology, Department of Agriculture, Crop Production and Rural Environment, University of Thessaly, Phytokou str, 3844, [1]Department of Zoology Rajshahi University Rajshahi 6205, Bangladesh

Abstract: The egg parasitoids, Trichogramma evanescens Westwood and T. chilonis Ishii (Hymenoptera: Trichogrammatidae) are important biological control agents for lepidopterous pests including the Indian meal moth Plodia interpunctella (Hübner) (Lepidoptera: Pyralidae). The role of low temperatures in inducing diapause of the parasitoids, reared on P. interpunctella, was studied in laboratory tests involving long term storage. Both species of Trichgramma could successfully undergo diapause. The temperature of 10°C was considered as a pre-storage requirement for pre-pupal stage for 7 days, while maintenance of temperature to 4°C caused diapause induction. Diapause was terminated after two months of storage with 37.67 and 53.33% of adult emergence in T. evanescens and T. chilonis, respectively. However, there was a significant reduction in longevity and parasitism rate for both species. At 37 days of storage (including pre-storage duration), adult emergence of T. evanescens and T. chilonis was 64.67 and 53.33%, respectively. Successful long term storage of both the species through diapause induction can facilitate commercial insectaries for large scale field releases.

Monitoring and Management of Drosophila suzukii (Diptera: Drosophilidae) in Berry Plantings in Florida

Authors: Haseeb Muhammad[2], Liburd Oscar[4], Parkins Albertha[1], Harmon Dasia[3], Legaspi Jesusa[5] and Kanga Lambert[1], [2]Center for Biological Control, Florida Agricultural and Mechanical University, Tallahassee, FL 32307, United States, [4]University of Florida, United States, [1]Center for Biological Control, Florida Agricultural and Mechanical University, Tallahassee, FL 32307, United States, [3]FoodCorps, Inc, Atlanta, GA 30303, United States, [5]USDA-ARS-IBBRU-CMAVE, Tallahassee, FL 32308, United States

Abstract: Drosophila suzukii (Diptera: Drosophilidae) is an invasive insect pest that was detected in Florida in August 2009 in Hillsborough County. Very limited information is available for berry growers to properly detect and monitor this serious pest in southern highbush blueberry (hybrids of Vaccinium corymbosum L. × V. darrowi Camp), rabbiteye blueberry (Vaccinium virgatum L.), and blackberry (Rubus fruticosus L.) production systems. We compared several D. suzukii traps and lures/baits at two sites in Florida. The traps evaluated included Trécé, Scentry, and a standard homemade cup trap. These traps were compared with various baits and lures, including Trécé lure, Scentry lure, yeast bait, and Suzukii trap, under Florida production systems. Early detection is important to develop an effective monitoring system so management action can be taken before economic damage occurs. Data were recorded as overall trends, as well as in 4–5 trapping periods from early to late season. Overall, the Scentry trap baited with Scentry lure, the Trécé trap baited with Trécé lure + yeast, and the Trécé trap baited with Scentry lure were the best performing traps. Yeast-based traps were also attractive to D. suzukii early in the season, but they did not provide consistent captures as the season progressed. The Scentry trap with yeast bait, the Scentry trap with Scentry lure, the Trécé trap with Trécé lure + yeast bait, and a cup trap with yeast bait caught most of the flies during the first trapping period in 2015 and 2016 in the rabbiteye blueberry. In the southern highbush blueberry, the population of D. suzukii was much lower than in the rabbiteye blueberry planting, and the Scentry trap with Scentry lure captured the highest number of flies during the first trapping period in 2016. In the blackberry, the Scentry trap with Scentry lure numerically had the highest captures during the first trapping period, but this was not significantly different from the cup trap with yeast bait, the Trécé trap baited with Suzukii trap, and the Trécé trap with Trécé lure. Overall, the Scentry trap with Scentry lure was the most consistent trap that captured D. suzukii flies throughout the season in the three production systems—rabbiteye blueberry, southern highbush blueberry, and blackberry. Growers in low pressure systems that are similar to Florida can use the Scentry trap with Scentry lure to monitor D. suzukii populations. In addition, results of the mulching practices on the density of D. suzuki in open field conditions will be discussed.

Transcriptome analysis of genes and metabolic pathways associated with nicotine metabolism and excretion in the midgut and Malpighian tubules of Trichoplusia ni. (Lepidoptera: Noctuidae)

Authors: Hassanpour Nazli[3], Kolosov Dennis[1] and Rheault Mark[2], [3]The University of British Columbia, Canada, [1]McMaster University, Canada, [2]The University of British Columbia, Canada

Abstract: The cabbage looper, Trichoplusia ni (T. ni) is a generalist insect (Lepidoptera: Noctuidae) that is an agricultural pest of crucifers and other crops of economic importance. The most common insecticides currently in use around the world are neonicotinoids, which are chemical derivatives of nicotine. Enriched metabolic detoxification of xenobiotics like nicotine have been linked to the increased expression of cytochrome P450s (CYPs) in insects. Recent studies in our lab have shown that the midgut and the Malpighian (renal) tubules of T. ni actively excrete and detoxify nicotine into the three major metabolites; cotinine, continine-N-oxide, and nicotine-N-oxide. In this study we have used High-throughput transcriptome sequencing methods to analyze the expression profile of transcripts in the midgut and Malpighian tubules of both control and nicotine exposed T. ni. Of the 24,653 putative transcripts in the T. ni transcriptome, our RNAseq analysis detected 22,331 transcripts in the midgut and 21,737 transcripts in the Malpighian tubules. In nicotine exposed insects, 21% and 14% of detected transcripts showed increased expression in the midgut and Malpighian tubules, respectively. Conversely, 16% and 10% of detected transcripts showed decreased expression in the midgut and Malpighian tubules, respectively. Of the transcripts that displayed up-regulation, 49 transcripts in the Malpighian tubules and 28 transcripts in the midgut were identified as cytochrome P450s (CYPs), which are known to play a primary role in insecticide and nicotine metabolism and detoxification. We have identified a number of additional xenobiotic metabolizing enzymes including 4 carboxylesterases (CEs), 11 glutathione-s-transferases (GSTs), and 9 uridine diphosphate-glucuronyltransferase (UGTs) that were up-regulated in the midgut tissue. In the Malpighian tubules, 11 CEs, 12 GSTs, and 16 UGTs were also shown to be up-regulated. In addition to the increased expression of metabolic transcripts, we have identified a number of transcripts associated with the excretion and transport of xenobiotics including nicotine. Dietary nicotine exposure increased expression of 2 transcripts in the midgut and 5 transcripts in the Malpighian tubules identified as ABC transporters, which have previously been shown to play a role in the excretion of nicotine by insects. 4 transcripts in the midgut and 14 transcripts in the Malpighian tubules identified as organic cation transporters (OCTs) also had increased expression. The combined use of transcriptomics, novel analytical methods and physiological studies will increase opportunities for development of new biochemical and physiological targets for the control of insect agricultural pests and disease vectors which are economically, environmentally, and medically valuable.

Tackling above and below ground pests in Potato Production in Kenya

Authors: Haukeland Solveig[2], Akutse Komivi[1], Nyongesa Moses[3], [1]ICIPE, Nairobi, Kenya, [2]International Centre of Insect Physiology and Ecology, Nairobi, Kenya, [3]KALRO Kenya Agriculture and Livestock Research Organization, Kenya

Abstract: Potato is a valuable food and cash crop in the East African region, and in Kenya it is ranked second in importance after maize. Production and yields have declined by about 50%, from about 20t/ha to less than 9t/ha in the last 15 years, despite an increase in the area grown. Pest infestations are likely to be one of the reasons for these declining yields. In Kenya, 90% of potatoes produced are grown by about 800,000 smallholder farmers often on less than an acre of land. This becomes a challenge regarding crop rotation (not enough land). Thus, year in year out growing potatoes on the same piece of land results in build up of pests and diseases. Unlike temperate climatic regions such as Europe, where potatoes are grown for one season in the summer, in Kenya the climate allows for potatoes to be grown for at least two seasons a year, three if irrigation is available, further allowing build up of pests and diseases. Reports have shown that the main production constraints are at the production level and a lack of GAP (good agricultural practices). In this presentation an overview of potato production in Kenya and the region will be presented, with emphasis on the key known pests that cause production losses. The presentation will also share current studies and results from field surveys and trials with respect to above and below ground pests recently detected in the region. Finally, points and suggestions for further studies and collaborative opportunities will be addressed.

Monitoring of insects at migratory hotspots: origins, diversity and their ecological impact on us all

Authors: Hawkes Will, University of Exeter, United Kingdom

Abstract: Insect migrants often number in the trillions and carry out vital ecological roles, connect distant ecosystems and transfer vast amounts of biomass and nutrients. Despite this, insect migration is still a comparatively understudied phenomenon with research thus far focusing primarily on Lepidoptera (moths and butterflies), Odonata (dragonflies) and the Syrphidae (hoverflies), many of which are known to co-migrate through Europe. Quantifying how the numbers and relative composition of different species vary across Europe is a formidable task but necessary if we are to understand the contribution these organisms make when moving between often-distant ecosystems. My research takes a comparative approach, identifying migratory assemblages of insects and quantifying numbers, across multiple migration hotspots during spring (northwards) and autumn (southwards) migrations in Europe across multiple years. My research combines traditional techniques of trapping, counts and transects together with high-resolution imaging to identify and quantify migrants from funnel points in European mountains and islands. We have recently quantified transit rates as high as 11 million flies per day, found evidence for multiple novel insect migrants, identified putative geographic sites of origin and began to identify drivers of annual variations in the makeup of migrant assemblages and numbers. Current research is focusing on understanding migratory routes, assessing the effect of migrants on the ecosystem as a whole and establishing long-term monitoring of migratory populations. In the current declining state of insect populations worldwide, finding out what insects are migrating (and in what numbers), as well as their effects on the global ecosystem, has never been more vital.

Updated Genome of the infamous Amikafer, Colorado potato beetle, L. decemlineata Say

Authors: Hawthorne David[1] and Schoville Sean[2], [1]Department of Entomology University of Maryland College Park, United States, [2]Dept. of Entomology University of Wisconsin, United States

Abstract: The Colorado potato beetle is a noxious insect pest on Solanum crops such as: potato, tomato and eggplant. Despite its native range of the South Western United States and Mexico it has expanded where potato is grown and become economically impactful in Europe and Asia. Its ability to develop resistance to insecticides and rapidly adapt to novel ecosystems makes it an ideal model to study genome evolution and population genetics. Using a trio-binning approach, (Koren et al., 2018) we significantly enhanced the original genome assembly from the first version, (Schoville et al., 2018), that had approximately 24K scaffolds with an N50 414Kb, to a new version with fewer than 1000 scaffolds and an N50 of approximately 8Mb. Trio binning assembly is carried out by crossing highly unrelated parents, sequencing their genomes using short, paired-end read data, sequencing their highly heterozygous offspring with long-read data at high depth of coverage, resolving the F1 haplotypes using parental short read data and ultimately generating two assemblies from one individual. These haplotype assemblies could elucidate recombination and mutation rates of this pestiferous insect, and may provide insight into novel genomic features that contribute to its success in agroecosystems.

Updated Genome of the infamous Amikafer, Colorado potato beetle, Leptinotarsa decemlineata Say

Authors: Hawthorne David[1] and Schoville Sean[2], [1]Department of Entomology University of Maryland College Park, United States, [2]Dept. of Entomology University of Wisconsin, United States

Abstract: The Colorado potato beetle is a noxious insect pest on Solanum crops such as: potato, tomato and eggplant. Modifying populations of wild Drosophila suzukii through gene drive

Authors: Hay Bruce[1], Oberhofer Georg[1], Guo Ming[2] and Ivy Tobin[1], [1]California Institute of Technology, United States, [2]UCLA David Geffen School of Medicine, departments of Neurology and Pharmacology, United States

Abstract: Drosophila suzukii is an invasive species and major pest of soft fruits. Thus an important goal is to develop ways of suppressing these populations. We recently developed a new method of gene drive known as Cleave and Rescue (ClvR). ClvR elements consist of two components. The first is Cas9 and gRNAs (the toxin). These target an essential gene for destruction through cleavage at multiple sites followed by inaccurate repair. The second component (the antidote) is a recoded version of the essential gene that is insensitive to clveavage and loss-of-function allele creation. Together these components create a novel selfish genetic element. Progeny of ClvR-bearing parents that fail to inherit ClvR die because they lack any functional copies of the essential gene. In contrast those who inherit ClvR always survive because they carry with them the recoded version of the essential gene. ClvR spreads under a variety of conditions, and when it spreads it proceeds to genotype or allele fixation.

We have created three different ClvR elements in Drosophila melanogaster and shown that they spread to genotype fixation in genetically diverse populations PNAS 2019). We have also shown that multiple cycles of ClvR-dependent population modification can be carried out, with second generation elements spreading into populations previously fixed for an earlier element, while at the same time driving the earlier generation element out of the population (PNAS 2020).

Here we describe our progress in developing ClvR-based strategies for population suppression for Drosophila suzukii. In brief, we are pursuing two approaches.

In the first we create ClvR elements in which the antidote is temperature sensitive, allowing susukii to survive at lower temperature, but causing death at higher temperatures. This may be useful as a control strategy in which the wildtype population of suzukii is initially replaced with ClvR-bearing versions during a low temperature season. As temperatures rise during the year the ts version of the essential gene becomes non-functional, resulting in a population crash.

In the second approach we use ClvR to drive a fitness load into the population such that 50% of individuals die in each generation. If several independently acting elements of this type were introduced into a population strong population suppression would be predicted to occur.

Potential impact of Trissolcus japonicus on populations of Halyomorpha halys and non-target species in Europe and North America

Authors: Haye Tim[1], Hoelmer Kim[2], [1]CABI, Switzerland, [2]USDA-ARS, Newark, United States

Abstract: The brown marmorated stink bug, Halyomorpha halys, native to East Asia, is an invasive alien pest that arrived in Europe and North America in the 1990s and early 2000s, respectively. The Asian egg parasitoid Trissolcus japonicus was identified as the most promising agent for classical biological control of H. halys. Host specificity testing of T. japonicus has been carried out under containment conditions in North America and Europe and overall, these studies came to the very similar conclusions that T. japonicus' fundamental host range is restricted to the Pentatomoidea, but the parasitoid is capable of successfully parasitizing the eggs of several pentatomids and a few species of scutellerids other than H. halys. Before any laboratory risk assessment studies for T. japonicus had been completed, adventive populations of T. japonicus were detected North America and Europe. These unintentional introduction of T. japonicus provided a unique opportunity to validate retrospectively estimates of fundamental host range with realized (ecological) `post arrival´ host range as it manifested over time.

Review on the biology of Trissolcus japonicus in China and implications for its use for biological control

Authors: Haye Tim[3], Zhang Jinping[2], zhang feng[1] and mi qianqian[1], [3]CABI, Rue des Grillons 1, 2800 Delémont, Switzerland, [2]1MoA-CABI Joint Laboratory for Bio-safety, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, 2 Yuanmingyuan West Road, Beijing 100193, Ch, China, [1]1MoA-CABI Joint Laboratory for Bio-safety, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, 2 Yuanmingyuan West Road, Beijing 100193, Ch

Abstract: The brown marmorated stink bug, Halyomorpha halys, native to subtropical and temperate areas of East Asia, has emerged as a harmful invasive pest of a variety of crops in America and Europe. In its native range eggs of H. halys are attacked by more than ten species of parasitoids, among which Trissolcus japonicus was identified as the most promising biocontrol candidate. It parasitizes H. halys eggs over the course of the entire season in China, from May to September, and is consistently the dominant parasitoid species on H. halys eggs, with reported parasitism levels ranging from 47% to 78%. However, its host range comprises at least seven additional pentatomid hosts. Trissolcus japonicus searches for host eggs in a variety of habitats and on several host plant species, including shrubs and trees within suburban peach orchards, and forested parks as well as maize fields and vegetable crops such as green beans, eggplant, tomato, and pepper. In areas of China where H. halys undergoes two generations per year, T. japonicus may complete up to ten overlapping generations over the course of a season. Its distribution ranges from the northern, temperate province Heilongjiang to the southern, subtopical province Guangdong. Single females can produce more than 100 offspring. The development time from egg to adult was10.5 days at 25°C and the minimum threshold temperature for development was estimated to be 12.2°C, with a thermal constant of 132.5 degree-days. Frozen and unfertilized egg of H. halys can be used for mass rearing T. japonicus and in addition, adult females can be stored up to 19 weeks at 11°C with 90% survival. The optimal timing and frequency of mass releases of T. japonicus in fruit orchards is still under development.

Is the symbiotic yeast Kodamaea ohmeri playing a role in the aggregative behaviour of the honeybee pest Aethina tumida?

Authors: Hayes R. Andrew[1], Amos Brogan[4], Leemon Diana[2] and Furlong Michael[3], [1]Forest Industries Research Centre, University of the Sunshine Coast, Australia, [4]School of Biological Sciences, The University of Queensland; Department of Entomology, University of California, Riverside, Australia, [2]Queensland Department of Agriculture and Fisheries, Australia, [3]School of Biological Sciences, The University of Queensland, Australia

Abstract: The small hive beetle Aethina tumida (Coleoptera: Nitidulidae) displays aggregative behaviour and previous research has identified an aggregation pheromone. We used laboratory assays to investigate the conditions under which of this aggregation occurs and its purpose, beyond its reported role in assisting reproduction, and to understand the role of the symbiotic yeast Kodamaea ohmeri (Ascomycotina: Saccharomycotina) in the aggregation. We investigated clustering of mated and unmated male and female conspecifics, as well as clustering with dead conspecifics. We also examined the beetle's ability to form clusters after bilateral anntenectomy; and without the associated yeast. Aggregation under laboratory conditions appears to be sex neutral, only occurs in response to other live A. tumida, and is facilitated by intact antennae (chemoreceptive organs) and the presence of K. ohmeri. We determined that antennectomised beetles and beetles reared without K. ohmeri each took longer to form clusters (=aggregation of five or more beetles) and the clusters formed were smaller. We determined that horizontal transmission of K. ohmeri is possible and appears to be facilitated by the beetle's aggregation behaviour. Following the differences in behaviour of K. ohmeri-free beetles, hexane extraction analysis showed differences in the cuticular compounds of K. ohmeri-free beetles and untreated beetles. This work extends our current understanding of A. tumida aggregative behaviour and conspecific communication, which may have potential in control and management strategies for this pest.

Harnessing EPN bacteria metabolites for new drugs and biocontrol agents

Authors: Hazir Selcuk, Aydin Adanan Menderes University, Faculty of Arts and Sciences, Department of Biology, AYDIN, Turkey

Abstract: Xenorhabdus and Photorhabdus species are insect pathogenic bacteria that are symbiotically associated with entomopathogenic nematodes. These bacteria produce various secondary metabolites to protect insect cadavers against competitors allowing them to survive in nature with their nematode host. Antibacterial, antifungal, antiprotozoal, insecticidal, ovicidal, larvicidal, anticancer, scavenger and mosquito deterrent activities of metabolites produced by Xenorhabdus and Photorhabdus spp. have been discovered. Recently, the antibacterial activity of bacterial supernatants was tested against the multi-drug resistant pathogen Enterococcus faecalis; as a result, a compound was identified having better activity than chlorhexidine and calcium hydroxide. The novel compound eliminated 99.9% of the bacteria in dental root canals. Xenorhabdus and Photorhabdus supernatants were screened on human parasitic protozoa, Acanthamoeba castellanii, Leishmania tropica and Trichomonas vaginalis and potential new antiparasitic drugs were identified. Researchers also evaluated the antifungal activity of secondary metabolites on various plant and human pathogenic fungi and obtained promising results by identifying new antifungal compounds. To control vector-borne diseases, bacterial metabolites have been assessed against developmental stages of mosquitoes and a novel larvicidal compound showing 100% mortality in 24h was explored.

Biosynthesis of Gold and Silver Nanoparticles from the Symbiotic Bacterium, Photorhabdus luminescens of Entomopathogenic Nematode: Larvicidal Properties against Mosquito and Galleria mellonella larvae

Authors: Hazir Selcuk[1], Raja Ramalingam Karthik[4], Arun A.[3], Sankaranarayanan C.[5] and Aiswarya D[2], [1]Aydin Adanan Menderes University, Faculty of Arts and Sciences, Department of Biology, AYDIN, Turkey, [4]Department of Microbiology, Alagappa University, India, [3]Department of Microbiology, Alagappa University, India, [5]Sugarcane Breeding Institute, Coimbatore, India, [2]Department of Biotechnology, Periyar University, India

Abstract: The present investigation focuses on the larvicidal property of gold and silver nanoparticles (AuNPs and AgNPs) that were synthesized using the supernatant of Photorhabdus luminescens strain KPR-8B from nematode. The synthesized AuNPs and AgNPs were characterized through UV–visible spectrophotometer, X-ray diffraction analysis, Fourier transform infrared spectroscopy, dynamic light scattering and high-resolution transmission electron microscopic analyses. The characterization studies confirmed the spherical shape and size (14–46 nm) of AuNPs and AgNPs. The synthesized AuNPs and AgNPs were evaluated against 4th instar larvae of three mosquitoes, Aedes aegypti, Anopheles stephensi and Culex quinquefasciatus. The highest larval mortality was observed after 24 h from the KPR-8B derived AuNPs against A. aegypti with the LC50 and LC90 values of 5.04 and 12.65 lg/ml, respectively.

Response of the Asian corn borer to high temperature extreme

Authors: He Kanglai[3], Wei Hongyi[2] and Quan Yudong[1], [3]State Key Laboratory for Biology, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing 100193, China, [2]Jiangxi Agricultural University,Nanchang 330045,Jiangxi Province, China, [1]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing 100193, China

Abstract: Global worming demonstrates not only a significant rise of average temperature, but also results in the frequent appearance of extraordinarily daily high temperature. A transient high temperature, particularly early in embryonic stage, could profoundly affect insect performance across all subsequent life stages. To understand the effects of the transient exposure to extremely high temperatures on egg, neonate and adult of Ostrinia furnacalis, the half lethal temperature (LT50) and the survival rate with 6 h high-temperature exposure,and the half lethal time (Lt50) under different high temperatures were examined. The LT50 values of egg, neonate and moth were 40.2-40.4, 38.6 and 42.8- 44.5?, respectively. The Lt50 values of egg,neonate and moth were 0.38-6.31, 0.22-8.35 and 3.80-24.15 h,respectively. In addition, we assessed the impact of a transient exposure to extremely high temperature on egg of O. furnacalis for biological parameters across subsequent life stages. Eggs were heat-shocked to 5 temperatures from 37 to 45 ? for 90 min, and then transferred to control of 25 ?. Effects of heat shock on egg hatching rate were significantly different among treatments. No larvae hatched out at treatment of 45 ?. The development times had no difference at egg stage, but a significant prolong at treatments of 41 and 43 ? at larval and pupal stages. Pupal masses were significantly increasing at treatment of 39 ? for male. There were no significant differences for fecundity and sex ratio among treatments. The phenomenon of protandry appeared at treatments of 39 and 41 ?, but faded away at treatment of 43 ?. Our findings indicate that extremely high temperatures significantly influenced the survival rate of O. furnacalis. A critical point of temperature may exist between 39 and 41 ?.

Effects of spruce budworm outbreaks and suppression on carbon dynamics in forest soils

Authors: Heard Stephen[3], Stastny Michael[2], Wagg Cameron[1] and Comeau Louis-Pierre[1], [3]University of New Brunswick, Canada, [2]Canadian Forest Service, Canada, [1]Agriculture and Agri-Food Canada, Canada

Abstract: Multi-year outbreaks of spruce budworm (Choristoneura fumiferana), a lepidopteran defoliator of fir and spruce, extend over millions of hectares and are the most important natural forest disturbance in the mixed and conifer forests of eastern Canada. Canopy loss and tree mortality reduce photosynthesis and presumably change microclimate and microbiota of forest soils. In the short term, defoliation also may increase carbon inputs to soil, in the form of insect frass and litterfall. However, the effects of these disruptions on carbon cycling are poorly understood. The regional management of spruce budworm through aerial application of biological insecticides offers an opportunity to understand impacts of budworm on carbon cycling. It also raises the possibility managing those effects in future – in one of the Earth's most extensive, and most C-rich, forest biomes.

We have begun a multi-year experiment in eastern Quebec, Canada to quantify carbon-cycle processes in 12 forest watersheds at the onset of a spruce budworm outbreak. We are experimentally manipulating defoliation in half of the watersheds through spraying with Btk. We are sampling soils for litter, carbon, nitrogen, and mycorrhizal colonization, measuring soil temperature, in-situ soil metabolism, and cotton-strip decomposition rates, and measuring frass and litter inputs to soils. Together, these data will reveal how defoliation influences soil biota and their roles in carbon cycling. Data from the first field season reveal patterns in frass- and litterfall among sites differing in baseline defoliation, but only subtle differences in soil parameters. These results are consistent with our pilot work in nearby sites with longer defoliation histories and suggest that carbon cycling effects are likely to accumulate over many years during the typically persistent outbreaks of spruce budworm.

Genome size evolution in the diverse insect order Trichoptera

Authors: Heckenhauer Jacqueline[1], Pauls Steffen, [1]LOEWE Centre for Translational Biodiversity Genomics, Germany

Abstract: Aquatic insects are underrepresented in genomic studies. To expand the availability of aquatic insect genomes, we generated de novo genome assemblies of 17 caddisflies covering major lineages of the order. We used these genomes to understand genome size evolution and detected a ~14-fold variation in genome size across the order. We find strong evidence that repetitive element expansions, particularly those of transposable elements (TEs), are important drivers of large caddisfly genome sizes. Using an innovative method to examine TEs associated with universal single copy orthologs (BUSCO genes), we find that TE expansions have a major impact on protein-coding gene regions, with TE-gene associations showing a linear relationship with increasing genome size. Expanded genomes preferentially evolved in caddisfly clades with a higher ecological diversity (i.e., various feeding modes, diversification in variable, less stable environments). Our findings provide a platform to test hypotheses about the potential evolutionary roles of TE activity and TE-gene associations, particularly in groups with high species, ecological, and functional diversities.

The application of environmental DNA technology to assess climate change extinction in arid-land invertebrate communities

Authors: Hedges Brock[2], Beasley-Hall Perry[3], Guzik Michelle[3], Austin Andy[1] and Weinstein Philip[2], [2]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, SA 5005, Australia, Au, [3]The University of Adelaide, [1]Australian Centre for Evolutionary Biology and Biodiversity, Department of Ecology and Evolutionary Biology, the University of Adelaide, SA 5005, Australia

Abstract: The granite rock-holes present across much of arid and semi-arid southern Australia are a unique ephemeral freshwater habitat. A complex but understudied community of invertebrates (primarily insects and crustaceans) is associated with these sites. Due to a projected drying climate over the next 100 years, the security of these ephemeral freshwater ecosystems is uncertain. Increased use by invasive vertebrates (namely goats and sheep) and over-abundant native species (primarily macropods), is also impacting water quality throughout the region. We employed environmental DNA (eDNA) techniques to assess the degree to which these invertebrate communities vary both spatially and temporally. Filtered water samples were taken from a series of rock-holes in the arid-lands of South Australia that varied in distribution, shape, water chemistry and habitat structure. Next generation sequencing reads from broad and targeted Cytochrome c oxidase I and 18S eDNA metabarcoding assays recovered Operational Taxonomic Units from a range of insect and crustacean taxa known from arid-lands freshwater ecosystems. Preliminary analyses show that communities vary between rock-holes and that resampled rock-holes vary in composition between sampling events. It is likely that invertebrate species richness is affected by characteristics of rock-hole shape and vegetation structure. The use of eDNA techniques in this study show promise as a tool for assessing community composition and as an indicator of overall ecosystem health. Preliminary conservation recommendations to safeguard the invertebrate communities of these unique Australian granite rock-holes include targeted pest management and prioritisation of high diversity sites. Future research and monitoring of rock-hole communities is needed to better understand the potential impacts of climate change on invertebrate gene flow in disconnected habitats.

A major overhaul of the lepidopteran fossil record in light of recent advances in the systematics of the order

Authors: Heikkilä Maria, Finnish Museum of Natural History, LUOMUS, University of Helsinki, Finland

Abstract: In recent years, advances in research on the morphology and systematics of many groups of Lepidoptera have been made. Now, this new knowledge is applied in the re-examination of the identifications of all known fossil Lepidoptera. Previous identifications have been considered doubtful as many of them were made in the late 1800s or early 1900s when the classification of Lepidoptera was very different. For a few years now, an international network of experts has been re-examining the fossils and reviewing previous identifications. This work has proven worthwhile as unfortunately many, if not most, of these identifications have turned out to be unsubstantiated and based on overall similarity to extant species, not apomorphies. In their work, the teams have encountered fossils that cannot securely be placed in any subgroup of Lepidoptera, are not lepidopterans at all, and fossils that have been misdated. The work has helped make identifications more accurate and provided reliably identified fossils to be used e.g. in studies exploring the evolutionary history of moths and butterflies. The project is ongoing — several publications have already come out and others will in the near future. I will present new results by the teams of experts examining these fossils.

The domed functional response: a review of its potential importance to biological control and a case study

Authors: Heimpel George[2], Asplen Mark[1], Carter Megan[2], [1]Metro State University, [2]University of Minnesota

Abstract: In the type four, or domed, functional response, per-capita attack rates by predators decline at high prey densities. This is in contrast to the more familiar functional response types 1-3, in which attack rates remain constant at high prey densities. Domed functional responses have not been routinely considered in biological control interactions but may have important implications for the ability of natural enemies to control populations of pests. We found that the aphid parasitoid Binodoxys communis exhibited a domed functional response to the soybean aphid, Aphis glycines, in a laboratory mesocosm experiment and discuss potential mechanisms that could lead to such a response. We also consider the possibility that domed functional responses may be underappreciated in biological interactions.

Ground-dwelling arthropods as vectors for phytopathogenic fungi- introducing the mobile link concept to vector biology

Authors: Heitmann Nadja[1], E. H. Müller Marina[1] and Glemnitz Michael[1], [1]Leibniz Centre for Agricultural Landscape Research (ZALF), Müncheberg, Germany

Abstract: The movement pattern of a vector has a crucial impact on its ability to spread pathogens. The mobile link concept focuses on how movement patterns effect processes, resources, genetic exchange and also the spread pathogenic microorganisms. This concept can provide a different approach on how to deal with and to identify possible vector species. With first results from empirical field work, we ´d like to point out the relevance of arthropods for the spread of agricultural diseases.

We focused on the transport of phytopathogenic fungi by the ground-dwelling carabid beetles that move regularly between small isolated natural wetlands (kettle holes) and adjacent crop fields. Ground beetles could be important vectors since kettle holes also provide ideal conditions for many fungi. Therefore an indirect spatial-temporal interaction is inevitable.

Our first analyses aimed to verify our basic assumption that phytopathogenic fungi can be found on the external body surface of ground beetles. 41 carabid beetles were collected in crop fields near kettle holes and treated with a washing method that removed superficial fungal propagules from the exoskeleton. We isolated 648 fungal colony forming units (CFU). 51 CFU belonged to 8 different Fusarium species, 24 identified as F. culmorum, a fungi able to infect plants also via the root system. Furthermore 9 CFU were identified as Alternaria fungi belonging to 4 different species-groups. Both fungal genera infect different weeds and crop plants, produce mycotoxins and cause yield loss.

Ground-dwelling arthropods carry a variety of fungal propagules including phytopathogenic species. It`s very likely that this transport mechanism favors more fungal propagules that are close to the ground than the wind dispersal. The effect of insect dispersal on the fungal community could therefore be different and relevant for agricultural management.

Genetically engineered crops: Challenges and opportunities for promoting biodiversity in the agroecosystem

Authors: Hellmich Richard, USDA and Iowa State University, United States

Abstract: Growers from a generation ago would find many differences if they walked through fields with genetically engineered (GE) crops today. Now there are fewer weeds due to herbicide-tolerance traits and much less insect damage due to insect-resistance traits. On closer inspection, compared with non-GM crops, they might even note improved grain quality and more insects that are beneficial. A grower today, however, walking through the same field with a grandchild might ask, “What lays ahead, will the agroecosystem a generation from now be better and how”? This talk will explore challenges and opportunities of GE crops related to biodiversity. The talk will emphasize the whole ecosystem including non-cropped lands near GE crops. Cool-season sod-forming grasses, particularly smooth brome (Bromus inermis), dominate many of the non-crop lands in the United States. These grasses historically have been used for erosion control but do not promote biodiversity. Studies in the state of Iowa in the U.S. have focused on replacing these grasses with native habitat that includes forbs for pollinators and other insects. In addition, there may be opportunities to improve the rhizosphere and accompanying biota within fields, especially if GE crops promote the use of cover crops. Finally, if future GE crops allow growers to further decrease chemical inputs and increase reduced tillage that too would promote sustainability and biodiversity.

Challenges and opportunities for promoting biodiversity in agroecosystem

Authors: Hellmich Richard[2], Fisher Kelsey[1], [2]USDA-ARS-CICGRU, [1]Iowa State University, United States

Abstract: Biodiversity in monoculture agroecosystems is limited. This presentation will discuss challenges and opportunities for improving biodiversity through the lens of monarch butterfly conservation in the north-central United States.

Phylogenetic relationships within Eutrichophora and Pyrrhocoroidea (Hemiptera: Heteroptera) inferred from the morphology of metathoracic scent efferent system, abdominal ventrites and trichobothria

Authors: Hemala Vladimír[2], Malenovský Igor[1] and Kment Petr[3], [2]Dpt. Botany and Zoology, Faculty of Science, Masaryk University, Brno, Czechia, [1]Department of Botany and Zoology, Faculty of Science, Masaryk University, Czech Republic, [3]Dpt. Entomology, National Museum, Praha, Czechia

Abstract: Eutrichophora forms a diverse, well-supported clade within pentatomomorphan true bugs, consisting of the superfamilies Coreoidea, Lygaeoidea and Pyrrhocoroidea. However, the precise phylogenetic relationships among these taxa are unclear. Previous studies proposed four mutually conflicting hypotheses, each supported by several molecular and/or morphological datasets. In our study, we focused on the comparative morphology of the external structures of the scent efferent system of metathoracic glands, including the microstructure of the metathoracic spiracle opening, and abdominal ventrites including their sensory organs (trichobothria). A cladistic analysis of 23 characters supported Pyrrhocoroidea as a sister-group to Coreoidea + Lygaeoidea. Hyocephalidae were supported as the most basal group within the Coreoidea. Within the previously poorly studied Pyrrhocoroidea (of which we examined 64 genera, i.e. 90%), Larginae, Physopeltinae and Pyrrhocoridae were each well-supported as monophyletic but their relationships to each other and their internal phylogenies remained largely unresolved. We have identified several new synapomorphies for individual superfamilies, families or subfamilies but have found no synapomorphies that support monophyly of Largidae or any of its currently recognised tribes. Future studies of additional morphological (e.g., male and female terminalia, mouthparts, and wing venation) and molecular characters are therefore necessary to better understand the evolution of the Pyrrhocoroidea.

A floral colour changing tree benefits from pollinator learning

Authors: Hempel de Ibarra Natalie[4], Somanathan Hema[1], MG Balamurali[2], Barua Deepak[3] and Chakravarthy Souparna[3], [1]Indian Institute of Science Education and Research Thiruvananthapuram, [2]School of Biology Indian Institute of Science Education and Research Maruthamala PO, Vithura Thiruvannanthapuram - 695551 Kerala, India, [3]School of Biology Indian Institute of Science Education and Research Pune, India, [4]University of Exeter, United Kingdom

Abstract: We report a hitherto unknown strategy that exploits pollinator learning while uncoupling pigment synthesis, reward production and fertility. Catuneregam spinosa flowers, whether pollinated or not. transform from white to yellow, extending stigma/pollen viability, nectar secretion and bee-visitation to yellow flowers. We hypothesised that bees utilise both colour cues for long-distance location and short-distance discrimination. In Y-maze experiments with differentially rewarding artificial flower arrays, bees preferred yellow-dominated over white-dominated arrays from longer distances both spontaneously and after training to equal-proportion white and yellow array. On reaching the array, they visited white which they had previously learnt as higher-rewarding. We demonstrate that post-change flowers generate an effective long-distance colour signal and can contribute to direct fitness. Differential rewards combined with extended fertility constitute an alternative mechanism to maximise visitation in colour-changing plants.

Larval feeding behaviour and host food plant preference of endangered Poweshiek skipperling (Oarisma poweshiek) in Canada

Authors: Henault Justis[2] and Westwood Richard[1], [2]Department of Biology, University of Winnipeg, Canada, [1]Department of Biology, University of Winnipeg, Canada

Abstract: We investigated biological and structural factors within larval microhabitats of the endangered Poweshiek skipperling (Oarisma poweshiek) in Canada. This once common butterfly is endemic to remnant tall grass prairie ecosystems in North America with only two remaining population centres found in Manitoba, Canada and Michigan, United States. The Poweshiek skipperling is now in imminent danger of extirpation and increased knowledge of adult and larvae habitat requirements are urgently needed to keep the remaining populations extant. For the first time in natural habitats we determined the specific larval host plants and documented larval development and behaviour. We found larvae remain in close proximity to host plants where the initial egg was laid but that they feed on several different grass species at different times during the summer season. Larval microhabitats are occupied for over 11 months and contain very specific physical characteristics and plant diversity which is essential to successful development to adulthood. This information will be essential to help conservation experts to increase the quality of remaining habitat, prioritize suitable tall grass prairie to support reintroduction and successfully protect this species from extinction.

Overcoming Barriers for Lesbian, Gay, Bisexual & Transgender Entomologists (LGBT) to Create a More Inclusive Discipline

Authors: Hendrix William[2], Jordan Kyle[1], [1]BASF, United States, [2]Valent USA LLC, United States

Abstract: As the population in many Western cultures rapidly changes to reflect a much more diverse population and the cis white male paradigm shifts, there has been increasing interest in looking at diversity in academia. Although laudable, these efforts often focus on the more visible signs of diversity such as race and gender. Over the last 20 years, lesbian, gay, bisexual, and transgender (LGBT) individuals have seen increased parity in society, the community and the workplace both in the US and abroad. However, with rapid social change also comes concern and visible opposition. Currently, numerous countries offer no protection from discrimination if you are perceived to be gay or lesbian or transgender. Stepping into the void, many universities, government agencies, and multi-national companies prohibit discrimination against LGBT individuals, creating a situation where a potential student or employee has more rights while on campus or at the workplace than they would have in their local communities. Understanding LGBT individuals' needs within entomology and the broader sciences is also difficult due to remaining societal stigma attached to being LGBT.

For many there is still a need to develop the business case for encouraging and supporting LGBT within the research community and workforce. This presentation will provide an overview of the current status of legal recognition for LGBT and provide evidence on the financial and emotional cost for lack of LGBT protections. Additionally, information will be provided on how a professor or hiring manager can attract and retain LGBT students and employees and create an inclusive culture. Coaching on inclusive language will also be provided. In addition, transgender students and employees face different challenges as there are far fewer protections in place for transgender students or employees and policies are less established. Ultimately, the goal of this presentation is to create a better understanding regarding LGBT parity within the University or workplace.

Aedes aegypti in California – resistant mosquitoes and novel control methods

Authors: Henke Jennifer, Coachella Valley Mosquito and Vector Control District

Abstract: Detections of Aedes aegypti have occurred in California recurrently since the 1930s. This cyclical nature of detections followed by the apparent disappearance of the species led many to think that California was not a conducive habitat to the mosquito species. The most recent detections began in 2013 in Madera County, California. In 2022, Ae. aegypti has been detected across the state.

This presentation will review the work being conducted across California to control Aedes aegypti. The introduction of Ae. aegypti, along with recent introductions of Ae. albopictus and Ae. notoscriptus has fundamentally changed the surveillance, control, and outreach programs of mosquito and vector control districts across the state. As mosquito sources have changes from larger, more visible bodies of water to cryptic hidden sources in backyards, agencies have evaluated potions of their integrated vector management plan as it relates to these mosquitoes. Highlights of control strategies targeting Ae. aegypti will be presented.

Dissecting the good and bad of morphology, molecules and phylogenetic hypotheses in the Hymenoptera

Authors: Heraty John[1], Cruaud Astrid[3], Rasplus Jean-Yves[3], Zhang Junxia[2], S. Peters Ralph[5] and Burks Roger[4], [1]Dept. of Entomology UC Riverside, United States, [2]Hebei University, China, [3]INRA, France, [4]University of California, Riverside, United States, [5]Zoologisches Forschungsmuseum Alexander Koenig, Germany

Abstract: Arguments over the results of phylogenetic hypotheses based on morphological or molecular still persist despite the increasing amount of data and plethora of analytical tools. This talk will focus on agreements and disagreements in hypotheses developed in large genomic data sets across Hymenoptera, but with a focus on Chalcidoidea and the families Eucharitidae and Perilampidae.

Comparative Anatomy of the Insect Tracheal System (Apterygotes, Paleoptera, Polyneoptera) using micro-CT

Authors: Herhold Hollister[1], Davis Steven[1] and Grimaldi David[1], [1]American Museum of Natural History, United States

Abstract: The respiratory system of insects is defined by tracheae, tube-like invaginations of the epidermis that wind throughout the body, providing tissues with direct access for gas exchange. Although some basic structure of the tracheal system has been known for several centuries, broad comparative studies of tracheal systems across multiple orders of insects are lacking. Micro-CT scanning enables non-destructive visualizations of micron-sized, intricate structures and is especially well suited for visualizing tracheae, where air spaces are easily distinguished from tissues. Here we present a broad comparative study of insect tracheal architecture visualized via micro-CT scanning with representatives from apterygotes, Paleoptera, and Polyneoptera, totaling 29 species across 13 insect orders. A unified system of tracheal nomenclature is presented using 3D visualizations of example species. Patterns in respiratory architecture, both phylogenetic and functional, are presented along with a discussion of future studies into evolutionary processes to be investigated.

Population genetic structure of the invasive insect Corythucha marmorata in North America and it´s invaded range in Japan

Authors: Hernandez-Lopez Antonio[3], Jose Cambero Acosta Maria[4], K. ITAMI JOANNE[6], Ohgushi Takayuki[2], Craig Timothy[5] and Sakata Yuzu[1], [3]ENES León, UNAM, Mexico, Mexico, [4]National School of Higher Studies, Leon Unit, UNAM, Mexico, [6]University of Minnesota, United States, [2]Center for Ecological Research Kyoto University, Japan, [5]University of Minnesota, Duluth, United States, [1]Akita Prefectural University, Japan

Abstract: The introduction of a species to a new environment can modify the ecological interactions that exist between the organisms at that place. The determination of the native geographical distribution or origin of invasive alien species is crucial for the development of management strategies and biological control, as well as offering a window to evolutionary processes at short time scales. The recent invasion of the North American lacebug Corythucha marmorata to Japan, is an important case study for recent introduction and spread of both host plant and herbivorous insects. For this reason we use the cytochrome oxidase I gene to perform an analysis of genetic diversity between the invaded range (Japan) and the native one (North America) to find the phylogenetic relationships. We sequenced only the inverse complement and the length of the sequences once edited was 233 base pairs. The results indicated a greater diversity in the native populations, just as the haplotype distribution was greater in the southern regions, both of the invaded range and of the native population. On the other hand, the phylogenetic tree shows a good support and a clear division of the populations of Japan, mixing in a clado populations of the south of Japan with the populations of the south of North America. These data suggest at least two introductions, with the South American region being one of the invasion routes. We compare and contrast these findings with the analyses of nuclear SNPs data, and discuss our results in the context of geography and potential adaptive variation in the invaded range.

Barcode and genomic inference of genetic structure of introduced lacebug (Corythucha marmorata) populations in Japan and in its native range in North America.

Authors: Hernandez-Lopez Antonio[3], K. ITAMI JOANNE[5], Ohgushi Takayuki[2], Craig Timothy[4] and Sakata Yuzu[1], [3]ENES León, UNAM, Mexico, Mexico, [5]University of Minnesota, United States, [2]Center for Ecological Research Kyoto University, Japan, [4]University of Minnesota, Duluth, United States, [1]Akita Prefectural University, Japan

Abstract: Debate continues over the extent to which diversification of insect herbivores is coupled to the diversification of their host plants, with the bulk of information derived from macro-evolutionary studies. Only recently has attention been shifted to the population and landscape levels of insect-plant herbivory, which represent the arena of the evolutionary arms race and diversification, as insects feed on plants that vary geographically in genetic structure, defence strategies, nutritional value or chemical composition, leading to local adaptation and variation in their resistance to herbivory. The interaction between the tall goldenrod Solidago altissima (Asteraceae), and the lace bug Corythucha marmorata (Hemiptera: Tingidae), provides an ideal system for understanding the potential role of genetic variation in local adaptation for an invasive plant - invasive herbivorous insect. S. altissima was introduced to Japan ca. 100 yr ago and it has extensively invaded abandoned fields and disturbed areas across the country. C. marmorata is one of the major herbivorous insects on S. altissima in North American native populations, and it was introduced to Japan around 15 yrs ago, much later than its host plant. It has quickly expanded its range from south to north, being absent only on Hokkaido Island in northern Japan. In all neocolonized regions in Japan where the lace bug is present, it maintains permanent outbreak densities, accounting for 61% of all herbivorous insects observed on S. altissima. Taking advantage of the good ecological and physiological characterisation of the interaction in both the native and invaded ranges, we analysed mithochondrial DNA (mtDNA) and nuclear (SNP) diversity and structure of multiple populations of C. marmorata at its native and invaded ranges. Our aims are to (1) determine the levels of variation and infer populations genetic structure; (2) identify the source populations of lineages invasive in Japan; and (3) to infer how it spread in Japan and whether the invasion pattern and routes track those of its host plant.

Microbiota protection against lepidopteran pathogens

Authors: Herniou Elisabeth[2], MUGO LORETTA[1], Raymond Ben[3], [1]IRBI CNRS, France, [2]IRBI, CNRS - Tours University, France, [3]University of Exeter

Abstract: Many moth species are serious agricultural pests, against which pathogenic bacteria, fungi, and viruses are widely used as biological control agents. But treatment efficacy may vary, in particular on different crops. Advances in sequencing technology have shown that the microbial community associated with insects varies on different food plants, while some of these natural gut microbes could evolve to facilitate pathogen infection. We have observed similar interactions with baculoviruses. Therefore, we aim to uncover how elements of the microbiota may confer additional pathogenic activities to microbial control agents or conversely protect insects against pathogens. Altogether, these investigations will integrate interactions between Lepidoptera, food, microbiota, and pathogens to understand how they affect insect health. The knowledge obtained will be fundamental to tailor new biological control applications and to optimize insect mass rearing methods.

DNA and eDNA metabarcoding approaches to characterize insect communities and their response to the ecological impact of conifer-dominated forest decline in the Pyrenees

Authors: Herniou Elisabeth[3], Lopez Vaamonde Carlos[8], Sire Lucas[4], Schmidt Yáñez Paul[7], Zizka Vera[6], Courtial Béatrice[2], Annie Bezier[4], Bouget Christophe[5], Larrieu Laurent[1], Monaghan Michael[7] and Rougerie Rodolphe[9], [1]INRA, UMR1201 DYNAFOR, INPT – Toulouse, France CRPF Occ – Toulouse, France, [2]INRA, UR0633 Forest Zoology – Orléans, France, [3]IRBI, CNRS - Tours University, France, [4]IRBI, UMR 7261, CNRS – University of Tours – Tours, France, [5]IRSTEA, UR EFNO – Nogent-sur-Vernisson, France, [6]Leibniz Institute for the Analysis of Biodiversity Change, Germany, [7]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) – Berlin, Germany, [8]National Institut of Agronomic Research (INRA)-Centre Val de Loire, Unité de Zoologie Forestière, Orléans, France, [9]National Museum of Natural History, UMR 7205 – Paris, France

Abstract: Forests suffer from an increase in frequency and severity of summer droughts and infestations of pathogens and insects. Those factors cause high mortality of some keystone tree species (forest die-offs). How tree mortality and associated changes in forest composition will affect local diversity and ecosystem functions remains unknown. Here, we aim to quantify the impact of climate-induced forest decline on biodiversity by measuring changes in the taxonomic structure of insect communities along silver fir (Abies alba) dieback and salvage logging gradients in the French Pyrenees.

From May to September 2017, a total of 224 samples of Malaise traps (filled with a solution of monopropylene glycol plus ethanol) and 448 Flight interception traps (filled with a solution of monopropylene glycol plus water) were collected over 56 different silver fir dominated plots in the Central and Eastern Pyrenees. We developed both DNA metabarcoding on milled insects as well as eDNA metabarcoding on preservative solutions used in the traps to characterize insect communities. We found more than 3000 OTUs and revealed the poor taxonomic coverage of DNA reference libraries for the Pyrenean biodiversity. We highlight their response to forest disturbance by their similar species richness but altered species compositions. Finally, we consider the usefulness of genomic techniques when implementing wide scale bio-monitoring programs, and we discuss the utility and limitations of eDNA metabarcoding of trap preservative solutions for bio-monitoring programs, in comparison to conventional metabarcoding approaches.

Could DNA metabarcoding of preservative media be used as a non-destructive method for insect biomonitoring?

Authors: Herniou Elisabeth[4], Lopez Vaamonde Carlos[10], Sire Lucas[6], Schmidt Yáñez Paul[9], Courtial Béatrice[3], Annie Bezier[5], Bouget Christophe[7], Larrieu Laurent[2], Monaghan Michael[8], Sparmann Sarah[1] and Mbedi Susan[1], [1]Berlin Center for Genomics in Biodiversity Research, Germany, [2]INRA, UMR1201 DYNAFOR, INPT – Toulouse, France CRPF Occ – Toulouse, France, [3]INRA, UR0633 Forest Zoology – Orléans, France, [4]IRBI, CNRS - Tours University, France, [5]IRBI, UMR 7261, CNRS – University of Tours – Tours, France, [6]IRBI, UMR 7261, CNRS – University of Tours – Tours, France, [7]IRSTEA, UR EFNO – Nogent-sur-Vernisson, France, [8]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) – Berlin, Germany, [9]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) – Berlin, Germany, [10]National Institut of Agronomic Research (INRA)-Centre Val de Loire, Unité de Zoologie Forestière, Orléans, France

Abstract: Large-scale biodiversity and biomonitoring programs are being developed worldwide to evaluate changes in species richness and composition across biomes. One method being used is DNA-metabarcoding of samples that are dried and homogenized. While this has made possible the harmonization and robustness of sampling, the destructive nature of this approach impedes voucher storage and thus morphological comparison with sequencing results, confirmation of descriptions and integrative taxonomical post-studies for long-term monitoring.

We filtered and extracted environmental DNA from preservative media (ethanol or monopropylene glycol) that was used in 26 Malaise traps and 27 window-flight traps (WFT) to collect insects for 30 days in the Central Pyrenees. We compared species diversity obtained from DNA metabarcoding of preservative media with that of destructive metabarcoding of bulk samples (Malaise) or morphological analysis (WFT) of the same traps. We also analyzed whether signals of community changes due to environmental conditions could be detected and if they were similar to signals found with destructive metabarcoding or morphological data. Finally, we discuss the cost, efficiency and reproducibility of this non-destructive method in large-scale monitoring programs.

Validating a metabarcoding pipeline for the assessment of local wild bee biodiversity in Luxembourg

Authors: Herrera-Mesías Fernanda[1], Kharrat Ep Jarboui Imen[2] and Weigand Alexander[2], [1]Department of Animal Ecology, Evolution and Biodiversity, Ruhr-Universität Bochu, [2]Musée national d'histoire naturelle de Luxembourg.

Abstract: Over the past few decades several investigations have reported large declines in insect diversity, abundance, and biomass, a trend from which wild bees are not excluded. The potentially catastrophic implications of this situation call for effective conservation efforts targeting wild bees. However, considerable documentation gaps complicate the implementation of efficient management strategies in Central Europe. Conservation projects aiming to protect local wild bee populations must first retrieve accurate taxonomic information, applying the pertinent tools. While facing the current shortage of taxonomic experts, the development of new DNA-based approaches rises as a promising approach for large data gathering. Among them, DNA metabarcoding is one of the leading techniques for biodiversity assessment, having the potential to become a cost-effective tool to identify large amounts of specimens.

Here we present the advances made in the development and validation of a metabarcoding pipeline targeting local wild bee biodiversity in Luxembourg. A sample processing designed for specimen-saving DNA extraction and customized metabarcoding protocols are at the core of a survey strategy that aims to supply valuable insights regarding the biodiversity of European wild bees in the country, providing genetic and ecological data to be considered in national conservation strategies.

Chemical aphid mimicry as a driver of host specialisation in parasitoid Lysiphlebus wasps

Authors: Hertaeg Corinne, ETH Zürich, eawag Dübendorf, Switzerland

Abstract: Parasitoids in the genus Lysiphlebus mimic the cuticular hydrocarbon (CHC) profiles of their aphid hosts to avoid detection by aphid-tending ants. This mimicry raises questions about how these wasps adapt to novel hosts. There is evidence of genetic differentiation among Lysiphlebus wasps collected from different hosts; however, no previous work has explored variation in the CHC profiles of wasps parasitizing different aphid species. We collected Lysiphlebus wasps from different aphids in the field and identified key features of their CHC profiles, including many methyl-branched alkanes, that were consistently more similar to the profile of the host aphid than to that of other aphid species. To explore how genetic and host-derived factors influence wasp CHC profiles, we reared asexual wasp lines on different aphid species and discovered that the wasps' short-chained methyl alkanes were host dependent, while linear and long-chain methyl alkanes were determined by wasp genetics. In behavioural experiments, aphid-tending ants attacked wasps based on their genetically determined CHCs, which indicates that these compounds are key mimicry compounds. Our research shows that Lysiphlebus wasps are chemically adapted to their host species and that the key mimicry compounds are heritable, which strongly suggests that this chemical mimicry drives host specialisation.

Variation in the diapause phenotype expression in Neotropical Euschistus (Hemiptera: Pentatomidae) species

Authors: Hickmann Frederico[2], Aurélio Mateus Souza Lima[1], Saldanha Alan Valdir[1] and Corrêa Alberto Soares[1], [2]University of Sao Paulo, United States, [1]University of Sao Paulo

Abstract: Diapause is a mechanism of developmental suppression employed by arthropods to survive unfavorable periods. Stink bugs may express a facultative adult diapause triggered by short-day photoperiod. The sibling Neotropical Euschistus species, E. taurulus, E. crenator and E. heros [this last represented by two strains (South Strain:SS; North Strain:NS)] are found in distinct latitudes in South America. Our aims were: 1) to verify the diapause phenotype expression of the three species/strains under different light and temperature regimes and, 2)to evaluate the adult reproductive resumption of the three species/strains after diapause induction. We submitted the insects to two photoperiods [long-day:14h light and 10h dark;short-day:10h light and 14h dark] and two temperatures [21ºC; 25ºC]. At 25ºC and long-day conditions, all species/strains did not express diapause. Under short-day and both temperatures, E. taurulus expressed an intense diapause and spent more time to resume reproduction than the other species. SS expressed the diapause with more intensity and spent more days to resume reproduction than NS under short-day and low temperature. Euschistus crenator did not express diapause and resumed reproduction immediately. Our results suggest that diapause is very plastic in Euschistus, and the expression of diapause is higher in Euschistus species/strains from regions with higher latitude.

Enhance Cytoplasmic Incompatibility in Wolbachia using Quorum Sensing Inducers to support Incompatible Insect Technique in Liriomyza trifolii

Authors: Hidayanti Ardhiani Kurnia[1], Yohsuke Tagami[2], Tagami Yohsuke[3], [1]Gifu University, Japan, [2]Shizuoka University, [3]Shizuoka University, Japan

Abstract: Liriomyza trifolii is a major insect pest around the world. The symbiosis between L. trifolii and Wolbachia is recognized as an important thing, because Wolbachia can manipulate host reproduction and offspring sex through cytoplasmic incompatibility (CI). Wolbachia induced CI is a promising tools for Incompatible Insect Technique (IIT). Previous studies have reported an association between CI and Wolbachia density, which may involve a quorum sensing (QS) mechanism. We study about the effect of manipulating QS in Wolbachia using several QS inducers including 3O-C12-HSL; C2HSL; and spermidine. The results showed that inducing QS with 3O-C12-HSL decreased the proportion of hatched eggs and increased Wolbachia density. We show for the first time that Wolbachia density and the proportion of hatched eggs of L. trifolii can be controlled by inducing QS in Wolbachia, which is potent to apply as an IIT.

The effect of pollinators on the microbiome of willow catkins

Authors: Hietaranta Elsi[2], Juottonen Heli[1] and Kytöviita Minna-Maarit[1], [2]Jyväskylä University, Finland, [1]Jyväskylä University, Finland

Abstract: Flowers are known to inhabit diverse and unique microbial communities. However, much of knowledge about the flower-associated microbiota comes from nectar, agricultural plants and managed growing conditions. Fundamental knowledge of flower-associated microbiota on natural plants remains largely unknown. Moreover, microbes associated with pollen are poorly investigated despite ecological relevance in plant-pollinator interactions. Even less well understood are the changes that flower-associated microbial communities experience through flower visitation. We investigated the effect of pollinator visitation on microbial community in willow (Salix phylicifolia) catkins. Salix phylicifolia is the first plant to offer pollen and nectar in large quantities in early spring as the first wild pollinators become active in Finland. It is of great importance especially to the survival of the bumblebee (Bombus spp.) queens during a period when few other productive sources are available. Queen bumblebees require pollen to feed their larvae and to establish the colony. In addition to bumblebees, the willow catkins are visited by cultivated honeybees (Apis mellifera) in some localities. These two insect groups are likely to mainly affect willow catkin microbiome and also receive microbes from each other through the shared resource. In our study, we specifically investigated the effect of i) native pollinators, mainly bumblebees and (ii) the additive effect of cultivated honeybees (Apis mellifera) on the composition of bacterial and fungal communities in willow male inflorescences under natural conditions in early spring. The microbiomes in the willow inflorescences were surveyed using amplicon sequencing of the bacterial 16S ribosomal RNA gene and fungal ITS (intergenic transcribed spacer) region. We hypothesized that the composition of flower microbiota differs between visited and non-visited inflorescences and visited inflorescences have higher diversity. The amount of pollen removed from catkins by insect visitors ranged between 0-90% and was on average 40%. Honeybees had no statistical effect on the amount of pollen removed from catkins in this study. We used pollen loss in visited flowers as a proxy for visitation frequency and related that to microbial diversity in visited flowers. We expected honeybees to increase microbial richness in willow catkins. Further determination of flower microbiome of different plant species is an important step to understand the plant-pollinator-microbe interaction.

Psyllid vectors of Candidatus Liberibacter solancearum in the Scottish landscape – is there a risk to agriculture when crops are not the preferred hosts?

Authors: Highet Fiona[3], Kenyon David[2], Sumner-Kalkun Jason[1], Carnegie Mairi[2], Madden Siobhan[2] and Arnsdorf Yvonne[2], [3]Science and Advice for Scottish Agriculture, United Kingdom, [2]Science and Advice for Scottish Agriculture, United Kingdom, [1]SASA; Scottish Government, United Kingdom

Abstract: Insect-vectored plant pathogens are generally well studied within agricultural systems, however their interactions with wild hosts are often overlooked. Pathogen spillover from natural reservoirs may significantly impact on the success of disease control within neighbouring crops. Additionally, as wild spaces become increasingly fragmented by agriculture, host-shifts of either the pathogen or its insect vector are increasingly likely, leading to the emergence of new crop diseases. ‘Candidatus Liberibacter solanacearum’ (Lso), a psyllid transmitted bacterium which was first reported as causing disease to Solanaceous crops in 1994 (Mexico) and Apiaceous crops in 2008 (Finland), has recently been found to be present in several species of psyllid in Scotland. Whilst disease symptoms associated with Lso have has not been reported in Scottish crops, Trioza anthrisci (whose preferred hosts are Apiaceous plants) was identified as a newly recorded species for the country and was also found to be carrying Lso. In order to better understand the potential risk posed to Scottish agriculture we carried out transmission studies from wild Apiaceous hosts to carrot (Daucus carota) using T. anthrisci and conducted further investigations into the diversity of psyllids and their associated Lso haplotypes in the Scottish landscape. By developing an understanding of the natural distribution and diversity of these plant-bacterium-insect interactions within our landscapes we aim to better inform policymakers of the risk posed by changes in land use, agricultural practice or the introduction of new potential vector species and/or bacterial haplotypes.

Investigating the feeding behaviour of UK psyllids and the potential for Candidatus Liberibacter solanacearum (Lso) transmission to commercial crops

Authors: Highet Fiona[4], Kenyon David[3], Sumner-Kalkun Jason[2], Newton Jennifer[1], [4]Science and Advice for Scottish Agriculture, United Kingdom, [3]Science and Advice for Scottish Agriculture, United Kingdom, [2]SASA; Scottish Government, United Kingdom, [1]SASA, United Kingdom

Abstract: ‘Candidatus Liberibacter solanacearum’ (Lso) is a phloem-limited bacterium transmitted by psyllids that causes disease in both Solanaceous and Apiaceous plants. Lso is responsible for significant losses to the potato industry in the Americas and New Zealand. In Europe, Lso predominantly affects Apiaceae such as carrot. Several new species of psyllid have been found to carry Lso in the UK, including Trioza anthrisci and Trioza urticae. However, very little is known about their ability to transmit Lso in their wild reproductive hosts and economically important crop species. As Lso is transmitted to plants through saliva when the psyllids feed, its success greatly depends on the feeding behaviour of these psyllids. One of the most powerful and widely accepted tools for studying insect feeding behaviour is the electrical penetration graph (EPG) technique. This allows for observation of psyllid feeding behaviours and how they may vary on a range of plants, along with the potential for Lso transmission. We are currently using EPG methods to investigate the feeding behaviours of T. anthrisci and T. urticae on their host plants (cow parsley (Anthriscus sylvestris) and nettle (Urtica dioica) respectively) and crop species, including carrot and potato. Initial experiments are being carried out to correlate waveforms to feeding behaviours.

Transmission experiments indicate that Trioza anthrisci can feed and reproduce carrot and Lso is detectable after 12 weeks of feeding. Survival rates on carrot and potato are lower than on cow parsley, while potato and carrot are unsuitable for Trioza urticae survival. The impact of T. anthrisci and T. urticae on carrot and potato seems minimal. Further transmission and EPG work will confirm this.

This work will also contribute to wider research into the risk of Lso to UK crops and provide advice for plant health policy and stakeholders.

Early herbivore alert: Plant chemical and molecular defense responses to insect eggs

Authors: Hilker Monika, Freie Universitaet Berlin, Institute of Biology-Applied Zoology / Animal Ecology, Germany

Abstract: Plants respond to egg depositions of herbivorous insects on their leaves by various defenses. The egg-induced plant responses may target the eggs themselves and the hatching larvae. When targeting the eggs, plant responses can directly harm the eggs by various means, or they result in indirect defense and attract egg parasitoids or predators by egg-induced leaf volatiles. In case of egg survival, the plant’s response to insect eggs can result in earlier and amplified feeding-induced defenses against the hatching larvae. This egg-mediated priming effect of feeding-induced plant defense is associated with fine-tuned changes in the kinetics of transcriptomic and phytohormonal plant responses. Based on the findings that plants can take eggs as warning of impending larval feeding damage and prime their defenses against the larvae, we asked whether plants can also respond to cues warning of impending egg deposition by priming their defenses against the eggs. We hypothesized that insect sex pheromones serve as such warning (priming) cues. Indeed, our studies showed that pine exposed to sex pheromones of the pine sawfly Diprion pini amplifies its defenses against sawfly eggs. Mortality of sawfly eggs laid on pine pre-exposed to sawfly sex pheromones is significantly higher than on non-exposed pine. The pheromone-mediated priming effect is linked with increased accumulation of hydrogen peroxide and differential expression of several defense-related genes in pheromone-exposed, egg-laden pine needles. Hence, plant defense against insect infestation follows a multi-step strategy starting with responses to the insect’s sex pheromones, thus priming defense against the eggs followed by well-prepared defense against the eggs, and, in case of egg survival, the plant responses to the eggs prepare defenses against hatching larvae.

Priming by timing: How plants use insect eggs to prepare their defense against impending larval herbivores in time?

Authors: Hilker Monika[1], Lortzing Vivien[2], Valsamakis Georgios[4], Paniagua Voirol Luis[4], Bittner Norbert[3], Kunze Reinhard[3], [1]Freie Universitaet Berlin, Institute of Biology-Applied Zoology / Animal Ecology, Germany, [2]Freie Universität Berlin, Germany, [4]Institute of Biology-Applied Zoology / Animal Ecology, Dahlem Centre of Plant Sciences, Freie Universität Berlin, Germany, [3]Institute of Biology-Applied Genetics, Dahlem Centre of Plant Sciences, Freie Universität Berlin, Germany

Abstract: When herbivorous insects lay eggs on plants, it is likely that they will be attacked by voracious larvae hatching from these eggs. To avoid the larval attack, plants can fend-off the eggs directly. Additionally, some plants use the eggs as warning cues to prepare their defense against the hatching larvae. Thus, larvae that start to feed on previously egg-deposited plants perform worse compared to larvae on egg-free plants.

We elucidate the molecular and chemical mechanisms that are involved in egg-mediated priming of plant defense and the ecological dependencies of these mechanisms. In particular, we ask i) why the larvae perform worse on previously egg-deposited plants, ii) how this egg-enhanced plant defense response is regulated, and iii) how the dynamics of these regulations change over time when a plant carries eggs, or when the larvae subsequently start feeding on the plant. For our studies we used the cabbage butterfly (Pieris brassicae), a Brassicaceae specialist, and the model plant Arabidopsis thaliana.

We found that A. thaliana maximizes its egg-priming response shortly before the P. brassicae larvae hatch. The subsequently enhanced defense response against the feeding larvae seems to result from an accelerated induction of the plant's anti-herbivore defenses. The egg-enhanced anti-herbivore defense response depends, amongst others, on salicylic acid-mediated signaling, enhanced expression of several defense-related genes, including PR5 (PATHOGENESIS-RELATED GENE 5), and it is linked to the induction of flavonoids.

Hence, the feeding-inducible plant defenses and their regulation can be optimized, when plants perceive insect eggs as an herbivore-related cue reliably indicating future stress by feeding larvae.

Can simple envelope ensembles improve transferability of invasive insect distributions?

Authors: Hill Matt[2], Camac James[1], Elith Jane[1], Caley Peter[2] and Barry Simon[2], [2]CSIRO Data61, Australia, [1]CEBRA, University of Melbourne, Australia

Abstract: Invasive insect species comprise some of the most recognised vectors of human disease, and cause billions of dollars in direct agricultural losses through reduced yields and transmission of plant pathogens, and indirect losses including increased application of pesticides and trade. Predicting the distribution, spread and impacts of invasive insects is thus an important challenge and is required to inform geographically-targeted policies in order to prevent new invasions and manage existing invasive species.

Species distribution models (SDMs) have become increasingly popular to predict the potential geographic range of invasive species, by correlating the known distribution of a species with environmental variables, and transferring these relationships into novel environments and geographic space. There are a range of challenges when using SDMs to predict distributions outside of native ranges, and to date the SDM literature has largely focused on improving the statistical fit of models when projecting into novel geographic space. An area that remains challenging and under-discussed is methods to choose predictive variables that will result in models that transfer between regions. This is challenging as non-causal variables may still show significant associations with distributions. Here we propose methods to finesse this problem by using multiple simple models to search for the most appropriate variables from a given set, and then apply them as two variable envelopes in an ensemble approach. We also explore the use of a presence-only method, range bagging, which examines how often a given environment occurs inside niche boundaries across all environmental dimensions, providing an alternative way to determine 'good' predictive variables.

We apply these methods to both virtual species and a dataset of 22 globally invasive insect species, and find that methods that focus on predictor uncertainty generally perform well against conventional approaches for statistically fitting numerous variables in a single model. While our methods only consider simple ecological relationships of species to environmental predictors, they allow for increased model transferability as they largely avoid over-fitting, background selection and collinearity issues. We transform a model selection problem, for which there is no true correct answer amongst the typically distal covariates on offer, to one of model uncertainty, which appears more tractable. We argue that increased model transferability at the expense of model interpretability is perhaps more important for effective rapid predictions and management of non-native insects and biological invasions.

Age matters: regulation of antennal transcription throughout a mosquito's first gonotrophic cycle

Authors: Hill Sharon Rose, Disease Vector Group, Chemical Ecology, Department of Plant Protection Biology, Swedish University of Agricultural Sciences, Alnarp, Sweden

Abstract: The behaviours of mosquitoes that are associated with maturation, feeding and reproduction, directly influence disease transmission capacity. Odours mediate each phase of the gonotrophic cycle from pre-blood meal host seeking through post-blood meal refuge seeking, oviposition site seeking and oviposition to post-oviposition reassertion of host seeking while sugar seeking throughout. The blood meal-induced regulation of chemosensory, neuromodulatory and other signal transduction genes was investigated in the antenna of female mosquitoes during maturation on 1 and 3 days post-eclosion, and subsequently every 24±1 h from 5 to 10 days post-eclosion from two cohorts: 1) blood fed and 2) non-blood fed. Using a transcriptomic approach, genes-of-interest implicated in the behavioural changes associated with age and with a blood meal were identified from multiple chemosensory-related gene families investigated. The observed concerted regulation of multiple genes within the sensory pathways of the antenna likely play a key role in modulating the behavioural changes observed with age and post-blood meal. Functional characterization of the proteins generated by the genes-of-interest identified in this study may provide a better understanding of the regulation of gonotrophic feeding and a pool of potential targets for vector control strategies.

Management and the role of Ips typographus in diverse environment – the case of Bialowieza primeval forest

Authors: Hilszczanski Jacek[1], Plewa Radoslaw[1] and Jaworski Tomasz[1], [1]Forest Research Institute, Poland

Abstract: Spruce bark beetle Ips typographus is considered a species which activity brings a number of beneficial phenomena in relation to the functioning of the ecosystem and broadly understood biodiversity, which is particularly important in the case of protected areas. Many studies indicate the ecological significance of spruce bark beetle as a key species or so-called "An ecosystem engineer". Nowadays, strong fragmentation and isolation of forest areas largely changes the positive meaning of the bark beetle, which is associated with limited possibilities of migration of living organisms. In specific cases, outbreak in large areas, also in species-diverse forests stands, pose a threat to sensitive stenotopic species, especially those with low dispersal capabilities. In the presentation, an attempt was made to assess the role of spruce bark beetle and its management in multi-species stands of the Bialowieza Primeval Forest.

Leveraging plant volatiles for enhanced biocontrol with entomopathogenic nematodes

Authors: Hiltpold Ivan, Agroscope, Switzerland

Abstract: There is an increasing number of evidences suggesting that entomopathogenic nematodes are able to use volatile cues to perceive and assess their environment. Either to recognize their potential insect host, to evaluate host health status, or to locate insect damaged root systems, entomopathogenic nematodes have evolved the ability to respond to diverse volatile organic compounds to locate, recognize, and efficiently infect hosts. Our recent understanding of these interactions and the identification of several of these environmental cues allows us to manipulate agroecosystems to enhance biological control potential of entomopathogenic nematodes. Focusing on plant emitted cues, we will discuss how to exploit these finely tuned signals to manage major insect pests threatening crop yield and food security in various systems. We will also explore some ideas on how to use this knowledge in the (close) future of digital farming.

Plant response to the third trophic level: An underestimated interplay shaping multitrophic interactions

Authors: Himmighofen Paul, University of Bern

Abstract: Volatile-mediated defense priming occurs in maize leaves, but not roots

Plant leaves that are exposed to herbivore induced plant volatiles (HIPVs) respond by increasing their defenses. Whether this phenomenon also occurs in the roots is unknown. Using maize (Zea mays), whose leaves respond strongly to leaf HIPVs, we measured the impact of HIPVs from maize roots that are infested by the banded cucumber beetle (Diabrotica balteata) on constitutive and herbivore-induced levels of root soluble sugars, starch, total soluble proteins, free amino acids, volatile and non-volatile secondary metabolites and defense gene expression of neighboring plants. HIPV exposure did not alter constitutive or induced levels of any of the measured root traits. Furthermore, HIPV exposure did not reduce the performance and survival of banded cucumber beetle larvae on maize or teosinte. Cross-exposure experiments revealed that maize roots neither emit nor respond strongly to defense-regulating HIPVs. Together, these results demonstrate that volatile-mediated defense regulation is restricted to maize leaves, which is in line with the lower diffusibility of volatiles in the soil and the availability of other, more efficient information conduits below ground

Males of West Indian sweetpotato weevil Euscepes postfasciatus (Coleoptera: Curculionidae) use accessory gland substances to inhibit remating by females

Authors: Himuro Chihiro[3], Honma Atsushi[2], Ohishi Tsuyoshi[1] and Ikegawa Yusuke[2], [3]Ryukyu Sankei Co, Ltd Okinawa Prefectural Plant Protection Center University of the Ryukyus, Japan, [2]Ryukyu Sankei Co, Ltd Okinawa Prefectural Plant Protection Center University of the Ryukyus, Japan, [1]Okinawa Prefectural Plant Protection Center, Japan

Abstract: The West Indian sweetpotato weevil, Euscepes postfasciatus (Fairmaire) (Coleoptera: Curculionidae), is a major pest of sweetpotato, Ipomoea batatas (L.) Lam. (Convolvulaceae), in the South Pacific, the Caribbean Basin, and parts of Central and South America. It is now distributed throughout the Ryukyu Islands (Okinawa Prefecture) and Amami Islands (Kagoshima Prefecture) in Japan. In Okinawa Prefecture, a sterile insect technique (SIT) program for eradicating this weevil is underway. Mated females of E. postfasciatus temporarily become unreceptive to subsequent mating, however the physiological mechanism underlying this has not been clarified, despite its practical importance. To elucidate this mechanism, we investigated the effects of male-derived substances on the inhibition of mating receptivity of virgin females by injecting the substances into their abdomens. The length of time from injection to mating in virgin females was significantly longer in females injected with an accessory gland solution than in those injected with control solution. For those injected with the contents of seminal vesicles, or other two accessory glands, there were no significant differences compared to the control. In this study, we showed that mated females have a long refractory period (about 14 d) because males of E. postfasciatus inhibit female remating by using seminal fluid substances. We discuss the optimal timing of the release of sterilized insects in SIT eradication programs, to exploit the mating system of E. postfasciatus.

New integrated strategy for controlling whiteflies in tomato greenhouses by a combined use of zoophytophagous mirid bugs, banker plants, violet LED lights, red insect-proof nets, and a novel repellent

Authors: Hinomoto Norihide[1] and Nagasaka Koukichi[2], [1]Kyoto University, Japan, [2]National Agriculture and Food Research Organization, Japan

Abstract: Whiteflies are one of the most important pests in global tomato production because they transmit plant viruses, causing serious damage to tomatoes. Whiteflies have developed resistance to the chemical insecticides frequently applied as a control. Therefore, a new strategy to reduce chemical pesticides use is now required. The zoophytophagous mirid bug, Nesidiocoris tenuis, is the most promising biological control agent (BCA); it feeds actively on whiteflies and other insect pests, whereas other commercially available predatory BCAs perform poorly on tomatoes due to glandular trichomes restricting their movement on the tomato surface. However, use of N. tenuis has some limitations: a relatively long developmental time, a strong preference for certain insectary plants, and tomato plant damage when numbers increase beyond requirements. In this study, we conducted experiments to develop a new strategy that overcomes these problems in the successful control of whiteflies.

The sides of greenhouses in which the experiments were conducted were covered with newly developed red insect-proof nets (mesh size, 0.8 mm). The nets did not prevent whitefly intrusion, but had advantages in preventing very high temperatures that would reduce tomato quality and quantity in mid-summer. The red-colored nets were able to reduce intrusion into the greenhouses in comparison with standard white-colored nets of the same mesh size. In order to enhance N. tenuis numbers prior to pest invasion into the greenhouses, we employed a banker plant system using insectary plants: garden verbena, spider flower, and sesame. At the time of transplanting, N. tenuis were released onto the insectary plants, on which their numbers increased without pest species. In the early stages of tomato cultivation before N. tenuis numbers had sufficiently increased, instead of spraying conventional chemical pesticides on the tomato plants we used a novel repellent, acetylated glyceride, reducing the risks of viral infection. Violet LED lights, for which N. tenuis shows a strong preference, were turned on when whiteflies were frequently observed in the greenhouses; and N. tenuis individuals were removed from the banker plants on which they had been reared and placed onto the tomatoes. The combination of these newly developed tools resulted in successful whitefly control while avoiding extreme tomato damage, through appropriate maintenance of N. tenuis.

Development of microsatellite markers for the Japanese orange fly, Bactrocera tsuneonis (Diptera: Tephritidae)

Authors: Hinomoto Norihide[1], Opadith Pattara[2] and Ono Hajime[1], [1]Kyoto University, [2]Kyoto University, Japan

Abstract: To monitor and control Japanese orange fly Bactrocera tsuneonis is subject to strict quarantine controls worldwide that is restricted to Japan, southern China, and Taiwan. There is a risk of expanding its distribution, several countries require quarantine and permit imports only from unaffected areas. Therefore it is important to determine their dispersal ability. If geographically isolated strains exist, the control are affected. Since information about genetic structure and geographical variability could contribute to the prediction of mobility of pest species, the development of molecular markers is crucial for the pest management. To determine the genetic structure of this species, we developed microsatellite markers at 17 loci from transcriptome data. A total of 80 adult females and males, which were randomly collected from abandoned orchards in the two prefectures isolated by sea, were used for polymorphism analysis. The average number of loci was relatively low at the value of 2.65, and observed heterozygosity was relatively low at 0.00 to 0.11. Although significant genetic differentiation between females and males of the same population was not observed, populations between both prefectures were diverse. These results suggest a high degree of inbreeding in this species and the adults only disperse short distance.

What makes a good classical weed biological control agent?

Authors: Hinz Hariet[1], Schwarzländer Mark[4], Panta Sujan[3] and Winston Rachel[2], [1]CABI, Switzerland, [4]University of Idaho, United States, [3]University of Idaho, [2]MIA Consulting

Abstract: Since the 1970s, biocontrol practitioners are trying to improve success rates of weed biological control programs. Initially, agent characteristics thought to be associated with greater success were based on experiences gleaned from previous programs, best guesses or simply intuition. From the 1980s, several retrospective analyses of existing data were conducted to identify specific agent life history traits and other characteristics associated with a greater probability of controlling a target weed. Similarly, analyses were conducted to identify traits of target weeds associated with greater biocontrol success. More recently, agent and target weed traits were combined in analyses to reach more refined conclusions. Alternatively, ecological theory has been to used to extrapolate and identify factors related to the agent the target weed or the receiving environments, which may influence control success. This talk will give an overview of existing approaches, their strengths and shortcomings, and recommend potential steps forward.

The residues required for nuclear localization and masculinization of Ostrinia furnacalis Masculinizer protein (Masc) are different from those of Bombyx mori Masc

Authors: Hirota Kanako[2], Matsuda-Imai Noriko[1], Kiuchi Takashi[1] and Katsuma Susumu[1], [2]The University of Tokyo, Japan, [1]The University of Tokyo

Abstract: The Masculinizer (Masc) gene was discovered in Bombyx mori as a regulator of both masculinization and dosage compensation. To date, Masc homologues have been identified from several lepidopteran insects. We previously reported B. mori Masc (BmMasc) has a bipartite nuclear localization signal (NLS) and two residues, lysine at 274 (K274) and arginine at 275 (R275), are essential for its function. We also identified two cysteines at residues 301 (C301) and 304 (C304) in BmMasc, both of which are required for its masculinizing activity. Although the sequences of NLS and masculinizing domain are conserved among lepidopteran insects, their functions are unknown in Masc proteins other than BmMasc. In this study, we characterized these domains in the Ostrinia furnacalis Masc (OfMasc) using B. mori ovary-derived cell line. Deletion and alanine scanning mutagenesis revealed the putative NLS is required for nuclear localization of OfMasc, but mutations at both K227 and R228, correspond to K274 and R275 of BmMasc, respectively, do not greatly abolish the NLS activity. Additional mutagenesis revealed triple mutations at K227, R228, and K240 almost completely inhibit OfMasc nuclear localization. Furthermore, mutations at C253 or C256, correspond to C301 and C304 of BmMasc, respectively, had little impact on its masculinizing activity.

Different parasitic strategies of chrysidid egg parasitoids of phasmids (Hymenoptera: Chrysididae)

Authors: Hisasue Yu[2], Pham Thai[3] and Mita Toshiharu[1], [2]Entomological Laboratory, Graduate School of Bioresource and Bioenvironmental Sciences, Kyushu University, Japan, [3]Vietnam National Museum of Nature, Academy of Science and Technology (VAST), Hanoi, Vietnam, Vietnam, [1]Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan

Abstract: Amiseginae and Loboscelidiinae are chrysidid wasps that are parasitoids of stick insects. It has been suggested that the two subfamilies are closely related (Kimsey & Bohart 1991). However, while Amiseginae retains the general morphological characteristics of the Chrysididae, Loboscelidiinae has an elongated vertex, ribbon-like setae that grow on it, and flat legs with flanges. It is so specialized that it deviates from the normal characteristics of the family. As the two subfamilies differ in morphology, it is surmised that their environments and parasitic behavior may also be different (Kimsey 2012), but the life histories are mostly unknown. No host relationship has been revealed in Loboscelidiinae other than its emergence from stick insect eggs, and there is only fragmentary evidence of parasitic behavior in Amiseginae (Tormos et al. 1998; Kimsey et al. 2012). Existing observations indicate that the wasps climb onto stick insect eggs, lay eggs on them (Redshaw 1965), and then transport the (stick insect) eggs (Windsor et al. 1996).

In this study, we observed two species, Nipponosega yamanei (Amiseginae) and Loboscelidia sp. (Loboscelidiinae), and recorded the stages and duration of their parasitic behavior. When N. yamanei found the egg, she climbed on it, touched it with her antennae, and carried the egg backward with her forelegs. She transported the egg to concealed environments, such as crevices, where she pierced the eggshell with her mandibles and laid an egg. This parasitic behavior, searching for hiding places and oviposition, was time-consuming. On the other hand, when Loboscelidia sp. found an egg, she made a hole in the eggshell using mandibles and laid her egg. Then, like N. yamanei, she carried the egg with her forelegs, but in this case, transported it to a hole in the ground, where she gathered soil with her forelegs and buried it. In Loboscelidia sp., much time was spent laying eggs and filling host eggs. In addition, a concentration of insects gathering on the stick insect eggs showed that the eggs concealed by fallen leaves showed a significantly lower detection rate than eggs exposed on the ground.

It was observed that the transport and hiding of host eggs found in other Chrysidoidea and primitive Aculeata also occur in N. yamanei, and Loboscelidia sp. Besides, experiments with stick insect eggs suggest that these actions help in avoiding detection by other parasitoids and predators. On the other hand, the burying of host eggs in soil, found only in Loboscelidia sp., implies a greater degree of concealment than that practiced by N. yamanei, which only placed the eggs out of sight. Egg burials in the soil pose the problem of the adult having to emerge to the ground, but the Loboscelidiinae have unique morphological characteristics (also found in Diapriidae and Tiphiidae) such as setae growing on the head and pronotum, large tegula, and legs with spines. For Loboscelidiinae, they may be useful for escape.

Urban heat island effects disrupt insect-plant interactions on street trees at multiple scales

Authors: Hochuli Dieter[2] and Chen Tony[1], [2]The University of Sydney, [1]School of Life and Environmental Sciences The University of Sydney, Australia

Abstract: Cities are typically perceived as hostile environments for biodiversity, with a combination of stressors disrupting interactions in these novel ecosystems. Street trees are seen as vital for enhancing human wellbeing, playing a role in combating urban heat islands and pollution. However, urban stressors may also affect their health and capacity to thrive. We examined the ecology of Sycamore Lace Bugs (Corythucha ciliata) on London Plane Trees (Plantanus x acerifolia), a common street tree in Sydney, Australia. We compare the insect assemblages, C. ciliata development and levels of damage at fourteen hot and cool sites. These sites were identified through satellite thermal imaging, and detailed 21 day thermal profiles of over 50 trees were described using data loggers to confirm thermal traits. Sites were sampled in spring, and summer.

While hot sites were significantly warmer than cool sites during both spring and summer, the ecological effects of urban heat on insect-plant interactions were only detected during summer. We found that trees at hot sites supported significantly higher densities of C. ciliata and suffered almost four times the leaf damage than trees at cool sites. Examination of individual tree thermal profiles revealed that variation within sites in these patterns was primarily driven by the extent of impervious surfaces within a 50m buffer of trees. Understanding how landscape traits drive the effects of urbanization at multiple scales, from individual trees to stands of trees, is central to identifying the most effective ways to maintain healthy green infrastructure in cities.

Phenological adjustment of the Pine Processionary Moth to contrasting climatic environments along an elevation gradient: how to cope with abiotic factors and biotic interactions

Authors: Hódar José A.[2], Suárez-Muñoz María[1] and Zamora Regino[1], [2]Department of Ecology, Faculty of Sciences, University of Granada, Spain, [1]Department of Ecology, Faculty of Sciences, University of Granada, Spain

Abstract: Survival of an ectothermal organism requires that development and reproduction be synchronized with the appropriate periods of the annual cycle, and those inadequate with the phases of inactivity, but the sum of the times required for all phases of the life cycle cannot exceed one year in univoltine species. It is known that the pupation time (prolonged diapause apart) of the pine processionary moth (Thaumetopoea pityocampa) is variable and adjusts to the climate of the site in which inhabits, but little is known on 1) what factors (genetic, ambient, or both) determine the time spent as pupae, and 2) how pupation time and larval development interact with the biotic pressures (predation, parasitoidism) operating at each site. Taking advantage of the altitudinal gradient of Sierra Nevada mountains (SE Spain), in which PPM inhabits from sea level to the altitudinal treeline (2200 m a.s.l.) showing a wide variation in pupation time, we want to understand if variation in the phenological strategy along the gradient responds to an optimization of the pupation length, dragging as a consequence the rest of the cycle, or if on the contrary, it aims to diversify the possibility of avoiding predators and parasites, tracking a less optimal but broader period and playing with the climatic variety between years. Answering this question implies to understand what factors regulate the pupation length of the processionary and how non-climatic selective pressures (mainly predators and parasitoids) vary in each environment of the gradient. We performed a translocation experiment, moving a total of 8100 larvae in three altitudinal levels (180, 1000 and 1900 m a.s.l.) evidencing that the locality of origin determines the duration of pupation and the rate of prolonged diapause, but that abiotic conditions modulate the phenology of moth emergence. Furthermore, egg batch predation and parasitoidism increases at lower altitudes, probably being the main factor setting the optimal window for emergence, while at higher altitudes climate is the determinant.

Leaning In: The case of proactive biological control of invasive insect pests

Authors: Hoddle Mark, Department of Entomology, University of California, Riverside, United States

Abstract: New macroarthropod species establish in California at rate of around nine per year, of which about three or so will become pests causing economic or ecological damage and subsequently requiring some form of control. A significant number of these new pests likely enter California from invasion bridgeheads established elsewhere in the USA. Typically, responses, such as the development of biocontrol programs, to these incursions are reactive and are initiated after the pest has established, spread, and caused damage. An alternative approach would be to take a proactive stance, identify potential invaders, like spotted lantern fly, brown marmorated stink bug, or Asian citrus psyllid, in advance of their anticipated arrival, and have natural enemies pre-screened and pre-approved for release. This presentation will cover the concepts underlying proactive biological control.

Are the Benefits of Classical Biological Control Under Appreciated?

Authors: Hoddle Mark, Department of Entomology, University of California, Riverside, United States

Abstract: Classical biological control of invasive arthropod pests is a powerful tool for suppressing damaging populations injurious to agricultural, wilderness, and urban areas. Despite numerous successes this powerful tool for population regulation is often not well understood or nor are successes widely appreciated. These are major obstacles for promoting the use of safe efficacious natural enemies for suppressing pest populations and for reducing pesticide use. This presentation will provide examples of successful classical biological control programs targeting an invasive pest that was killing native plants in the Galapagos Islands, a world heritage site, the complete halt of the invasion South Pacific Islands by the glassy-winged sharpshooter, and successful suppression of the Asian citrus psyllid in urban citrus in southern California.

Flight Mills as Tools for Assessing the Invasion Potential of Pest Insects

Authors: Hoddle Mark[1], Kresslein Robert[2], [1]Department of Entomology, University of California, Riverside, United States, [2]University of California Riverside, United States

Abstract: The natural dispersal capabilities of an invasive pest can play an important role in population growth and phenology which in turn influences understanding of factors affecting aspects of pest invasion biology (e.g., rates of spread) and development of management plans (e.g., establishment of quarantine boundaries and deployment distances between traps). Natural flight dispersal of insects is difficult to observe and quantify in the field. Laboratory-based systems, such as computerized flight mills, which measure the flight activity of tethered insects, can provide useful insight into dispersal potential and assessment of experimental co-factors influencing flight capacity. Factors of interest affecting flight propensity may include effects of sex, size, and time of year and age and diet. The spread of invasive insect pests may be characterized by long range movement which can occur with considerable frequency and result in faster than expected rates of range expansion as long distance dispersants may establish incipient infestation foci from which new populations develop and coalesce. Measuring these natural types of dispersal events in the field are almost impossible to do. Flight mills are ideally suited for identifying and assessing invasion risk posed by insect pests by elucidating whether or not they are capable of long distance dispersal. This presentation will cover aspects of 24 hr flight mill studies for three species of invasive palm weevil, Rhynchophorus ferrugineus, R. vulneratus, and R. palmarum. Of interest here is whether or not flight distance data exhibit a leptokurtic distribution which is considered characteristic of pests capable of rapid natural spread at the leading edge of the invasion front.

Quantifying Potential Lifetime Flight Capacity of South American Palm Weevil: Management Implications

Authors: Hoddle Mark[1], Kresslein Robert[2], [1]Department of Entomology, University of California, Riverside, United States, [2]University of California Riverside, United States

Abstract: Palm weevils, Rhynchophorus spp. (Coleoptera: Curculionidae), are a perennial invasion threat to areas with large ornamental and edible date palm industries. Once established in new areas weevils may spread naturally via flight or through movement of infested palms. The lifetime flight capacity of R. palmarum, the South American palm weevil, an invasive pest in the USA, is unknown. In order to assess risk of natural spread via flight, we first need to understand the lifetime flight potential for these insects. Computerized flight mills were used to quantify life time flight capacity. While not all palm weevil species will have the same life time flight capabilities, they may be similar enough that these data for R. palmarum could help with the development of quarantine and containment regulations that manage natural spread via flight. Here, I will discuss the results of lifetime flight capacity generated from mill data for 80 R. palmarum that were field collected from San Diego County in southern California (USA). Results will be used to assess invasion risk via natural flight and potential management applications for palm weevils.

Repellent semiochemicals for effective areawide management of agriculture, forest and urban pests

Authors: Hoddle Mark[2], Mafra-Neto Agenor[5], Coats Joel[3], Bernardi Carmem[4], Fettig Christopher[7], Barai James[4], Saroli Jesse[5], Bortoli Ligia[6], Wright Mark[9], Borges Rafael[6], Silva Rodrigo[1], Machota Ruben[6], and Dekker Teun[8], [1]Bedoukian Research, United States, [2]Department of Entomology, University of California, Riverside, United States, [3]Iowa State University, United States, [4]ISCA Inc., CA, United States,[5]ISCA Technologies, Inc., CA, United States, [6]ISCA Tecnologias Ltda, Brazil, [7]Research Entomologist and Team Leader Forest Service Pacific Southwest Research Station, United States, [8]SLU Swedish University of Agricultural Sciences, Alnarp, Sweden, [9]University of Hawaii at Manoa Honolulu, Hawaii, United States

Abstract: An insect repellent is a chemical compound or a blend of compounds that deters insect activity on or near otherwise attractive substrates. Although contact repellents have played a key role in the control of hematophagous insect bites (e.g., DEET), and a number of repellent semiochemicals, including some pheromones, have already been characterized for insect pests, repellents have not been widely commercialized in agriculture or forestry. The vast majority of repellents are labile semiochemicals that quickly vanish once applied in the field, as conventional slow-release formulation technologies are often difficult to apply and/or inefficient in controlling the emission rate of the active ingredient. Though the use of repellents, alone or in combination with attractants as part of a push-pull strategy, has been shown to be effective in a few circumstances, the effective application of such compounds requires the user to have a more comprehensive knowledge of insect behavior than the use of conventional insecticides, which are not only simpler to use, but typically less costly.

The specificity of semiochemical repellents, which are often best adapted for a limited number of insect species in a restricted number of crop or forest systems, presents another challenge to their successful implementation on a large scale, as do the intricacies of the regulatory agencies ruling the registration process for new biopesticides, which can be very costly and time-consuming. This specific market, currently seen as small-size, combined with the high cost of AIs, product development, and registration, hamper the commercialization of repellent technologies for pest control in agriculture and vector control. Despite the many impediments to the commercialization of insect repellents, there are some situations where their use in agriculture and forestry is desirable and warranted. ISCA Inc., together with collaborators from academia, government and private sectors, has actively been developing and commercializing novel repellent formulations against several important pest and vector species around the globe. Here we will describe a few case studies on the use and commercialization of repellants against phytophagous and hematophagous arthropods of importance.

Can selection of biological control agents be improved to decrease the risk of releasing ineffective agents?

Authors: Hoelmer Kim A., U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States

Abstract: My presentation addresses advances that help to improve the success in identifying effective natural enemies. Although classical and augmentation biological control differ in scope, agents used for both approaches share many of the requisite characteristics needed to be effective natural enemies. Accurate identification of species is a cornerstone of biological control, and close collaboration with taxonomists ensures that important biological and identifying characteristics are properly associated with the correct taxa and biotypes. Advances in molecular biology have enhanced this collaboration. Native range studies are important to identify natural enemies that cause significant mortality of the target pest, as well as contributing information on anticipated non-targets. While tried-and-true physiological no-choice and choice tests conducted in the laboratory are still used to estimate host specificity for regulatory applications, they are recognized as often being overly conservative, which risks rendering an effective agent off-limits. Modern genomics research now has the potential to identify the genetic bases of host specificity, along with advances in electrophysiology and chemical ecology that help to identify the environmental and behavioral cues important in host habitat recognition and host finding. Increased awareness of endosymbionts and their influence on natural enemy biology has become another consideration in agent evaluation.

Risk and impact assessment for exotic natural enemies

Authors: Hoelmer Kim A.[2] and Haye Tim[1], [1]CABI, Delémont, Switzerland, [2]U.S. Dept. of Agriculture, Agricultural Research Service, Beneficial Insect Introduction Research, Newark, Delaware, United States,

Abstract: Our presentation addresses various risks to consider when utilizing exotic natural enemies for biological control of invasive species. These include not only accurately assessing the risk of reproducing in non-target species, but also non-reproductive mortality due to unsuccessful attacks, competitive interactions with native biocontrol agents and potential secondary effects on non-target hosts that are not directly attacked by the exotic agents. Risk also includes considering the consequences of not including biological control as a management option. Accurate identification of biocontrol agents is a cornerstone of biological control, thus close collaboration with taxonomists ensures that important biological and identifying characteristics are correctly associated with taxa and biotypes. Advances in molecular biology have enhanced this collaboration. Native range studies contribute information on anticipated non-targets. Traditional laboratory physiological no-choice and choice tests remain valuable for estimating host specificity for regulatory applications, although they are likely to be excessively conservative, which risks rendering an effective agent off-limits. Advances in electrophysiology and chemical ecology now make it possible to identify the environmental and behavioral cues important in host habitat recognition and host finding and which may moderate physiological host ranges.

Status of adventive Trissolcus japonicus in the United States

Authors: Hoelmer Kim A.[1] and Tatman Kathleen[1], [1]U.S. Department of Agriculture Agricultural Research Service Beneficial Insects Introduction Research Unit Newark, DE, United States

Abstract: The egg parasitoid Trissolcus japonicus (Hymenoptera: Scelionidae) is thought to be the most important natural enemy suppressing the agricultural pest Halyomorpha halys (Hemiptera: Pentatomidae) in its native range in China. Since the invasion of H. halys into the United States (first record from 1996), adventive populations of T. japonicus have been documented in several states where H. halys is present. The first report of adventive T. japonicus was in Maryland in 2014, and it is now present in at least 13 other U.S. states and Washington D.C. Within many states where adventive populations have been documented, mass rearing and redistribution efforts are underway. Additionally, because quarantine requirements have been lifted in these areas, an increase in research capability has improved our understanding of T. japonicus biology and its impact on H. halys. We will discuss some highlights of this research, including studies on longevity, maximum fecundity, and attempts to understand colonization processes as T. japonicus moves into new habitats and regions.

Using acoustic signals to manage bark beetles and other wood-infesting pests

Authors: Hofstetter Richard[2], Copp Brennan[3], Bedoya Carol[4], Dunn David[5], Lukic Ivan[3] and Aflitto Nick[1], [2]Northern Arizona University, United States, [3]School of Forestry, Northern Arizona University, United States, [4]University of Canterbury, Christchurch, New Zealand, [5]University of Santa Cruz, United States, [1]Department of Entomology, Cornell University, United States

Abstract: Wood-infesting insects (such as termites, bark beetles, wood borers and ambrosia beetles) are one of the most significant biotic disturbance agents in forest ecosystems, and when introduced into new habitats typically lead to extensive economic losses, transitions of forest communities, and negative impacts on local recreation and food production. These insects have well developed chemical communication systems that allow for aggregations on host trees, which is often exploited in control strategies and management. However, these insects also use acoustic signals to communicate at the tree surface and within tree tissues. These acoustic signals can be complex and provide a context for species recognition, premating interactions, pair formation, mate selection, intra-species aggression, territoriality and predator deterrence. Acoustic communication provides an avenue for species detection in wood materials and also strategy for beetle management and tree protection. We will discuss technical and applied applications of acoustic tools for management of wood-infesting insects and fungi.

Prospects for biological control of bagrada bug in California using egg parasitoids

Authors: Hogg Brian[2], Pickett Charlie[1] and Grettenberger Ian[3], [2]United States Department of Agriculture, United States, [1]California Department of Food and Agriculture, United States, [3]University of California, Davis, United States

Abstract: Bagrada bug, Bagrada hilaris, a native of southern Asia, quickly became a damaging pest of cole crops (i.e., cabbage, broccoli, cauliflower, kale) in California after its discovery near Los Angeles in 2008. Conventional pesticides are currently the most effective means for controlling bagrada bug, but are unavailable to organic growers. Two potential biological control agents for bagrada bug, the egg parasitoids Gryon gonikopalense and Trissolcus hyalinipennis, were collected from Pakistan in 2016. Host specificity testing indicates that G. gonikopalense is more specific to bagrada bug than T. hyalinipennis. Further tests showed that G. gonikopalense could locate and attack bagrada bug eggs in the soil, where most bagrada bug eggs are laid, and appears to search preferentially at ground level. In contrast, T. hyalinipennis could only attack eggs on the soil surface. In 2016-2019 we also conducted surveys throughout northern and central California to evaluate attack rates by resident egg parasitoids on bagrada bug eggs. To survey parasitoids, we used sentinel bagrada bug eggs glued to waterproof index cards, and placed the cards in plant foliage and on the ground in cole crop fields and adjacent patches of weedy bagrada bug hosts. Few parasitoids emerged from the 1000s of eggs we deployed, and parasitism occurred almost exclusively in plant foliage and not on the ground. Several adventive egg parasitoid species attacked bagrada bug eggs in laboratory tests, but only at low levels of efficiency. Thus, results indicate that an exotic egg parasitoid is needed to help control bagrada bug in California, and that G. gonikopalense is a particularly promising candidate.

More stable flies, Stomoxys calcitrans, will be captured with proper placement of traps

Authors: Hogsette Jerome, USDA–ARS, Center for Medical, Agricultural and Veterinary Entomology, 1600 SW 23rd Drive, Gainesville, FL 32608, United States

Abstract: Stable flies are an important livestock pest in many parts of the world. Both sexes are blood feeders and they can adversely affect production and animal comfort. Traps have been used for many years, mainly to sample stable fly populations, but with some efforts to affect a population reduction. Claims have been made that traps will protect host animals by catching the stable flies before they can bite the animals. Some claims also include the size of the area protected by individual traps. We could not substantiate these claims by surrounding tethered horses with traps placed only 3.7 m from the animals. Traps must be placed out of the reach of host animals because animals tend to destroy traps. This limits the placement sites for traps. Stable flies on animals are usually there to feed and afterwards they tend to rest on nearby objects while digesting their meal. If traps must be placed outside of fenced paddocks and fields, the traps are outnumbered as resting sites for blood-fed flies by the many other choices in the environment. Traps placed outside of fences do not necessarily reflect fly activity, population size and fluctuation. Traps surrounds by small squares of electric fence can be placed inside of pastures and paddocks where they are quite close to the host animals. Numbers of trapped flies increases compared with traps placed outside of the fences as does the sensitivity of population fluctuations. Flies can be so numerous in locations near host animals that more than one trap is required inside the protective electric fence if traps are to be serviced on a weekly basis. Converting the traps into attract and kill devices increases the life of the traps in the field and reduces the time required for servicing.

Lycaenid caterpillar secretions manipulate attendant ant behavior

Authors: Hojo Masaru, Kwansei Gakuin University, Japan

Abstract: Ants engage in mutualistic interactions with various organisms, such as plants, aphids and butterflies, by exchanging defense and nutritious rewards. In such mutualism, partner recognition and behavioral flexibility based on the inter-specific communication are important mechanisms underlying the regulation of mutualism. In a mutualistic interaction between a Pristomyrmex punctatus ant and a lycaenid Narathura japonica butterfly, the ant workers learn to recognize mutualistic lycaenid caterpillars as partners by feeding on the nectars provided from the caterpillars. Caterpillar’s cuticular hydrocarbons are used as a key recognition olfactory signature in this context. Furthermore, naïve workers who have interacted with learned workers also increased attending behavior to caterpillars, so the ants can transmit the partner information through social interactions. However, after feeding on the nectar secretions of the caterpillars, the workers modified aggressiveness, locomotor activity and brain biogenic amine levels. This suggests that the chemical signals contained in nectar secretions manipulate worker behavior to enforce the cooperation. I will discuss the possible function and mechanisms of behavioral manipulation in a lycaenid-ant mutualism.

Entomopathogenic nematodes as a component of IPM and Ecosystem Services

Authors: Hokkanen Heikki[2], Menzler-Hokkanen Ingeborg[1], [2]Organizer, Finland, [1]Department of Environmental and Biological Sciences, University of Eastern Finland, Kuopio, Finland

Abstract: Several ways of incorporating entomopathogenic nematodes (EPN) in IPM systems are possible, and indeed they are a highly potent but underexploited component of ecosystem services. EPN can in many cases, and increasingly so, be used as directly substituting chemical pesticides as means of curative treatment. They can for example substitute for neonicotinoid seed dressing for the control of the corn rootworm in maize, or for flea beetle control in oilseed rape. EPN can also be utilised inundatively in sensitive ecosystems to control outbreaking pest species, to allow other natural enemies (parasitoids, predators, pathogens) to gain back control. We have shown this possibility at a large scale in successfully stopping an outbreak of the great web spinning sawfly Acantholyda posticalis in Finland. When EPN occur in the soil at densities typical of many natural habitats, they can be very effective parts of the insect pathogen complex constituting “insect pest suppressive soils”. Unfortunately, this role of EPN in supporting pest control ecosystem services has largely been lost, because agricultural soils usually harbour EPN at very low densities. We have shown that with very basic IPM measures it is possible rapidly to increase the incidence of EPN in agricultural soils, and with targeted management EPN densities can reach levels where they can permanently suppress some key pests. One such management measure is to increase the botanical diversity in the field, and we have shown that particularly the inclusion of leguminous plants results in higher densities of EPN in the soil over time. We propose to develop crop and field management practices that support the natural occurrence of EPN in the soil at densities that provide good control of many key crop pests. This transition can be accelerated by augmentation of field soils with EPN at the beginning of this process.

Landscape influences on an invasion front

Authors: Holland Jeffrey, Department of Entomology Purdue University, United States

Abstract: Landscape spatial characteristics can influence the velocity of insect invasion fronts. Small-scale movements and mating success of individuals coalesce to determine the speed and direction of the population. Insect invasions provide an opportunity to explore influences on range boundaries. We used 30 years of trapping data on the gypsy moth Lymantria dispar invasion of north-eastern United States to examine the influence that the arrangement of host tree density in the landscape had upon the spread of this species. Various techniques for modeling the spread were compared. This landscape ecology work is being combined with concurrent studies of gene flow and population dynamics to build a complete cross-scale model of invasion processes.

Long-term changes in invertebrate abundance on two areas of arable farmland in England.

Authors: Holland John[2], Ewald Julie[1], Aebischer Nicholas[1] and Moreby Steve[1], [1]Game & Wildlife Conservation Trust, United Kingdom

Abstract: The Game and Wildlife Conservation Trust has monitored “in crop” invertebrate abundance in two areas of arable farmland in the southern half of England, with invertebrate collection beginning in 1970 at one of the study areas in the county of West Sussex, and in 1992 at the other in the county of Leicestershire. Overall invertebrate numbers on the Sussex area have declined by a third since 1970, but individual taxa showed a variety of patterns of change. For example, most families of Coleopterans have declined by over 80%, while Dipterans as whole have declined by a third and Lepidopterans have increased by 80%. The effect of cropping, pesticide use, weather and field size on these changes will be considered as drivers of the trends identified. Results from the Leicestershire site, where monitoring began later and management has been directed towards best practice for wildlife, have shown fewer significant changes. The ability of agri-environment options directed towards conserving farmland wildlife (conservation headlands, beetle banks) and agricultural practices aimed at conserving soil (reduced tillage) to mitigate some of these changes in invertebrate abundance will be discussed.

The BEESPOKE project

Authors: Holland John[3], Fountain Michelle[8], Sigsgaard Lene[11], Strijkstra Arjen[14], Albach Dirk[13], Stubbe Frank[15], Smagghe Guy[4], Elmquist Helena[9], Mathiasen Helle[6], Fraser Iain[12], van Kruyssen Jan-Willem[2], Bijkerk Jojanneke[1], Arno Krause[5], Fabricius Kristiansen Lotta[10] and Van Loo Thomas[7], [11]Cruydt-Hoeck, Netherlands, [2]Freelance/ Provincie Fryslân, Silence of the Bees, Netherlands, [3]Game & Wildlife Conservation Trust, United Kingdom, [4]Ghent University, Belgium, [5]Grünlandzentrum Niedersachsen/Bremen, Germany, [6]HortiAdvice Scandinavia A/S, Denmark, [7]Inagro VZW, Belgium, [8]NIAB EMR, United Kingdom, [9]Odling I Balans, Sweden, [0]Swedish University of Agricultural Sciences, Sweden, [11]University of Copenhagen Department of Plant and Environmental Sciences, Denmark, Denmark, [12]University of Kent, United Kingdom, [13]University of Oldenburg, Germany, [14]Van Hall Larenstein, Netherlands, [15]Vlaamse Landmaatschappij, Belgium

Abstract: Insect pollination is worth €15 Billion in the EU, however, wild pollinators are declining because of loss in flower-rich habitats. The North Sea Region (NSR) of Europe is one of the most productive agricultural areas but has been identified as having low pollination potential. A new project called BEESPOKE (Benefitting Ecosystems through Evaluation of food Supplies for Pollination to Open up Knowledge for End users) aims to increase levels of pollinators and crop pollination at local and landscape scales by providing land managers and policy makers with new expertise, tools and financial knowledge to create more sustainable and resilient agroecosystems. BEESPOKE brings together a wide range of partners from policy makers, research institutes, advisory and end users from 6 NSR countries to develop new products and approaches to increase the diversity of insect pollinators and crop yields. We will develop bespoke seed mixes and habitat management guidelines to support the suite of pollinators required for 14 crop types across 72 demonstration sites. Sites for each crop will showcase best management practices and training materials will be developed for biodiversity monitoring and measuring pollination. The same agroecosystems occur across the NSR and transnational cooperation will also give economies of scale for development of these novel tools. The approach will empower land managers to adopt pollinator management as a routine practice, fostering a bottom-up, land manager approach, creating a legacy to ensure continuing improvements for insect pollination of food crops. The project will run from July 2019 until January 2023.

BEESPOKE is carried out in the framework of the Interreg North Sea Region Programme (www.northsearegion.eu) under the Programme Priority 3 “Sustainable North Sea Region” and the Specific Objective 3.2 “Develop new methods for the long-term sustainable management of North Sea ecosystems”. The programme is funded by the European Regional Development Fund (ERDF) of the European Union.

Comparative ecology of geometrid moths: in search of contrasts between a temperate and a tropical forest

Authors: Holm Sille[1], Davis Robert[5], Kaasik Ants[4], Õunap Erki[4], Molleman Freerk[2], Roininen Heikki[3] and Javoiš Juhan[4], [1] University of Tartu, Estonia; University of Eastern Finland, Finland, Estonia, [5]University of Tartu, Estonia, Estonia, [4]University of Tartu, Estonia, [2]A. Mickiewicz University, Poland, [3]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland

Abstract: Understanding the variation in life-history strategies lies at the core of modern evolutionary ecology. Comparative studies on insect life histories are facilitated by the increasing availability of reliable phylogenies but are hampered by the scarcity of comparable data. Data are especially scant for the highly vulnerable tropical regions, where the species themselves and interactions between them are still largely unknown.

Worldwide there are approximately 24 000 described geometrid species, but we know very little about the life histories of tropical species. We present the results of a phylogenetically informed analysis comparing the values of life-history traits for a sample of tropical geometrid moth species to a selection of species representing a temperate habitat. For about 250 temperate and tropical region geometrid species, data on host-plant specificity, longevity and breeding strategy were collected. A phylogeny was derived for these species and the collected data compared in phylogenetically informed analyses.

Larval diet breadth of tropical and temperate species was compared in host-plant acceptance trials. There were broadly polyphagous species in both regions. Oviposition latency (i.e. pre-oviposition waiting time of a female; an indirect measure of host specificity) was also found to be similar in both regions. Adult lifespans of wild-caught individuals were found to be similar for both regions. Larger species showed a tendency to have longer lifespans. Although, it was predicted that income breeding (i.e. usage of adult-derived nutrients for reproduction) may be more prevalent in the tropics than in temperate habitats, the patterns found were inconclusive and do not provide clear evidence in support of major differences

The results of this study suggest that host-plant specificity, longevity and breeding strategy are rather similar for the studied temperate and tropical moths. This allows us to conclude that the world the moths experience and the factors that shape their life histories may not be so different for the tropical and temperate regions after all.

Assembly of food webs during Afrotropical forest restoration

Authors: Holm Sille[1], Valtonen Anu[5], Nyman Tommi[4], Wutke Saskia[6], Malinga Geoffrey[2] and Roininen Heikki[3], [1] University of Tartu, Estonia; University of Eastern Finland, Finland, Estonia, [5]University of Eastern Finland, Joensuu, Finland, [4]Dept. of Ecosystems in the Barents Region Norwegian Inst. of Bioeconomy Research Norway, Norway, [6]University of Eastern Finland, Finland, [2]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland Department of Biology, Gulu University, Gulu, Uganda, Ugand, [3]Department of Environmental and Biological Sciences, University of Eastern Finland, Joensuu, Finland

Abstract: The rapid decline of natural tropical forest ecosystems has caused severe changes and the loss of insect communities. Restoration of these forests has now emerged as a global priority. Yet, it is still poorly understood how efficiently forest restoration can bring back the complexity of functioning ecosystems, such as the crucial networks of species interactions.

We study the assembly of food webs in different-aged natural and actively restored Afrotropical rainforests at Kibale National Park, Uganda. We are focusing on food webs consisting of trees, lepidopteran larvae feeding on them, and the parasitoids of the lepidopteran larvae. In this presentation, we will report the first results of the fieldwork season carried out in 2019. We will make a preliminary overview on lepidopteran communities from the different-aged restored forest and show how these communities change during the restoration process. We will also briefly introduce our fieldwork results from 2021.

Long-term population census of the mulberry tiger moth, Lemyra imparilis (Butler) in Japan

Authors: HONDO MASARU, Osaka City, Japan

Abstract: The population density of some insects occasionally reaches outbreak level. As such extraordinary density changes often cause serious damage on forests and farm products, to monitor the density of insect pests and analyze the pattern of population fluctuations is an important task economically. The mulberry tiger moth, Lemyra imparilis (Butler) (Lepidoptera: Erebidae), is a univoltine species that is distributed from south to east Asia. It is widely distributed across Japan. The larvae hatched from the egg mass are gregarious and form communal nests covered with silk webs on the host tree during autumn. By contrast, the larvae in spring are solitary and feed on various plant species. The mature larvae pupate in underground litter from May to June. In the southwestern Japan, outbreaks of the moth have widely occurred from the eastern area, Shizuoka Prefecture to western area, Kyushu Island during 1968 and 1973. In these periods, various crops, for example, citrus, pears and tea plants were severely damaged by the sprig larvae. Thereafter, outbreaks have been sometimes observed at local areas in the southwestern Japan. Historical records of population peak years of the moth observed in the southwestern Japan exhibited that the peaks appeared periodically with periods of 7 or 9 years. In the northeastern Japan, on the other hand, it is well known as an insect pest of the mulberry tree. However, no wide-ranged outbreaks like those in the southwestern Japan have been recorded. On Hachijo Island where is oceanic island far from about 300Km south from Tokyo, moreover, the outbreak of the moth was suddenly observed in late 1970s and the moth has been recognized as a major pest of ornamental plants that is specialty of the island since then. In this work, the population changes have been surveyed by counting larval nests of the moth every year at several sites in Japan since 1989. It was found that the population fluctuations of the mulberry tiger moth in Japan exhibited four patterns of geographic variation: (A) cyclic population fluctuations with relatively high amplitude and sharp peak shape in the southwestern Japan, (B) non-cyclic population fluctuations with high density and flat peaks at the southern coastal Kinki in the southwestern Japan, (C) non-cyclic population fluctuations with low density and stable density change in the northeastern Japan, and (D) non-cyclic population fluctuations with very high density and stable density change on Hachijo Island. Comparing to some moth populations which exhibited cyclic fluctuations in harsh environments, for example, in the north rather than in the south and in mountainous rather than in lowland regions, the mulberry tiger moth showed cycles in mild environments in the southwestern Japan. To clarify mechanisms making these different geographic patterns of population fluctuations of the mulberry tiger moth is a next challenge.

A new Mymaromma sp. (Mymarommatoidea: Mymarommatidae) in Hawaii and first host record for the superfamily

Authors: Honsberger David[1], Huber John and WRIGHT MARK[1], [1]University of Hawaii at Manoa Honolulu, Hawaii, United States

Abstract: A new species of Mymaromma (Mymarommatoidea: Mymarommatidae) was found emerging from eggs of a Lepidopsocus sp. (Psocodea: Lepidopsocidae) in Hawaii. This provides the first host record for the superfamily Mymarommatoidea, the last superfamily of parasitoid Hymenoptera for which no hosts were known, and comes approximately 100 years after the first extant species was described.

Tiny Targets – from a research project to large scale tsetse control operations for the elimination of gambiense Human African Trypanosomiasis in Uganda

Authors: Hope Andrew[5], Mugenyi Albert[1], Waiswa Charles[2], Mangwiro Clement[3], Tirados Inaki[5], Esterhuizen Johan[5], Lehane Michael[5], Selby Richard[5] and Torr Steve[4], [1]Coordinating Office for Control of Trypanosomiasis in Uganda Buganda Road Kampala, Uganda, [2]Coordinating Office for Control of Trypanosomiasis in Uganda Buganda Road Kampala, Uganda, [3]Department of Animal Science Bindura University of Science Education Bindura, Zimbabwe, [4]Liverpool School of Tropical Medicine, United Kingdom, [5]Vector Biology Department Liverpool School of Tropical Medicine Pembroke Place Liverpool, United Kingdom

Abstract: Historically, the control of gambiense Human African Trypanosomiasis (gHAT) has relied on the large-scale screening and treatment of populations. Great progress has been made reducing case numbers, but it is recognised that additional interventions are required if elimination goals are to be met. Vector control did not play a major role in gHAT control initiatives because methods that were developed for the control of “savannah” tsetse flies were too expensive and logistically challenging for use against the “riverine” species that transmit gHAT. Research into the responses of “riverine” tsetse to visual and olfactory cues led to the development of a new tool, the Tiny Target.

In 2011, Tiny Targets were trialled on islands in Lake Victoria, 20 Tiny Targets were deployed per round of deployment and this led to a greater than 99% reduction in tsetse densities. Further trials followed in Uganda using 50km2 blocks, then increasing to 500km2 before launching into a large-scale control operation covering 2,500km2 in five Districts in 2014, representing the largest gHAT vector control programme in the world. The intervention area doubled in size in 2016 and include two further Districts. Further expansion was initiated when northern Uganda experienced a huge influx of refugee populations from gHAT endemic South Sudan. Currently, over 40,000 Tiny Targets are deployed annually in Uganda. Regular monitoring of tsetse densities across the intervention areas demonstrates that Tiny Targets are achieving reductions of more than 80% in tsetse densities. Uganda has had a great decline in gHAT case numbers over the last decade, only one case was recorded in 2018, and in the next phase of our programme we will start to scale back vector control.

Tiny Targets provide a cost-effective, easy to use technology which can be readily implemented by national control programmes. Tsetse control is now recognised as an essential part of the fight to eliminate gHAT and is a named part of the WHO elimination strategy. The Tiny Target story provides an example of how a new technology can be developed and rolled out at scale in a relatively short time period.

Genetics of host specificity, climatic tolerance, and other traits affecting biological control by introduced parasitoids

Authors: Hopper Keith, United States Department of Agriculture, Agricultural Research Service, Beneficial Insect Introductions Research Unit, Newark, DE, United States

Abstract: One way to increase the efficiency of species used in biological control would be to breed or transform organisms to improve their performance. To do this, we would need to determine which traits are likely to improve performance, how much variation already exists in these traits, how this variation is distributed within and among populations, and the genetic architectures underlying this variation. Multiple approaches are used to measure genetic variation in traits, and these include resemblance in traits among family members, crosses between lines that differ in traits, response to selection on traits, association between traits and genetic differences within populations and between populations, differences in gene expression underlying trait differences, analysis of tissue-specific expression of candidate genes, effects of manipulation of expression of candidate genes on traits, and effects of genetic transformation on traits. All these approaches can be used separately but are most powerful when used in combination. I discuss how some of the older approaches, in particular, family resemblance, line crosses, response to selection, can be used in any laboratory were insects are reared to gather information about genetic variation with small changes in book-keeping or protocol. This being said, there have been huge advances over the last decade in DNA/RNA sequencing that have provided much higher throughput at much lower costs for genotyping-by-sequencing and analysis of gene expression. Furthermore, there has been a revolution in our capacities to manipulate gene expression using RNAi, to study tissue-specific expression of genes using fluorescent in-situ hybridization and modern imaging, and to silence, modify, or insert gene sequences using CRISPR/Cas9. These advances in technology have opened up the possibility of using these approaches in a wide variety of non-model organisms, and I discuss examples of each, where possible in biological control introductions. I review the evidence concerning genetic variation in traits that are considered likely to affect performance of species introduced for biological control and discuss the implications for breeding or transformation to improve performance. In particular, I discuss what is known about the genetics of host specificity and climatic adaption. The latter is particularly important given the likely impact of climate changes on interactions between pests and natural enemies. Although the pace of progress is accelerating, we still have much to learn, and given imminent changes in climate, we need to learn rapidly.

Genetics of insect rearing

Authors: Hopper Keith, United States Department of Agriculture, Agricultural Research Service, Beneficial Insect Introductions Research Unit, Newark, DE, United States

Abstract: Rearing insects is critical to much of entomological research and pest management, and genetic changes, i.e., evolution, during rearing can have profound implications for the results of research and management. Whether evolution in traits of importance occurs depends on how much variation exists in the traits and the genetic architecture underlying this variation. Several processes can cause genetic changes: mutation, migration, drift, non-random mating, and selection. Mutation and migration are the original sources of genetic variation in natural populations. However, mutation is unlikely to be important in reared insects because the populations are small and mutation is rare. Furthermore, migration can be controlled with reared insects so it is more easily managed than the other processes. Genetic drift is random loss of genetic variation in small populations, either from founder effects or population bottlenecks. Drift can lead to loss of adaptability and poor performance in field. Non-random mating can cause inbreeding depression when mating of close relatives exposes deleterious alleles or to outbreeding depression when crosses between populations create deleterious genotypes. Both inbreeding and outbreeding depression lower fitness and cause colony decline. Selection is systematic change in gene frequencies, and it can be intentional in a breeding program or unintentional when there is inadvertent adaptation to the rearing environment, which can lead to poor performance in field. I review methods managing drift, non-random mating, and selection during insect rearing. Drift and inbreeding depression can be reduced by starting and maintaining large colonies. Inbreeding depression can also be reduced by controlling matings. Outbreeding depression can be avoided by not mixing different source populations. Inadvertent selection can be reduced by making the laboratory environment resemble the field environment and by maintaining sub-populations or even isolines. I review methods for measuring genetic variation: family resemblance, line crosses, selection responses, associations between genetic markers and traits, gene expression especially tissue-specific expression, manipulation of expression of candidate genes, and genetic transformation. These approaches can be used separately but are most powerful when used in combination. I discuss how some of these approaches can be used in any rearing program with small changes in book-keeping or protocol. There have been huge advances over the last decade in DNA/RNA sequencing and a revolution in our capacities to manipulate gene expression, study tissue-specific expression, and modify sequences. These advances in technology have opened up the possibility of using all these approaches in model and non-model organisms.

Role of tarsal gustation in chrysomelid beetles

Authors: Hori Masatoshi[2], Chiba Yuki[1] and Yosano Shun[1], [1]Graduate School of Agricultural Science, Tohoku University, Japan, [2]Tohoku University, Japan

Abstract: It is known that Diptera and Lepidoptera have tarsal gustatory sensilla that allow them to recognize tastes and select suitable hosts by using their legs. However, in Coleoptera, the largest insect order, the existence of tarsal gustatory sensilla and their role in taste recognition have not been fully investigated. In a previous study, through morphological observations by using a scanning and transmission electron microscope, we found that all subfamilies of Chrysomelidae have gustatory sensilla on the tarsus. Additionally, we revealed that Galerucella grisescens (Coleoptera: Chrysomelidae) could positively respond to the leaf surface wax of host plants with their legs but not to the waxes of the non-host plants. These results indicate that tarsal gustatory sensilla are used for host selection in Chrysomelidae. However, the mechanism for reception of the diverse tastants by the tarsal gustatory sensilla of chrysomelid beetles is still unclear. In this study, we investigated the electrophysiological response of the tarsal gustatory sensilla of G. grisescens to a range of substances with different tastes by using a tip-recording method. Various tastants, including NaCl, KCl, brucine, sucrose, and the leaf surface wax of Rumex obtusifolius (the host plant of G. grisescens), were perceived by the tarsal gustatory sensilla of the beetles in a dose-dependent manner. The previous and present studies indicate that tarsal taste recognition is important in host selection. On the other hand, in some insect species, including members of Chrysomelidae, it is known that gustation is important in mate recognition as well as host selection. We have previously reported that chrysomelid beetles use cuticular wax as a contact sex pheromone. However, the role of tarsal gustation in mating behavior has not yet been clarified. Therefore, we investigated the ability of G. grisescens to recognize contact sex pheromone through their tarsi by using a behavioral test. The male beetles could mate with female beetles even if their antennae and maxillary and labial palps were ablated. This suggested that male beetles can recognize female contact sex pheromone with their tarsi alone. Next, we compared the chemical composition of the leaf surface wax of R. obtusifolius and the cuticular wax of G. grisescens by GC-MS analysis. The chemical compositions of both waxes were very different, although a small number of common components (e.g., n-alkanes) were detected. Therefore, the beetles may also be able to perceive contact-sex-pheromone components that are not contained in the leaf surface wax by their tarsal gustatory sensilla. Further studies are necessary to clarify the relationships between the mechanisms of taste recognition in host selection and those used in mating behavior.

Blue light irradiation: a novel method for mosquito control.

Authors: Hori Masatoshi[1], Taniyama Katsuya[1] and Saito Yoshino[1], [1]Tohoku University, Japan

Abstract: We previously reported that visible blue light (400-500 nm) has lethal effects on several insect species (i.e. Drosophila melanogaster, Galerucella grisescens). However, the details of these effects on mosquitoes are not yet clear. In this study, we examined the toxicity of blue light in two species of mosquitoes, Culex pipiens molestus and Aedes albopictus., which are important pests and vectors of various diseases. C. pipiens molestus occurs mostly in urban underground structures and transmits the West Nile virus to humans, while A. albopictus occurs mostly in natural areas and transmits Zika and dengue viruses. We first investigated the effects of various wavelengths of blue light (375, 406, 417, 427, 438, 452, 467, and 493 nm) at different photon flux densities (5, 10, and 15 × 10^18 photons·m^-2·s^-1) on the eggs, larvae, pupae, and adults of C. pipiens molestus using light emitting diodes. The mortality of larvae that hatched from eggs irradiated with 417 and 427 nm lights at 10 × 10^18 photons·m^-2·s^-1 was 70% or more, whereas that in the dark condition (control treatment) was less than 10%. Seventy percent or more of larvae irradiated with 417, 427, and 438 nm lights at 10 × 10^18 photons·m^-2·s^-1 died before eclosion, whereas only 10% of death was observed in the dark condition. The mortality of pupae irradiated with 417 nm light at 10 × 10^18 photons·m^-2·s^-1 was approximately 60%, whereas that in the dark condition was less than 5%. The longevity of the adult males and females irradiated with any of the tested wavelengths of light at 10 × 10^18 photons·m^-2·s^-1 were approximately half of that for individuals in the dark condition. Blue light also had lethal effects on A. albopictus larvae. All larvae irradiated with 417 nm light at 10 × 10^18 photons·m^-2·s^-1 died before eclosion, whereas the mortality of larvae in the dark condition was less than 10%. Our results show that blue light around 420 nm was the most effective wavelength to kill C. pipiens molestus and A. albopictus species. Our findings may lead to the development of non-chemical killing techniques for mosquitoes with the use of blue light.

Lethal effects of blue light on insects and mechanisms of action

Authors: Hori Masatoshi[3], Kobayashi Atsuki[2], Aso Hisashi[1], Hosaka Kazuki[1], Shibuya Kazuki[1], Harata Masahiko[1] and Onodera Shun[1], [1]Graduate School of Agricultural Science, Tohoku University, Japan, [2]Graduate School of Agricultural Science, Tohoku University, Japan, [3]Tohoku University, Japan

Abstract: We previously reported that blue light (400–500 nm) has lethal effects on various insects. The effective wavelength of blue light is species-specific and is not always associated with the amount of photon energy delivered. However, the mechanism responsible for the lethal effects is not known. Blue light injures organisms by inducing the production of reactive oxygen species (ROS). We, therefore, investigated the generation of H2O2, which is one of the main ROS, by irradiating Drosophila melanogaster pupae with blue light. The generation of H2O2 increased with an increase in the number of photons at all the tested wavelengths of blue light. Furthermore, the H2O2 generation was wavelength-specific. This specificity was similar to the wavelength-specific lethal effect on fly pupae. We surmised that blue light transmitted through the integument and/or compound eyes is absorbed in certain inner tissues and induces the production of ROS. Next, we compared the lethal effects of blue light between the adults of nine fly strains, namely two wild-type (Canton-S and Sumika) and seven mutant (white: white eyes, sepia: sepia eyes, Bar: bar eyes, eye missing: absence of eyes, Cryb: loss of cryptochrome function, norpA: defection of phototransduction, ebony: melanic integument) strains of D. melanogaster. The mortality of Cryb was similar to that of wild type strains. Therefore, we believe that cryptochrome does not contribute to the toxicity of blue light. The tolerance of Bar and eye missing to blue-light irradiation was lower than that of the wild type strains. Hence, it is believed that the penetration of blue light through the compound eyes is not very important for toxicity. In contrast, the mortality of ebony was notably lower than that of the other strains. The blue-light transmittance through the integument was measured using a hyperspectral camera and it was observed that the fly strains with lower transmittance tended to be more tolerant to blue light.
Blue light also exerted injurious effects on Drosophila Schneider 2 (S2) cells. Irradiation with blue light (405–470 nm) suppressed the growth of S2 cells whereas irradiation with blue-green, green, yellow, and red light (490–660 nm) did not do so. Interestingly, fluorescence microscopy revealed that the mechanisms underlying the injurious effects on S2 cells differed between blue light of short (405 nm) and long wavelengths (470 nm). Furthermore, we analyzed the cell-cycle distribution of non-irradiated S2 cells and those irradiated with 405 or 470 nm light using flow cytometry. It was inferred that the growth of S2 cells irradiated with short-wavelength blue light was suppressed because of S-phase arrest, whereas in cells irradiated with long-wavelength blue light, the growth was suppressed because of G2/M arrest. Our findings suggest that the toxicity of blue light to insects results from cell injury caused by the ROS produced upon irradiation with blue light transmitted thorough the integument.

How mating disruption controlled an orchard pest when insecticides could not.

Authors: Horton Dan, Department of Entomology University of Georgia Athens, GA 30602, United States

Abstract: Synanthedon pictipes (Lepidoptera: Sesiidae) is a serious pest of peach in the eastern US. Larvae feed on the cambium of trunks and limbs where their tunneling behavior protects them from applied insecticides. Historically, in-season cover sprays of the organophosphate insecticide methyl-parathion, having a long residual on limbs, prevented populations of S. pictipes from building in orchards. After this insecticide was removed from peach production, populations of S. pictipes increased in the southeastern US and their management with other insecticides was negligible. Part of this poor control is due to the tunneling behavior of larvae but also due to the seasonal activity of this pest being active from mid-March through late November thus preventing an economical solution with insecticide application. Mating disruption was tested as a management technique for this pest. Trap shutdown in plots treated with the mating disruption pheromone was easily achieved regardless of plot size. Over years of testing with increasing plot sizes, even up to 8 ha, plots were not large enough to prevent larval feeding injury. Even at 8 ha, plots were not large enough to exceed the flight capacity of females mated outside the treated plot from invading mating disruption plots. Results from these replicated failures supported the need to address the problem at an areawide scale. Using an areawide approach to mating disruption, all peaches in a 50 sq km area (about 400 ha) were treated with a mating disruption product. As with past studies, male capture in traps was negligible. In stark contrast to past studies, S. pictipes reproduction in these orchards declined significantly. After a two-year demonstration, the success of this areawide mating disruption trial has led to the adoption of mating disruption of S. pictipes as a grower management strategy in the southeastern USA.

Characterization of the piercing behaviors of white-backed planthopper in transmission of a plant virus

Authors: Hou Maolin[2], Li Pei[1] and Lei Wenbin[1], [2]State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [1]State Key Laboratory for Biology of Plant Diseases and Insect Pests, Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

Abstract: Using an electrical penetration graph, we characterized the piercing behaviors of the white-backed planthopper (WBPH) in relation to infection status of the southern rice black-streaked dwarf virus (SRBSDV), transmission success, and host plant species.

When feeding on uninfected rice plants, viruliferous WBPH spent more time in salivation and phloem sap ingestion than non-viruliferous insects. In contrast, infected rice plants showed an arresting effect on non-viruliferous WBPH for phloem sap ingestion.

The WBPH that inoculated SRBSDV exhibited more probing bouts, salivation events and phloem sap ingestion events and longer salivation than those that failed to. The WBPH that acquired SRBSDV were quicker to reach phloem and spent more time in phloem sap ingestion than those that failed to.

When provided with different species of infected plants, the insects showed impaired phloem sap ingestion on corn plants in comparison with on rice plants, which accounted for the high mortality of and low virus acquisition by WBPH on corn plants and resulted in asymmetric spread of SRBSDV between rice and corn.

The vector’s behaviors in relation with viral infections status may have adaptive advantages for virus transmission because greater salivation by viruliferous vectors will promote virus inoculation, whereas more sap ingestion by non-viruliferous vectors will promote virus acquisition. The asymmetric spread of SRBSDV between rice and corn is of significance for assessing SRBSDV transmission risks and field epidemiology.

Consumer acceptance of insects as food and feed in Europe

Authors: House Jonas, Wageningen University, Netherlands

Abstract: The potential of insects as an environmentally-friendly and resource-efficient protein source is now clearly established, and considerable advances have been made across the insect value chain in Europe. Nevertheless, consumer acceptance remains a key challenge for the broader success of the sector. This presentation draws on research with European consumers, outlining a number of key findings and considerations regarding consumer acceptance of insects as food and feed. The presentation highlights a ‘demand-side’ tendency in current research, in which public attitudes are identified as the main barrier to consumer acceptance. Some drawbacks of this perspective are discussed, and an alternative ‘supply-side’ approach is proposed. In this view, attainment of consumer acceptance is the responsibility of actors in the insect value chain, who must work together to create insect-based products which are tasty, affordable, easily available, and which integrate into existing diets in a coherent manner. Key recommendations include a focus on potential ‘early adopter’ consumers rather than whole populations, and consideration of appropriate dishes and cuisines for the introduction of insect-based products.

Towards global standards for automated insect monitoring

Authors: Hoye Toke[1], Alison Jamie[2], [1]Aarhus University, [2]Aarhus University, Denmark

Abstract: Advances in computer vision and deep learning provide new solutions to the challenge of understanding the potentially global insect decline. Cameras and other sensors can effectively, continuously, and non-invasively perform entomological observations throughout diurnal and seasonal cycles. The physical appearance of specimens can also be captured by automated imaging in the lab. When trained on these data, deep learning models can provide estimates of insect abundance, biomass, and diversity. Further, deep learning models can quantify variation in phenotypic traits, behaviour, and interactions. Emerging prototypes of new digital sensors hold the potential to generate automated and globally standardised insect monitoring data. However, to reach this transformative goal, international collaboration and coordination on a range of outstanding challenges is critical. Such challenges include defining minimal requirements and standards for hardware design, recording software, metadata collection, machine learning models, analyses pipelines, and the integration with existing monitoring programs. I will present examples of how these technologies are being applied to longstanding questions in insect monitoring. I will also present current steps towards global collaboration on these challenges and highlight future research avenues to facilitate the transition of these technologies from the current level of demonstration to broad scale application in global insect monitoring.

Use of Biological Control for Fall Armyworm by Smallholder Farmers

Authors: Hruska Allan, Michigan State University

Abstract: Fall Armyworm (FAW) (Spodoptera frugidperda) has been an important invasive pest of maize and other crops in Africa, Asia, and Oceania since 2016. Native to the Americas, FAW is an important pest of maize and other crops throughout its range. While commercial maize farmers who produce for stable markets use a wide range of integrated management tactics, the vast majority of maize farmers in Africa, Asia, and Oceania are smallholder farmers who produce maize under very different economic conditions. These conditions severely constrain the farmers' access to and viability of certain tactics, including among biological control options. The economic and risk management context of commercial farmers permit the development and use of commercial biological control approaches, including the use of VPN, Bt, egg parasitoids, and botanical insecticides. Smallholder farmers may have access to the some of the same organisms, but their use of them is constrained to local, non-commercial uses, largely based on farmer recognition of the organisms and how to attract or use the organisms. This work reviews the subset of biological control options that are accessible and economically viable for smallholder maize farmers to manage FAW.

Wolbachia titer affects the fitness of biological control hosts and its proliferation after Wolbachia transmission

Authors: Hsiao Yi-Ting, Lai Ching-Ting and Wu Li-Hsin

Abstract: Wolbachia is arguably among the most abundant endosymbiont in arthropods, and two major reasons accounted for such success are effective maternal transmission and various phenotypic traits induced. However, Wolbachia transfer to a new host through interaction, but it may not always proliferate and transfer successfully. In this study, we found Wolbachia strain wCcep infected Trichogramma chilonis in Taiwan, which came from the alternative host Corcyra cephalonica that raring mass in our laboratory. To realize the association between horizontal transmission of wCcep and wCcep titer on the host, we found that the host egg hatch rate declined gradually (49%) as Wolbachia titer decreased. After we established the uninfected wCcep C. cephalonica population (wCcep-) and re-established the uninfected wCcep T. chilonis population, T. chilonis (wCcep-) parasitized the host egg separately. The result shows that the titer of wCcep rises rapidly on the second generation of the T. chilonis population, presenting no significant difference with the infected population. In summary, the decreasing concentration of wCcep on C. cephalonica affected its fitness negatively. The higher titer of wCcep when parasitism occurs, the titer of wCcep on T. chilonis increased more efficiently, and the chance of successful horizontal transmission of wCcep is improved.

Integrated Trichogramma wasp control for Asian corn borer can help decrease insecticide use on maize in Taiwan

Authors: Hsieh Chia-Hung[1], Lin Chung-Pin[6], Chang Kuang-Hua[3], Lin Li[2], Chen Sheng-Kuan[5] and Chuang Yu-Hsiang[4], [1]Department of Forestry and Nature Conservation, Chinese Culture University, Taiwan, [6]Taiwan Sugar Research Institute, Taiwan Sugar Corporation, Taiwan, [3]Hualien District Agricultural Research and Extension Station, Taiwan, [2]Hualien District Agricultural Research and Extension Statiom, Taiwan, [5]Tainan District Agricultural Research and Extension Station, Taiwan, [4]Huatung Operation Branch, Taiwan Sugar Corporation, Taiwan

Abstract: The Asian corn borer (Ostrinia furnacalis) is the main pest of maize in Taiwan. The larvae damage all parts of the maize plant and causes corn yield loss. Chemical control is commonly used by farmers to manage this pest. However, insecticides residues raises problematic issues of food safety, insecticide resistance, and environmental pollution. Reducing insecticide use has become a current global issue. Biological control of nature enemies can help manage pest and reduce insecticide use. In this study, integrated parasitoid wasps and insecticide controls were designed to evaluate the pest management efficiency. Parasitoid wasps of Trichogramma have been proposed to control the Asian corn borer. Three pest control programs (commercial insecticide control, parasitoid wasp control, and integrated parasitoid wasp and insecticide controls) were designed to compare the pest management efficiency for Asian corn borer. The results showed that integrated parasitoid wasp and insecticide controls program could efficiency reduce corn damage, insecticide use and cost. The integrated control program combined the advantage of commercial insecticide control and parasitoid wasp control to reach the goal of reducing insecticide use.

Ant rafts are both liquid and solid

Authors: Hu David, Georgia Institute of Technology, United States

Abstract: Fire ants can link their bodies together to build waterproof rafts to survive floods. In this talk, I will discuss the structures that fire ants build, and how these structures are limited by the strength of the connections between the ants. We use time-lapse photography and x-ray scanning to characterize the construction of rafts and towers. We relate the shapes observed to the rheology of the ants, their viscosity and their elasticity, which are measured using a rheometer, a device which usually characterizes the properties of chocolate and yogurt.

Self-introduced egg-parasitoid established and successfully suppressed an invasive pest: a 10-y case study

Authors: Hu Xing Ping[1] and Liu Yang[2], [1]Auburn University, United States, [2]Cortiva

Abstract: The kudzu bug, Megacopta cribraria (F.), a native to the Old World, was first observed in Georgia of the United States in 2009. The following couple of years, the bug moved rapidly into all the southeastern states. The exponential increase in numbers and populations of the kudzu bug enhanced its pest status from an urban nuisance problem to be a top yield-limiting pest of soybean crops and a great concern of international trade and commerce. The failure in discovering native egg parasitoids or effective predators of Kudzu bug in the US motivated initiation of introduction-acclimatization of an exotic host-specific egg-parasitoid wasp that has been successfully used in kudzu bug's native regions. Paratelenomus saccharalis (Dodd) was identified as the candidate, evaluated, and propagated in quarantine at the USDA-ARS Biological Control Research Laboratory in 2011 and 2012. In May 2013, a month before the scheduled initial field release, this egg-parasitoid wasp was surprisingly observed in soybean fields across several states. Here we report a 10-year systematic survey of population dynamics of kudzu bugs and the parasitism rates of kudzu bug eggs and in 4 soybean fields across the state of Alabama.

Understanding the impact of temperature change on niche dynamics among Drosophila parasitoids?

Authors: Hua Lue Chia, Biology Centre of the Czech Academy of Sciences, Czech Republic

Abstract: Climate change can impact ecological communities in many ways, including altering the niche breadth of component species. But precisely how abiotic change such as warming interacts with biotic factors to determine niche breadth remains unclear. Host-parasitoid systems offer a unique opportunity to investigate this important question. Many studies have documented how climate affects host-parasitoid interactions, and there are also the possibilities with this system to perform experimental works. Drosophila species and their parasitoids are one such group. In this study, we examine how warming impacts host-parasitoid interactions, specifically focusing on the shift of their niche breadth. We set out to address three questions 1) Does elevated temperature reduce the change in the degree of specialization for parasitoids? 2) Does the presence of multiple parasitoids narrow alter the diet breadth of parasitoids? 3) Is temperature and parasitoid niche-breadth correlated? What are the impacts on their life-history traits? We conducted laboratory experiments using a naturally co-occurring Australian Drosophila-parasitoid system at three temperatures. Here, 24°C is ambient temperature, 28°C is experimental warming, and 20°C is the coldest temperature they experience in the field. Seven host species and three larval parasitoid species were tested and reared for a total of 58,500 individuals. Results from question one showed that experimental warming caused a decrease in niche breadth across the three parasitoid species, and that successful hatching rate was significantly lower at 28°C. Among the three species Leptopilina sp. is a specialist, specialization follow by Asobara sp., and Ganaspis sp. is a generalist. The results from multiple parasitoid species showed that niche breadth decreased when multiple parasitoid species were present, but the niche breadth of the specialist occasionally increased when in the presence of other parasitoid species. In this experiment, we also found that temperature impacted the diet breadth of the generalist species more strongly than the specialist species. Finally, as temperature increased, mean interaction strength increased as a consequence of the narrowing of parasitoid diet breadth. Changes in temperature affect life-history traits, and significantly shifted trait values (mean and variance) in developmental time, body size and sex ratio of parasitoids. This has the potential to alter host-parasitoid community structures. Our study provides a better understanding of how climate change could impact the complex pattern of interactions in host-parasitoid communities, with implications for predicting the consequences for biological control and ecosystem functioning.

Dengue Vector Monitoring and Management in Southern Taiwan

Authors: Huang Chin-Gi[2], Liao Chin-Len[2], Hsiao Hsiang-Yu[2], Ho Hsin-Yi[2], Cheng Hui-Ching[2], Tseng Jing-Chun[2], Wu Kuo-Chih[2], Chen Pei-Qi[2], Chen Szu-En[2], Shih Ting-Chun[2], Tsai Tsung-Ju[2], Tu Wu-Chun[1], Chen Yi[3] and Wu Yi-Jun[2], [1]Department of Entomology, National Chung Hsing University, Taiwan, [2]National Mosquito-Borne Diseases Control Research Center, National Health Research Institutes, Taiwan, [3]Public Health Bureau, Tainan City Government, Taiwan

Abstract: Among factors associated with the 2015 dengue fever outbreak in southern Taiwan, the existence of vector mosquitoes in communities is probably the most prominent factor in the spread of the disease. Thus, the existing mosquito vector surveillance systems which focused on adult mosquito survey and the Breteau index may need to be improved. In the autumn of 2016, we started the pilot program: deploying ovitraps widely to monitor dengue vectors in hot zones – recording the numbers of mosquito eggs and the percentage of positive ovitraps weekly. Based on this, the standard operating procedure is established. In 2017, a partnership between local governments and ourselves set up 4,109 ovitrap monitoring sites in 359 villages in Tainan, Kaohsiung and Pingtung. Relevant data were presented weekly for immediate reference and appropriate environmental management measures for all levels of governments. Also, the effectiveness of the management can be evaluated by comparing the data before and after the measures were taken. Furthermore, the current data revealed that mosquito vectors increase significantly in the second week after rain, and the distribution of mosquito species are affected by human population densities. This information will be valuable for governments to prioritize areas and timing of management measures' execution in the future. In addition to this surveillance system, we also developed indoor control method for dengue vector. Our survey revealed that mosquitos of Aedes tend to lay eggs primarily in the bathroom and toilet, followed by kitchen, living room, and lastly the bedroom. So for indoor control, we propose the deployment of two small-scale indoor gravitraps on those egg-laying sites described above at each household in communities. We anticipate a significant decline of indoor vector in number while the installed rate of gravitrap reaches 50 percent in the tested community. With the implements of surveillance system and the indoor gravitrap strategies into current precise chemical control and other control strategies such as biology control, we can construct a more Integrated vector management for Taiwanese dengue fever to more efficiently decrease the vector number and prevent it from spreading

Rethinking the functional dominance levels and fitness costs of insect resistance to Bacillus thuringiensis crops

Authors: Huang Fangneng, Department of Entomology, Louisiana State University Agricultural Center, United States

Abstract: Transgenic crops expressing Bacillus thuringiensis (Bt) proteins have become an important tool for managing some major insect pests of corn, cotton and soybean. Evolution of resistance to Bt crops in target pest populations is a great threat to the sustainability of the Bt crop technology. Incidents of field resistance that led to control problems of Bt crops have increased rapidly, especially during the recent years. Based on the knowledge generated from earlier studies on resistance to Bt insecticides, high level of resistance to Bt plants was typically thought to be functional recessive with fitness costs. The objective of this study was to use the recently published data to test if this early inference is valid. Very surprisingly, functionally non-recessive resistance and lack of fitness costs in resistance to Bt crops are found to be not uncommon. Analysis of globally published data showed that 61.5% and 60.0% of the cases of resistance with major alleles that allowed homozygous resistant genotypes to survival on Bt crops were functionally non-recessive and did not involve fitness costs, respectively. Dominance levels (DFLs) measured on Bt plants ranged from –0.02 to 1.56 with a mean (± sem) of 0.35 ± 0.13 for the 13 cases of single-gene resistance to Bt plants that have been evaluated. Among these, all six cases with field control problems were functionally non-recessive with a mean DFL of 0.63 ± 0.24, which was significantly greater than the DFL (0.11 ± 0.07) of the seven cases without field resistance. In addition, index of fitness costs (IFC) of major resistance was calculated for each case based on the fitness of resistant (RR) and heterozygous (RS) genotypes on non-Bt plants divided by the fitness of their susceptible (SS) counterparts. The estimated IFCs for 15 cases of single-gene resistance were similar for RR and RS, and for the cases with and without field resistance; and the values averaged 1.10 ± 0.12 for R'R' and 1.20 ± 0.18 for R'S'. Limited published data suggest that resistance of insects to dual/multiple-gene Bt crops is likely to be more recessive than the related single-gene resistance, but their IFCs are similar. The quantitative analysis of the global data documents that the prevalence of non-recessive resistance has played an essential role in the widespread evolution of resistance to Bt crops, while the lack of fitness costs is apparently not as critical as the non-recessive resistance. The results suggest that planting of 'high dose' traits is an effective method for Bt crop IRM and more comprehensive management strategies that are also effective for functionally non-recessive resistance should be deployed.

Salivary DNase II from Laodelphax[4] striatellus acts as an effector that suppresses plant defence

Authors: Huang Hai-Jian, Institute of Plant Virology, Ningbo University, Ningbo, China

Abstract: • Extracellular DNA, released by damaged plant cells, acts as a damage-associated molecular pattern (DAMP). We demonstrated previously that the small brown planthopper (Laodelphax striatellus, SBPH) secreted DNase II when feeding on rice plants. However, the function of DNase II in plant-insect interactions remained elusive.

- The influences of DNase II on SBPHs and rice plants were investigated by suppressing expression of DNase II or application of heterogeneously expressed DNase II.
- We demonstrated that salivary DNase II is mainly expressed in the salivary gland and is responsible for DNA degrading activity of saliva. Knocking down the expression of DNase II resulted in decreased performance of SBPH reared on rice plants. The dsDNase II-treated SBPH not influenced JA, SA, ET-pathways, but elicited a higher level of H2O2 and callose accumulation. Application of heterogeneously expressed DNase II in DNase II-deficient saliva reduced the wound-induced defense response.
- We propose a DNase II-based invading model for SBPH feeding on host plants, and provide a potential target for pest management.

Nicotinic acetylcholine receptor modulator insecticides act on diverse receptor subtypes with distinct subunit compositions

Authors: Huang Jia, Institute of Insect Science, Zhejiang University, China

Abstract: Insect nicotinic acetylcholine receptors (nAChRs) are pentameric ligand-gated ion channels mainly expressed in the central nervous system of insects. They are the directed targets of many insecticides, including neonicotinoids, which are the most widely used insecticides in the world. However, the development of resistance in pests and the negative impacts on bee pollinators affect the application of insecticides and have created a demand for alternatives. Thus, it is very important to understand the mode of action of these insecticides, which is not fully understood at the molecular level. In this study, we systematically examined the susceptibility of ten Drosophila melanogaster nAChR subunit mutants to eleven insecticides acting on nAChRs. Our results showed that there are several subtypes of nAChRs with distinct subunit compositions that are responsible for the toxicity of different insecticides. At least three of them are the major molecular targets of seven structurally similar neonicotinoids in vivo. Moreover, spinosyns may act exclusively on the alpha6 homomeric pentamers but not any other nAChRs. Behavioral assays using thermogenetic tools further confirmed the bioassay results and supported the idea that receptor activation rather than inhibition leads to the insecticidal effects of neonicotinoids. The present findings reveal native nAChR subunit interactions with various insecticides and have important implications for the management of resistance and the development of novel insecticides targeting these important ion channels.

Identification of potential mechanosensitive ion channels involved in egg-laying behavior of the fruit pest Drosophila suzukii

Authors: Huang Jia[1], Lei Guo[3], Mao Feng[4], Liu Gen-yan[2], Qiao Xiao-mu[3], Fan Xin_yu[3] and Zhou Zhen-dong[3], [1]Institute of Insect Science, Zhejiang University, China, [3]Ministry of Agriculture Key Laboratory of Molecular Biology of Crop Pathogens and Insects, Insititute of Insect Sciences, Zhejiang University, China, [4]Zhejiang University, China, [2]Key Laboratory for Green Chemical Process of Ministry of Education, School of Chemical Engineering and Pharmacy, Wuhan Insititute of Technology, China

Abstract: Drosophila suzukii (spotted wing drosophila) has become a major invasive insect pest of soft fruits in the America and Europe, causing severe yield losses every year. The female D. suzukii shows the oviposition preference for ripening or ripe fruit by cutting the hard skin with its serrated ovipositor. A recent study reported that mechanosensation is involved in the texture discrimination during egg-laying behavior in D. suzukii. However, the underlying mechanism and molecular entity that control this behavior are not known. We first identified candidate ion channels with known mechanosensory roles from the D. suzukii genome by bioinformatic analysis, including Transient Receptor Potential (TRP) channels, Degenerin/Epithelial Sodium Channels (DEG/ENaC), Piezo and TMC. The reverse transcription PCR results showed that some of them are expressed in the ovipositor. Besides, transcriptome sequencing of ovipositors from D. melanogaster and D. suzukii have identified additional TRP and DEG/ENaC channels expressed in both species. Exposure to drugs targeting TRP and DEG/ENaC channels abolished the oviposition preference for harder texture in female D. suzukii. Therefore, mechanosensitive ion channels may play significant roles in the texture assessment of egg-laying behavior in D. suzukii, which has promising implications to further research on the development of novel control measures.

Multiple immune-regulation roles of serine protease inhibitors in Cotesia vestalis teratocytes

Authors: Huang Jianhua[2], Chen Xuexin[1], Shi Min[2], Gu Qijuan[2] and Zhou Shimin[2], [1]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, Hangzhou, China, [2]Institute of Insect Sciences, Zhejiang University, China

Abstract: Endoparasitoid wasps have developed strategies to regulate host's inner-physiological environment to guarantee the survival and growth of their progenies. The parasitic factors including venom, polydnavirus, and teratocytes were found to have the immune-suppression, nutrient metabolism alteration and developmental regulation abilities when wasps parasitized their hosts. In some literatures, teratocytes, an embryonic factor formed by parasitoid progeny self were shown to has multiple functions during the parasitism. Serine proteases inhibitors (SPIs) play an important physiological role in regulating immunity and nutrient metabolism in insects by specifically acting on serine proteases (SPs). The transcriptome analysis of Cotesia vestalis teratocytes indicated 27 SPIs in total were produced and delivered into the hemocoel of Plutella xylostella host. In this study, we summarized the immune-suppression functions of the SPIs derived from C. vestalis teratocytes: (1) strongly suppress the prophenoloxidase (proPO) activation of host hemolymph by interacting with phenoloxidase activating proteases (PAPs) of PO cascade; (2) reduce the mortality of P. xylostella larvae by inhibiting the growth of bacterial pathogens. Our results will not only provide evidences for the roles of teratocyte SPIs in inhibitions of host immunity, but also expand our knowledge about the regulating mechanisms of parasitoid on host physiology.

Inhibition of encapsulation and bacterial agglutination activity in Bracoviruse-like lectin

Authors: Huang Jianhua[3], Wu Xiaotong[1], Chen Xuexin[2], Shi Min[4], [3]Institute of Insect Sciences at Zhejiang University in Hangzhou, China, [1]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, China, [2]Institute of Insect Science, College of Agriculture and Biotechnology, Zhejiang University, Hangzhou, China, [4]Institute of Insect Sciences, Zhejiang University, China

Abstract: C-type lectin acts as a pattern-recognition receptor which participates in diverse cellular activities such as cell-cell adhesion, apoptosis and immune response to pathogens. Polydnaviruses (PDVs), mutualism of parasitoid wasps, can express several genes to regulate physiology of the host for their development. However, the function of lectins in PDVs remain largely unknown. In association with PDVs from Cotesia vestalis (CvBV), an endoparasitoid of diamondback moth, Plutella xylostella, we found a lectin gene CvBV-BLL28-1 can specifically induce Gram+ bacterial agglutination, but not for Gram–. We further showed that CvBV-BLL28-1 could inhibit the differentiation of plasmatocyte and lamellocyte lineages, subsequently reduce the encapsulation reaction in host larvae after wasp infection. Therefore, the bracovirus-like lectin provides compensatory anti-microbial function and help to suppress the host cellular immune responses for the successful parasitism.

Effects of salts on eggshell structure and gene expression of Aedes aegypti, Culex quinquefasciatus and Forcipomyia taiwana

Authors: Huang Rong Nan[1], Weng Ling-Wei[2], Chen Mu-En[2] and Jiuun Chen Shiang[3], [1]Department of Entomology and Research Center for Plant Medicine, College of Bioresources and Agriculture, National Taiwan University, Taipei, Taiwan, [2]Department of Entomology, College of Bioresources and Agriculture, National Taiwan University, Taipei, Taiwan, [3]Department of Life Science, College of Life Science, National Taiwan University, Taipei, Taiwan

Abstract: Allergy to blood-sucking pests, such as Aedes aegypti (Linnaeus), Culex quinquefasciatus Say, and Forcipomyia taiwana (Shiraki) is common and impairs the quality of life for many people around the world. Traditional control strategies for these annoying pests mostly ignored the egg stage, since it is the least known life stage. We investigated the effect of salts on the structure and gene expression of eggs. The results showed that melanization of eggs was significantly reduced when laid on milieu containing NaCl, but not MgSO4. The NaCl-infiltrated eggs became shorter in length and possessed enlarged central tubercles occupying the whole area of the outer chorionic cell, indicating shrinking due to the failure of melanization. Moreover, eggs laid on salted milieu had no serosal cuticle, as evidenced by the absence of chitin-staining. Transmission electron microscopy analysis showed that intact exochorion and endochorion layers existed in NaCl-infiltrated eggshells, however the endochorion layer was significantly widened compared to that of melanized eggs. Three down-regulated (yellow, chorion peroxidase (CpO) and cytochrome P450) and four up-regulated (glutathione s-transferase (GST), superoxide dismutase (SOD), aromatic-L-amino acid decarboxylase (DDC) and tyrosine 3-monooxygenase(TH)) genes in NaCl-infiltrated eggs were first identified by next generation sequence (NGS) and further confirmed using quantitative reverse transcription-polymerase chain reaction. This information might aid in understanding the mechanisms involved in the process of chorion hardening, and will be the basis for further studies on molecular mechanisms of NaCl-induced failure of egg melanization.

Drought and vector-borne disease: thresholds, cycles, and potential futures

Authors: Hudson Amy, USDA-ARS, United States

Abstract: The typical narrative of climate effects on vector-borne diseases and futures is dominated by the role of warmer temperatures in increasing vector abundance and expanding the transmission season. However, especially in the case of aquatic insect vectors, particular attention needs to be paid to drought thresholds and spatio-temporal characteristics. Leveraging multiple drought indices, streamflow gages, and a satellite-derived surface water product, we explore the role of drought on the spread of multiple livestock diseases in the United States. Vesicular Stomatitis (VS) disease, with symptoms similar to foot and mouth disease, experiences a full stop in spread when drought corresponds to low streamflow. Black flies are the primary vector of VS and require flowing water for their abundance and lifecycle, likely driving this response. West Nile has a more nuanced response to drought in different regions, linked to thresholds and lagged effects of mosquito and avian reservoir hosts on spread. We then explore the frequency of these respective drought events. Finally, we weave in how other vector-borne diseases and data collection efforts can supplement our conceptual understanding of temperature-drought interaction likelihoods and impact on transmission cycles and spread.

Japanese Beetle Incursion on the West Coast of Canada: Now What?

Authors: Hueppelsheuser Tracy, British Columbia Ministry of Agriculture, Canada

Abstract: Japanese Beetle Popillia japonica was detected in annual survey by the Canadian Food Inspection Agency for the first time in July 2017 in Vancouver, British Columbia, Canada. The climate is ideal for establishment of most temperate insects, with moderate summers and lots of moisture and minimal freezing during the winter. The Vancouver area is highly urbanized and surrounded by a highly valued and diverse agriculture sector, as well as unique and diverse natural environment. In response to the beetle detection, we established a steering committee and operations committees made up of staff from various agencies. Partner organizations include federal, provincial, and local governments, the landscape, nursery, and turf industry, and non-government organizations such as invasive species councils. A Regulated Area and Treatment Area have been determined based on beetle trap catches.

Movement control of green waste (grass clippings, tree prunings) and soil has been implemented. Ground treatment of turf and landscape beds with insecticide has been done for two seasons, 2018 and 2019. In 2019, the number of beetles caught decreased over 85% compared to 2018. We are very encouraged by this significant decrease in beetles and believe it represents a drop in the pest population. There is a coordinated communications effort to inform the public and partners, and to date, response to the program has been generally positive. Our efforts will continue until we reach our goal of pest eradication, which we expect will take at least 2 more years. The partners unanimously agree that no individual group would have been successful on their own and successes to date are a result of the collaborative efforts of all the partners.

Transcriptomic analysis of the photoperiodic response of pea aphid lineages genetically able or not to switch of reproductive mode

Authors: Huguet Melanie Denise[5], Le Trionnaire Gaël[5], Robin Stéphanie[1], TAGU Denis[2], Jaquiéry Julie[4], Legoix-Né Patricia[6], Cloteau Romuald[4], Baulande Sylvain[6], Hudaverdian Sylvie[4] and Tanguy Sylvie[3], [1]BIPAA Platform, INRAE, IGEPP, Le Rheu GenOuest Platform, INRIA/IRISA, Rennes, France, [2]IGEPP, INRAE, Le Rheu, France, [3]IGEPP, INRAE, Rennes, France, [4]INRAE, Agrocampus Ouest, University of Rennes, IGEPP, Le Rheu, France, [5]INRAE, Agrocampus Ouest, University of Rennes, IGEPP, Le Rheu, France, [6]Next Generation Sequencing (IC-NGS) Platform, Institut Curie, 75248 Paris Cedex 05, France

Abstract: As phloem sap feeding hemipteran, aphids can strongly affect the physiology of the plants but also transmit phytoviruses, making them important crop pests worldwide. They are also particularly well adapted to the fluctuations in their environment due to their remarkable ability to display phenotypic plasticity. The most striking example is the reproductive polyphenism they can display during their life cycle. In response to the autumnal photoperiod shortening signal, they are indeed able to switch from parthenogenetic reproduction (viviparous females) that causes most of the damages during spring and summer to sexual reproduction ended up with the production of sexual morphs (oviparous females and males) that mate to lay overwintering diapausing eggs. Lineages that are able to perform this switch are termed as CP (Cyclical Parthenogenesis). In nature, some lineages lost this ability and are referred as to OP (Obligate Parthenogenesis). Population genomic studies revealed that a region under divergent selection located on the X chromosome discriminates CP and OP lineages. The genes present in this genomic region show homologies with Drosophila genes known to be involved in functions such as embryogenesis, oogenesis and the development of the visual and nervous systems. Mutations on the sequence of genes located in the region are likely to explain the inability of the OP lineages to form oviparous females. We can hypothesize that these causal mutations might affect either the perception and neuroendocrine transduction of the photoperiodic signal (that occur in the head) or the ability of embryos germlines to switch their reproductive fate. To characterize the consequences of these mutations on the transcriptomic response of OP and CP lineages when submitted to short photoperiod we used RNA-seq approaches to compare the expression of the genes in the heads and embryos of a CP and an OP lineage at different stages of development. We thus collected, in 3 replicates, heads of aphids at the larval stages L2, L3, L4 and L4 + 24h and embryos at developmental stages 17 and 18 for each of the two lines. The 36 RNAs samples were sequenced (Illumina, PE100, 4 lanes) and analyzed using the latest version of the pea aphid genome. Statistical analyzes revealed that approximately 500, 700, 400 and 1700 genes were differentially expressed between the heads of the CP and OP lineages at the L2, L3, L4 and L4 + 24h stages respectively. In addition, more than 2000 genes were found as differentially expressed between CP and OP embryos both at stages 17 and 18. Functional annotation of the sets of differentially expressed genes will help reveal the tissue where the photoperiodic response is affected in OP lineages but also the biological functions that are no more operative in those lineages as a downstream consequence of the causal mutations.

Communication is power: let’s use it

Authors: Hulcr Jiri, School of Forest, Fisheries, and Geomatics Sciences, University of Florida, United States

Abstract: Entomologists can offer solutions to many major problems of humanity, but complex entomology messages compete poorly in the current information avalanche. One reason for it is the widespread belief among academics in the “information deficit model”, which assumes that the public will change attitudes and behaviors if given greater amount of information. This model has been discredited in contemporary communication research. Instead, I suggest that entomologists, and the academia as a whole, take several powerful lessons from the contemporary world of strategic communication.

First, the most important part of communication is strategy. I will discuss designing communication campaigns from the end goal backwards. First we define the goal, which then defines the ideal audience and the desired change. Only afterwards we choose the medium, and content comes last.

Second, I will argue that in today’s media landscape oversaturated with professional content, only attractive content has a chance to have impact. Rather than imploring scientists to focus on both research and communication and being less effective in each, I will present examples of collaboration with professional communicators where the investment paid off.

Lastly, even though the research community and the well-being of nations both depend on public science literacy, science communication is under-rewarded in contemporary academia. I will discuss strategies to advocate for science communication support to university and agency administrators.

Invasive ambrosia symbioses: paradigm changes and questionable assumptions

Authors: Hulcr Jiri, School of Forest, Fisheries, and Geomatics Sciences, University of Florida, United States

Abstract: Ambrosia beetle research is experiencing a boom of interest, partly because of several destructive invasions. The goal of this presentation is to discuss important new paradigm shifts in our understanding of the symbiosis in light of recent new data, and challenge assumptions that lack evidence and seem to hinder conceptual progress.

1) There is not one, but many ambrosia symbioses. The 14 origins in beetles and at least 8 in fungi offer a unique array of symbiotic phenotypes, degree of specificity, and symbiont swaps on evolutionary as well as ecological timescales. This replication of independent cases not only offers statistical convenience, but it actually requires comparative phylogenetic approach.

2) Do ambrosia beetles change their behavior in newly invaded regions? I will argue that this is an anthropocentric observation of an emergent ecological effect, while there are no data documenting a change in individual beetles’ behavior or symbiotic associations during or after the invasion.

3) Symbiosis, metasymbiosis or holobiont – which ecological concept fits the ambrosia symbiosis? In the wood, ambrosia fungi interact with each other and with free-living fungi, and the interactions mediate interactions between the beetles. This is important for understanding the ecology of invasive beetle-fungus symbioses.

The effect of apple orchard management and landscape on pollinator communities, pollination and production in reference to a semi-natural benchmark

Authors: Hulsmans Eva[2], Daelemans Robin[1] and Honnay Olivier[1], [2]KU Leuven, Belgium, [1]KU Leuven

Abstract: Agricultural land use change and intensification are among the main drivers of global insect pollinator declines, yet many crops depend on these pollinating insects to enhance production. Alternative farming systems, such as organic farming, aim to mitigate the negative impact of intensive farming on biodiversity and have indeed been indicated to sustain a higher diversity of pollinators. However, evaluations of the effectiveness of agricultural management for biodiversity conservation mostly lack an appropriate natural benchmark. Here, we assess the direct and indirect effects of management and the surrounding landscape on bee and hoverfly communities in 24 Belgian apple orchards. We used structural equation modelling to quantify management and landscape effects on pollinator abundance and diversity, functional diversity, pollination services and fruit production. We also included 12 semi-natural grasslands as a benchmark in general(ized) linear mixed models and redundancy analyses to adequately evaluate the effectiveness of management for wild pollinator conservation. Though we found positive effects of organic management on biodiversity indices and pollination - but not on functional diversity - direct negative effects of organic management on production counteracted higher net productivity. Including a semi-natural benchmark reduced the significance of biodiversity gains in organic farming.

Distribution of Gonipterus species and their egg parasitoids in Australia: Implications for biological control

Authors: Hurley Brett[1], Slippers Bernard[4], Nahrung Helen[6], Schroder Michelle[2], Lawson Simon[5], Wingfield Michael[3] and Souza Natalia[7], [1]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa, [2]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa, South Africa, South Africa, [3]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, South Africa [4]FABI, University of Pretoria, South Africa, [5]Forest Industries Research Centre (FIRC), University of the Sunshine Coast, Brisbane, Queensland, Australia, Australia, [6]Forest Industries Research Centre, The University of the Sunshine Coast, Queensland, Australia, [7]University of the Sunshine Coast, Brazil

Abstract: An appropriate taxonomic understanding of the native distribution and species diversity of pests and their natural enemies is a fundamentally important requirement in classical biological control. The egg parasitoid Anaphes nitens has been introduced into many countries on five continents as a biological control agent to manage populations of the Eucalyptus snout beetle (ESB), an insect native to Australia. Recent taxonomic advances have revealed that the ESB, previously considered the single species, Gonipterus scutellatus, represents a cryptic species complex, including three species that have become invasive. These taxonomic changes have important implications for the biological control of ESB. Consequently the native species composition and distribution of the ESB and its parasitoids were investigated to better understand opportunities for improved biological control. ESB adults and egg capsules were collected in south-eastern Australia and Tasmania. Adult Gonipterus were identified using morphology and DNA barcoding techniques. Parasitoids were reared and identified from Gonipterus egg capsules. Twelve Gonipterus species were identified in this study: seven described and five undescribed species. Eight of the twelve species were grouped based on phylogeny as part of the G. scutellatus complex. Five egg parasitoid species that infest Gonipterus were identified. Eleven Gonipterus species were found on the Australian mainland and one species in Tasmania. Three parasitoid species were found on the Australian mainland and two species in Tasmania. The distribution records for both Gonipterus and their parasitoid species will play an important role in improving ESB biological control.

Invasive forest insect pests of plantation trees in Africa

Authors: Hurley Brett[2], Slippers Bernard[3] and Wondafrash Mesfin[1], [1]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, School of Plant Sciences, [2]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa, [3]FABI, University of Pretoria, South Africa

Abstract: Plantation forestry is growing in sub-Saharan Africa and provides an important socio-economic role in many countries, providing fuel and fibre and supporting a diverse range of stakeholders. These plantations mainly comprise non-native trees such as Pinus and Eucalyptus. However, the sustainability of these plantations is challenged by the introduction of invasive forest insect species. We provide a summary of current and ongoing studies to investigate the distribution and diversity of these insect pests, to determine pathways of invasion and to develop management responses and regional networks. Survey data has revealed a much broader distribution of these invasive insects then previously realized, with high diversity in some of the species indicating possible multiple introductions. Fortunately, in some cases the natural enemies of the insect pests have also been unintentionally introduced. South Africa is indicated as a donor of insect pests to other regions, although this is likely influenced by differences in reporting efficiency. Issues in terms of governance and limited capacity are likely contributors to the increased introduction and regional spread of invasive species.

Understanding the gall community associated with Leptocybe invasa (Hymenoptera: Eulophidae) using the South African community as a case study

Authors: Hurley Brett[1], Slippers Bernard[2], R Gevers Caitlin[1] and Dittrich-Schroder Gudrun[3], [1]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa, [2]FABI, University of Pretoria, South Africa, [3]University of Pretoria, FABI & Department of Zoology and Entomology, South Africa

Abstract: The gall wasp, Leptocybe invasa, is native to Australia and induces bump-like galls on various species of Eucalyptus. Since 2000, it has been detected outside its native range, with two genetically distinct lineages. Lineage A has been reported worldwide, whereas Lineage B has a more limited distribution in Asia and Africa. Gall wasps have intricate and unique communities consisting of the gall former, parasitoids and inquilines. The communities will differ in each country. It is difficult to study the gall communities as most of the interactions between species occurs within the confines of the gall. We investigated the interactions between the hymenopteran species associated with L. invasa in South Africa. The species investigated included the parasitoid wasp, Selitrichodes neseri, a biological control agent released in 2012 and three other hymenopteran species found to emerge from L. invasa galls, namely Quadrastichus mendeli, a known parasitoid of L. invasa, Megastigmus zebrinus and M. pretorianensis. Galls were dissected and the interactions within a single gall were observed. For each interaction, DNA was extracted from both larvae and species-specific primers and restriction enzymes were used to confirm larval identity. The results showed that Selitrichodes neseri, Q. mendeli and M. zebrinus parasitize Lineage A, and S. neseri was also confirmed to parasitize Lineage B. The results also showed direct interactions between these parasitoids. The role of M. pretorianensis was not confirmed from this study. Furthermore, the distribution and prevalence of these species was examined. Galled Eucalyptus material was collected at infested sites across South Africa, and emerging adults collected and identified. Morphology and restriction enzymes were used to differentiate between the various species and lineages. The results indicated that L. invasa lineage A has spread throughout South Africa while lineage B has a more limited distribution. The Leptocybe lineages were found to co-occur on individual trees increasing the chances of admixture. Selitrichodes neseri, M. zebrinus and M. pretorianensis were present throughout South Africa and all emerged from trees that contained both Leptocybe lineages.

Sentinel plant research reveals two cryptic non-native cypress-feeding aphid species in South Africa

Authors: Hurley Brett[3], Slippers Bernard[5], Wondafrash Mesfin[2], Wingfield Michael[4] and Paap Trudy[1], [3]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria, 0002, South Africa, [5]FABI, University of Pretoria, South Africa, [2]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria, 0002 School of Plant Sciences, [4]Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, 0002 Department of Department of Bio, [1]Department of Biochemistry, Genetics and Microbiology; Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, Pretoria, 0002, South A

Abstract: Aphids residing in the sub-genus Cinara (Cupressobium) are important pests of trees in the Cupressaceae. Two of these species, C (C). cupressi and C (C). tujafilina, native to North America and Asia, respectively, have become invasive in various parts of the world. Cinara (C) cupressi has been reported as an invasive in Africa, Europe, the Middle East and South America. In Africa, it has established in several Eastern and Southern African countries, causing severe damage to Cupressus, Juniperus and Widdringtonia trees. Cinara (C) tujafilina has been reported as an invasive in many countries of Europe and South America. It feeds on a broader host range, infesting species of Callitris, Chamaecyparis, Cupressus, Juniperus, Libocedrus, Thuja, Thujopsis and Widdringtonia. Distinguishing between these aphid species based on morphological features is difficult because the two species share many morphometric characters. In South Africa, a project monitoring plant health in botanic gardens and arboreta was initiated under the framework of the International Plant Sentinel Network (IPSN) with the aim of using botanic gardens and arboreta as sentinel sites to improve surveillance and identification of new and emerging pest and pathogen risks. As part of this project, aphid samples were collected from Widdringtonia wallichi and W. nodiflora trees exhibiting branch dieback in Kirstenbosch National Botanical Garden, Cape Town. The barcoding region of the cytochrome oxidase I (COI) gene of the aphid specimens was sequenced. Analysis of sequence data revealed the presence of C (C). cupressi and C (C). tujafilina, the former on W. nodiflora and the later on W. wallichi. Cinara (C) cupressi was previously reported from South Africa, but with little information regarding its distribution and host range. This is the first report of C. tujafilina in South Africa as well as on the African continent.

The greenhead horse fly as bioindicator of marsh health – population decline and recovery after the Gulf of Mexico oil spill

Authors: Husseneder Claudia[2], Park Jong-Seok[1] and Foil Lane[2], [1]Chungbuk National University, South Korea, [2]Louisiana State University Agricultural Center, United States

Abstract: Population census and genetics studies in the aftermath of the 2010 Gulf of Mexico oil spill established the greenhead horse fly (Tabanus nigrovittatus Macquart) as an invertebrate bioindicator of saltmarsh health. This species is bound to coastal marshes, since its larval stages develop as top invertebrate predators in the marsh soil and are thus dependent on a diverse food web in the Spartina saltmarsh. Immediately after the oil spill (2010-2011) populations of this horse fly crashed in oiled areas of Louisiana marshes with significant impacts on genetic structure detected via microsatellite genotyping. However, five years after the catastrophic event (2015-2016) we observed signs of recovery of populations in oiled areas. Fly numbers were rising. Genetic bottlenecks detected in formerly oiled populations were disappearing. Migration into oiled areas replenished formerly depleted horse fly populations in impacted regions. Parameters of family structure that had been impacted by the oil spill (number of breeding parents, effective population size, number of family clusters) rebounded to levels similar or exceeding those in non-oiled control areas. Saltmarsh horse flies are useful bioindicators for the assessment of changes in Spartina marsh caused, for example, by pollution and saltwater intrusion with sea level rise.

Popillia japonica in the Midwestern U.S.: Overwintering larval survival, adult monitoring, and foliar feeding impact on wine grapes and raspberry

Authors: Hutchison William[1], Ebbenga Dominique[1], Toninato Adam[1] and Burkness Eric[1], [1]University of MInnesota, United States

Abstract: Although Popillia japonica Newman was first detected in the U.S. in 1916, the pest did not reach Minnesota (MN, Midwest region) until 1968. As P. japonica continues to spread, it's important to better understand the larval overwintering capacity in a cold-climate as well as efficiently monitor adult populations. For 3 years we confirmed high levels of larval overwintering survival, 35-70% (October-April). This level of survival is much higher than other insect species studied in the Midwest. High survival is attributed to the overwintering depth of 15-20cm. To assist growers with monitoring, we evaluated the use of commercially available semiochemical-based traps. Due to high beetle densities, a volumetric calibration ($R2=0.98$) was developed. For wine grapes, foliar feeding studies found negative effects on titratable acid, soluble solid content, and phenolic compounds ($P<0.05$). Yield was not affected. An action threshold of 25 beetles/m-row, or ~30% defoliation would warrant management action. For primocane raspberry, cumulative insect days (CID) were used to quantify beetle pressure on marketable yield. We found a non-linear relationship between proportional yield loss as a function of CIDs; yield began to decline quickly at ~400 CIDs. This information is being used to develop an economic threshold.

The role of GPCRs in metabolism and physiology of the pea aphid, Acyrthosiphon pisum

Authors: Huygens Cissy[1], Ribeiro Lopes Mélanie[2], Gaget Karen[2], Duport Gabrielle[2], Calevro Federica[2] and Callaerts Patrick[1], [1]KU Leuven, Belgium, [2]Univ Lyon, INSA Lyon

Abstract: G-protein coupled receptors (GPCRs) mediate many important physiological and behavioral processes. In insects, neuropeptides regulate development, growth, reproduction, metabolism and behavior. Neuropeptides signal through GPCRs and stimulate multiple intracellular downstream signaling cascades. Many insect neuropeptides and GPCRs were found to regulate gut motility and feeding behavior.

The order of Hemiptera is ranked in the top three of important insect orders with the largest number of high-risk pest species. To date, little is known about the role of GPCRs in regulating feeding and metabolism of Hemiptera. A well-known family of Hemiptera are the aphids which feed exclusively on carbohydrate-rich plant phloem sap. To cope with the lack of essential amino acids in their diet, aphids rely on the obligatory endosymbiotic bacteria Buchnera aphidicola, located in the bacteriocytes.

In this study five pea aphid GPCRs were selected based on their expression in two metabolism-associated essential tissues, gut and bacteriocytes. The ligand specificity for these GPCRs has been determined in an in vitro cell system. The spatiotemporal distribution of the ligands and the receptors was mapped and dynamic changes following nutrition-related changes determined. We are currently working on characterizing the role of the GPCRs in physiology and metabolism in vivo.

Novel Pest Control Method of Spodoptera litura using Plant Extracts

Authors: Hyoung Jeon Jun[1], Park Doo-Sang[1], Oh Hyun-Woo[2] and Woon Shin Sang[2], [1]Biological Resource Center, Korea Research Institute of Bioscience and Biotechnology, South Korea, [2]Core Facility Management Center, Korea Research Institute of Bioscience and Biotechnology, South Korea

Abstract: Since juvenile hormone (JH) controls development and reproduction in insects, we constructed insect species-specific assay systems to identify phytochemicals that function as juvenile hormone disrupt (JHD), which disrupt JH-mediated insect development by interfering with the binding of JH receptors to methoprene-tolerant (Met) and its partner protein, steroid receptor coactivator (SRC). Using a yeast two-hybrid system transformed with Met and SRC from the Spodopter litura, we tested the interfering activity of 3704 plant extracts against JH III mediated Met-SRC binding. Plant extracts from iridaceae, especially members of the gladiolus exhibited strong interfering activity. As a result of the bioassy, the larvae fed the gladiolus did not develop into pupae. These results suggest that the JHD of Gladiolas prevents the development of pupae by interfering with JH-mediated binding of Spodoptera litura Met and SRC.

Symbionts and microbiome diversity in sucking lice

Authors: Hypša Václav[1], Nováková Eva[3], Batani Giampiero[3], Martinu Jana[2], Ríhová Jana[1] and Rodríguez-Ruano Sonia[1], [1]Department of Parasitology, Faculty of Science, University of South Bohemia, Ceské Budejovice, Czech Republic, [2]Department of Parasitology, University of South Bohemia, Ceské Budejovice, Czech Republic, [3]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic

Abstract: Sucking lice (Anoplura) host phylogenetically diverse spectrum of symbiotic bacteria. This indicates that the lice experienced a complex history of symbiont acquisition, loss, and replacement during their evolution. The symbionts which have so far been phylogenetically characterized show relationships to very different ecological types of bacteria. Some of them originated within the groups known as frequent insect symbionts (e.g. Arsenophonus or Sodalis) others within groups only rarely associated with insects. Recently, we described two louse symbionts with phylogenetic affiliations to vertebrate pathogens, namely Legionella polyplacis in Polyplax spp. and Neisseria-related symbiont in Hoplopleura spp. Combination of genomic and amplicon data shows that these two bacteria differ considerably in many genomic characteristics, and are probably symbionts in different stages of evolution. L. polyplacis possesses features typical for obligate mutualist. It has small genome (approx. 0.5 Mb, coding for less than 500 genes) with severe AT bias. It also displays striking genomic similarity with Riesia and Puchtella, possibly due to convergent adaptation to similar hosts. On the other hand, some metabolic differences are likely to reflect different phylogenetic origins of these three genera, and hence availability of particular metabolic function in the ancestor. This can be demonstrated, for example, by different arrangements of thiamine metabolism in L. polyplacis and Riesia. An interesting adaptive feature, associated with the role of L. polyplacis in the host's metabolism, is horizontally acquired operon coding for synthesis of biotin. In contrast to the strongly reduced L. polyplacis, the Neisseria-related symbiont in Hoplopleura lice has three times larger genome with many features similar to free living relatives: it possesses much more complete metabolic pathways, many mobile elements, and signatures of a frequent horizontal gene transfer. On the other hand, its regular presence in amplicon data, and intracellular localization within bacteriocytes, suggests that the bacterium is already an obligate symbiont, probably in its early stage of symbiogenesis. Interestingly, another Neisseria-related bacterium, closely related to the Hoplopleura symbiont, is occasionally found in microbiomes of Polyplax lice, accompanying the dominant L. polyplacis. Finally, microbiomes of both louse genera display phylogeny dependent pattern of their composition. In some lineages of the lice, they contain various additional bacteria related to the known insect symbionts, such as Arsenophonus or Buchnera. The distribution and characteristics of L. polyplacis and Neisseria-related symbionts, and phylogenetic background of the louse microbiomes, thus illustrate high ecological dynamics of the symbiogenesis in Anoplura.

A new symbiotic lineage related to Neisseria and Snodgrassella arises from the dynamic and diverse microbiomes in sucking lice

Authors: Hypša Václav[1], Nováková Eva[3], Ríhová Jana[1], Batani Giampiero[3], Martinu Jana[2], and Rodríguez-Ruano Sonia[1], [1]Department of Parasitology, Faculty of Science, University of South Bohemia, Ceské Budejovice, Czech Republic, [2]Department of Parasitology, University of South Bohemia, Ceské Budejovice, Czech Republic, [3]University of South Bohemia, Faculty of Science, Ceske Budejovice, Czech Republic

Abstract: Most of the examined lice (Anoplura) harbour intracellular, highly modified bacterial symbionts. The best known examples are Riesia pediculicola from human lice and Legionella polyplacis, described in our previous work from the genus Polyplax. For many lice, only 16S rRNA genes or morphological observations are available, indicating that this insect group has been undergoing particularly dynamic acquisition, loss, and replacement of symbionts. In this this study, we analyze the background of these processes by combining several approaches (genomics, phylogenetics, amplicons, FISH) across several populations of the two louse genera Polyplax and Hoplopleura. We reveal a novel louse symbiont lineage related to Neisseria (common human pathogen) and Snodgrassella (symbiont of bees), and show its evolutionary origin as an independent event in these two unrelated louse genera.

Characterization of this Neisseria-related symbionts includes comparison of their genomes, distribution across several populations, phylogenetic origin and intra-bacteriocyte localization demonstrated by FISH. While the genomes of these symbionts are highly similar in both lice genera, their respective distributions and status within lice microbiomes indicate that they have different functions and history. In Hoplopleura acanthopus, the Neisseria-related bacterium is a dominant obligate symbiont universally present across several host's populations, and seems to be replacing a presumably older and more degenerated obligate symbiont. In contrast, the Polyplax microbiomes are dominated by the obligate symbiont Legionella polyplacis with the Neisseria-related bacterium co-occurring only in some samples and with much lower abundance. In addition the extensive amplicon screening of Hoplopleura and Polyplax microbiomes revealed presence of other possible symbiotic lineages from the Enterobacteriaceae family distributed in some louse populations.
Using broad spectrum of approaches, we demonstrate that sucking lice possess taxonomically diverse microbiomes which harbour both the bacteria related to vertebrate pathogens (Neisseria-related bacteria) and the typical insect-associated taxa (Enterobacteriaceae symbionts). We show an independent origin of Neisseria-related symbionts in two unrelated louse genera, Hoplopleura and Polyplax, and present their taxonomically diverse microbiomes as background/source for acquisition of obligate mutualistic symbionts.

How dark of a taxon is Microgastrinae (Braconidae) really?

Authors: Höcherl Amelie[2] and Hübner Jeremy[1], [2]SNSB-ZSM, Germany, [1]SNSB-ZSM

Abstract: Entire families or subfamilies Hymenoptera are referred to as so-called “Dark Taxa”: They are hyperdiverse, taxonomically neglected and with numerous overseen and undescribed species – even in Germany. In order to make these enormously species-rich groups more tangible to science, we use an integrative approach within the project GBOL III: Dark Taxa for the Microgastrinae, a subfamily of parasitoid wasps within the Braconidae (Hymenoptera) specialized in attacking Lepidoptera larvae. Specimens are selected from a large number of malaise trap samples from various habitats in Germany. Samples are sorted and individuals selected for DNA-Barcoding by parataxonomists. Using DNA-Barcoding as a way of pre-sorting samples, we are able to identify distinct clusters and lineages that putatively represent species. Finally, representative specimens of these clusters (which correlate with BINs = Barcode Index Numbers) are morphologically verified by experts. Using this workflow allows to accelerate taxonomic work and glance at results, even with morphological identifications still in the future. We were able to identify 245 BINs within one single bulk submission of 1,898 specimens. This almost equals the number of Microgastrinae species recorded for Germany (248), and indicates that the actual species diversity must be much higher than currently known.

Phenotypic plasticity in a myrmecophile that exploits multiple ant hosts (Orthoptera: Myrmecophilidae)

Authors: Hölldobler Bert[1] and A. Johnson Robert[1], [1]Arizona State University School of Life Sciences, United States

Abstract: Ant colonies act as islands for numerous arthropod parasites and guests that invade them. Like islands, ant colonies differ in size and quality. The desert ant-cricket, Myrmecophilus manni, is a generalist parasite (myrmecophile) found with at least 24 ant host species. Ant hosts vary tremendously in body size, colony size and diet. Although it is one of the world’s smallest Orthopterans (< 5 mm), M. manni exhibits surprising phenotypic plasticity across its many hosts. We found that cricket body size, shape, color, abundance, development, dispersal ability, egg number, sex ratio, and cuticular hydrocarbon profile corresponded to host species traits.

Cricket identity was confirmed using mitochondrial DNA barcoding for major and minor morphs from 15 sites across Mexico and the Western United States. Individual sites included up to 8 unique hosts, and a full range of cricket phenotypes. In the laboratory, we bred crickets and cross-fostered offspring to parse out the heritable and environmental aspects of cricket phenotype.

Our results suggest that certain host-colony characteristics increase clutch size and mating opportunity for parasitic crickets. We ask why M. manni maintains its generalist lifestyle, and consider how the use of spermatophores, and risk of desiccation during dispersal might favor plasticity over host specialization in this unusual myrmecophile.

Monitoring of Tuta absoluta (Meyrick, 1917) (Lepidoptera: Gelechiidae) on tomato under greenhouse conditions and various environmental zones in Romania

Authors: Iamandei Maria[1], Nanu Stefan, Radulea Madalina, Popa Ionut Cristian, Chiriloaie-Palade Andrei, Keresztesi Agnes Zsuzsa, Sfîrloagă Loredana-Mirela, Paraschiv Alina, Chireceanu Constantina and Roșca Ioan, [1]Research Development Institute for Plant Protection, Romania

Abstract: Careful monitoring and regular inspection of solanaceous plants in greenhouses and adjacent areas for Tuta absoluta presence represent crucial activity in developing the integrated control program for this invasive species. The study was done in two successive years, in a sampling network that included 20 greenhouses cultivated with tomatoes from south and central Romania in which pest monitoring was performed by placing pheromone traps, Delta type with pheromone lure Atra-TUT-S. Dynamics of the traps captures were correlated with associated local pedo-climatic conditions in order to establish the influences of abiotic parameters on moth activity and pest population build-up across various environmental zones in Romania. The paper further discusses the influence of local factors on the potential for the establishment of the pest on the area of central Romania and also the variability of factors influencing the numbers of adults caught in pheromone traps and the relationship between trap catches and tomato damages.

Literature-based food webs and agro-ecological community characteristics

Authors: Ian Hardy[1], KS Shameer[2] and Almandhari Tarik[3], [1]Helsinki, [2]Univ Helsinki, [3]Univ.Nottingham

Abstract: Understanding the inter-organism interactions in ecological communities allows assessment, and even prediction, of how communities respond to natural and anthropomorphic impacts. The trophic interrelationships of invertebrates within a community often form an extensive feeding web composed of several trophic levels. Food webs, or trophic webs, can be constructed directly from empirical field studies or, alternatively, by using literature records to map all the trophic interrelationships in natural and agro-ecosystems. For terrestrial communities, this includes the plants, herbivores and the complex of natural enemies associated with these herbivores. We will focus on the literature-based trophic webs that were recently constructed for coconut and date palm agro-ecosystems to infer large-scale community ecology consequences of shared and non-shared natural enemies, such as the relative importance of direct and apparent competition. We will discuss the utility of the less labour-intensive, though likely less local-scale and accurate literature-based approach as an alternative or supplement to field-based studies.

Factors from Tachinid fly can attract host fat body cells.

Authors: Ichiki Ryoko[2], Nakamura Satoshi[2] and Furukawa Seiichi[1], [1]Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan, [2]National Agriculture and Food Research Organization, Japan

Abstract: The tachinidae are one of the largest families of Diptera with more than 10,000 species worldwide. Tachinid flies are also considered to be useful natural enemies against agricultural pests, especially Lepidopteran larvae. Drino inconspicuoides (Diptera: Tachinidae) is an ovolarviparous endoparasitoid that develops in a host body during the larval period. The host responds by using hemocyte encapsulation defense mechanisms. In order to survive, a mechanism for tachinid fly larvae to avoid this defense mechanism is necessary. How D. inconspicuoides can survive in the host is still unknown. Therefore, in this study we focused on clarifying the parasitic strategies of this tachinid fly. In a previous study, Yamashita et al. (2019) showed that D. inconspicuoides larvae form a structure, called the cloak, by surrounding themselves with hemocyte cells and fat body cells derived from the host Mythimna separata (Lepidoptera: Noctuidae). On the contrary, only hemocytes were found in the encapsulated transplanted dead fly larvae. From these results, we hypothesized that the fat body cells contained in the cloak were attracted to the fly larvae by secretions. Therefore, to analysis whether secretions can attract host fat body cells, we collected first instar flies from the hosts (final stage) 2 hours after parasitism and tested the secretions of fly larvae by incubating larvae in physiological saline for 24 hours. Six hundred µm polystyrene beads were soaked in this solution for 12 hours to coat the beads with the fly secretions. Then, the beads were transplanted into M. separata larvae (final stage) and the attractant activity of host fat body examined. Although only hemocytes were attached to uncoated beads, both hemoctyes and fat body cells were attached to the coated beads. Therefore, we concluded that fly larvae secrete substances that attract host fat body to create the cloak after parasitism. To identify the secretory organ of the host fat body attractant, candidate secretory organs of the tachinid larvae such as the salivary glands, midgut, malpighian tubules and epidermis were collected 24 hours after parasitism. Extracts from the tissues were then mixed with 600 µm beads in saline to prepare coated beads. The beads were then transplanted into M. separata larvae and adhesion of fat body on the bead surface examined 24 hours later. As a result, host fat body attractant activity was observed in the homogenate from the salivary glands. These results indicate that D. inconspicuoides larvae secret factors from the salivary gland to attract host fat body cells.

Historical review of Japanese rose gall wasps (Hymenoptera: Cynipidae: Diplolepidini) and their communities

Authors: Ide Tatsuya[2], Koyama Asuka[1] and Kanzaki Natsumi[1], [2]NMNS, Tokyo, Japan, [1]FFPRI, Japan

Abstract: Two species of rose gall wasp occur in Japan: Diplolepis japonica (Walker) and Liebelia fukudae (Shinji). The former induces spherical galls, scattered with short spikes on the surface, with diameters of 7–9 mm on leaves and young twigs of Rosa multiflora. This species was described from Japan as Rhodites japonica in 1874 and then transferred to Diplolepis in 1967. At the same time of this transfer, Rhodites hakonensis Ashmead, which was described from Japan in 1904, was synonymized with D. japonica based on examinations of both type specimens. The latter induces irregularly globular galls, covered with thorns, with diameters of 30–60 mm on buds of Rosa rugosa and R. nipponensis in Japan. This species was described from Japan as Rhodite [sic] fukudae Shinji in 1941 and then transferred to Liebelia in 1963. In addition to the two species, Rhodites eglanteriae Hartig was recorded from Japan in 1919 as a gall inducer of R. multiflora. However, this record has been regarded as D. japonica and ignored in recent studies. Moreover, some other Japanese cynipid species were also treated as Diplolepis but they can be regarded as being not true rose gall wasps. Inquilines and parasitoids of Japanese rose gall wasps were also reported. In D. japonica, Peliclistus natalis Taketani & Yasumatsu and P. quinlani Taketani & Yasumatsu were described as inquilines in 1973, and Eurytoma sp. (Eurytomidae) and Tetrastichus sp. (Eulophidae) were reported as parasitoids. Orthopelma japonicum Kusigemati (Ichneumonidae) was also described as a parasitoid of D. japonica in 1974, but this D. japonica is thought to be an unidentified rose gall wasp species because its gall was collected from R. rugosa. In L. fukudae, no inquilines have been recorded including our observations, and Glyphomerus stigma (Fabricius) (Torymidae), Eurytoma sp., and Orthopelma sp. were reported as parasitoids. In addition to L. fukudae, two unidentified cynipid galls are known from R. rugosa in Japan. Our field surveys focusing on R. rugosa reveals presence of additional cynipid galls induced on this plant in Japan. Galls of Japanese rose gall wasps have been found only from three common Rosa species. Since there are 12 native Rosa spp. in Japan, more field surveys concerned with various Rosa species will clarify Japanese rose gall wasp fauna and its communities in the future.

Genetic diversity of Citellophilus tesquorum (Siphonaptera: Ceratophyllidae)

Authors: Ilinsky Yury[2], Lapshina Vasilina[1], Verzhutsky Dmitry[3], Kotti Boris[4], Sedikhin Nikolay [5] and Medvedev Sergey[5], [2]Institute of Cytology and Genetics SB RAS, Russia, [1]Insitute of Cytology and Genetics, SB RAS, Novosibirsk, Russia, [3]Irkutsk Antiplague Institute, Irkutsk, Russia, [4]North-Caucasus Federal University, Stavropol, Russia, [5]Zoological Institute, RAS, Saint-Petersburg, Russia

Abstract: Citellophilus tesquorum is a flea with the trans-Palearctic range that parasites on different species of ground squirrels. In most regions, this species is considered an active plague vector. Nine subspecies are described, namely C. t. tesquorum and C. t. transvolgensis in the Southern of the East Europe; C. t. transcaucasicus (Ioff et Argyropulo, 1934), C. t. elbrusensis Goncharov, 2011, C. t. ciscaucasicus in the Caucasus, C. t. altaicus in the South Siberia and west of Mongolia, C. t. dzetysuensis and C. t. mongolicus in Mongolia and the Northern China, and C. t. sungaris in the Transbaikal and the Northeast China. Delimitation of these subspecies is based on morphology traits such as the shape of the movable process of the sex clasper, and also 8th and 9th abdominal sternites in males and the shape of the apical margin of 7th abdominal sternum in females. Variation of these traits often overlaps between subspecies. Here we report the results of comparative analyses of morphology and genetic data on C. tesquorum diversity.

Transcriptome analysis of cotton aphid, Aphis gossypii in response to the entomopathogenic fungi Beauveria bassiana JEF-544

Authors: Im Yeram[1], Kim Jae Su[1], Kim Jong-Cheol[1], Park Soeun[1], Jeon Insoo[1], Park Yulim[1], Kim Kijung[1], Jeong Yujin[1] and Song Gahyeon[1], [1]Jeonbuk National University, South Korea

Abstract: In agricultural pest management, cotton aphid, Aphis gossypii is a widespread crop pest and acts as a vector of serious plant viruses. Cotton aphid shows high resistance to chemical insecticides due to its rapidly growing genetic diversity which is resulted from a short life cycle and geographical migration. As an alternative, entomopathogenic fungi can be used to control cotton aphids in an environmentally sound way. Herein, the early stage of the response of aphid to Beauveria bassiana JEF-544 was analyzed at transcriptome level to figure out how the cotton aphid responds to the fungal infection. First, B. bassiana JEF-544 with high virulence against cotton aphids was selected through bioassays. Infected aphids were collected two days after treatment, which was LT_{25}, and total RNA of uninfected and infected aphids were sequenced. When JEF-544-infected aphids, a large proportion of aphid genes were up-regulated from an enrichment analysis, energy production-related, and immune response genes were significantly up-regulated. Particularly, insect hormone biosynthesis pathway that included ecdysone and juvenile hormone was actively working when infected. In conclusion, when infected by the B. bassiana JEF-544 at an early stage, cotton aphids seemed to protect themselves by immune response or molting hormones biosynthesis to remove infected cuticles.

Moss resemblance par excellence: a synthesis of crypsis, herbivory, and ecomorphology of long-bodied crane flies (Diptera: Cylindrotomidae: Cylindrotominae)

Authors: Imada Yume, Graduate School of Science and Engineering, Ehime University, Japan

Abstract: Many animals camouflage themselves in the surrounding environment, making use of various components including body coloration, patterning, morphological structures, and behavior. Ecological and evolutionary significance of such structures (i.e. devices for mimicry) are, in general, much less investigated than the coloration and patterning. Larvae of long-bodied crane flies, Cylindrotominae (Diptera: Cylindrotomidae), resemble plants due to a combined set of morphological and behavioral traits. They are all free-living, obligate plant-feeders and consist of three ecologically distinct groups: terrestrial moss-feeders, aquatic moss-feeders, and terrestrial herbaceous plant-feeders. Notably, numerous elongated cuticular projections, the most conspicuous morphological feature of the cylindrotomines, is various in size and shape among these groups. Although this structure apparently constitutes a device for mimicry, it may also be the accessory device for respiration and locomotion. A question therefore arises as to how a device for mimicry can simultaneously be physiological, structural, and behavioral adaptations to habitat. In this talk, I lay out a synthetic overview on biology and morphology of this group as the first step to explore the evolution of cryptic mimicry in Cylindrotominae. This will contribute to our understanding of the complex adaptive traits that constitute cryptic mimicry from the ecomorphological perspectives.

STING-dependent antiviral immunity in drosophila

Authors: Imler Jean-Luc, University of Strasbourg, CNRS, France

Abstract: Insects evolved powerful systems to fight against viruses, among which the best known is the RNA interference pathway. However, it is now clear that insects also developed other strategies to resist viral infections, including inducible responses. Working on the model organism Drosophila melanogaster, we recently discovered a new antiviral pathway involving the ortholog of the well-known mammalian antiviral protein STING (Stimulator of interferon genes). We showed that two cGAS-like receptors, cGLR1 and cGLR2 sense viral RNA and produce cyclic dinucleotides (CDN) that act as second messengers and activate drosophila STING (dSTING). STING in turn triggers activation of two components of the IMD pathway, the kinase IKKβ and the NF-kB-like transcription factor Relish, resulting in expression of antiviral genes. Strikingly, co-injection of the CDN 2′-3′-cGAMP or 3′-2′-cGAMP together with several viruses belonging to different families results in significantly reduced viral replication. The protective effect of the CDN is abolished in Relish mutant flies, but not in AGO2 and Atg7 null mutant flies, indicating that it does not require RNAi or classical autophagy. Altogether, our results reveal that, besides RNAi, an inducible transcriptional response controlled by STING and NF-kB participates in immunity against a broad range of viruses in flies.

Climate change is a great challenge for the conservation of an endangered stingless bees species in Brazil

Authors: Imperatriz Fonseca Vera L.[4], Imperatriz-Fonseca Vera L[3], Siqueira de Castro Marina[5], Acosta Andre Luis[2], Giannini Tereza Cristina[1], Feitosa Martins Celso[7], Freitas de Oliveira Favizia[6] and Torres Carvalho Airton[8], [1]Instituto Tecnologico Vale, [2]Instituto Tecnológico Vale, [3]Sao Paulo University, [4]São Paulo University, [5]Universidade Estadual de Feira de Santana, [6]Universidade Federal da Bahia, [7]Universidade Federal da Paraiba, [8]Universidade Rural do Semiárido

Abstract: Melipona scutellaris is an endemic stingless bee species considered endangered on the Brazilian red list and locally (Bahia state) vulnerable. Therefore, understanding whether its natural habitat will lose area due to climate change may assist in their future conservation. The main goal was to assess such a potential habitat loss on climate change for two periods (2021-2040; 2041-2060), under the CMIP6 scenarios being SSP5-8.5 the selected scenario. Occurrence data of the target species were collected from GBIF, SpeciesLink Network, and Brazilian scientific collections. Suitability area was modeled with five algorithms (GLM, GBM, GAM, RF, MAXENT) and five rounds (75% training, 25% tests) using 12 layers of environmental variables selected after variance inflation factor. We generated 375 models according to 207 exclusive occurrence points for M. scutellaris. Our findings suggest that, currently, this species has a suitable area of 230,000 km2. Nevertheless, for the next 20 years, it is expected a loss of 100,000 km2 (or 41%) of suitable area. Similarly, within 40 years the loss will be 130,000 km2 (or 55.8%). The main area loss will be in the Bahia state.

The complexity of insecticide resistance in malaria mosquitoes

Authors: Ingham Victoria, Liverpool School of Tropical Medicine, United Kingdom

Abstract: Vector control tools are the most important contributor to malaria eradication programs; foremost amongst these are long lasting insecticide treated bednets, which accounted for around 70% of the reduction in malaria cases between 2000 and 2015. All distributed bednets are impregnated with pyrethroid insecticide; resistance to which is now widespread. Worryingly, the WHO World Malaria Report details a plateauing of averted malaria cases for the past three years, which closely mirrors the spread of insecticide resistance.

Insecticide resistance in Anopheles mosquitoes has, until recently, been attributed to four characterised resistance mechanisms: changes in the target site; differential regulation of detoxification enzymes; behavioural changes; and thickening of the cuticle. Recently, through data mining multiple transcriptomic datasets of resistant mosquitoes we have shown that resistance is multi-faceted and involves a number of gene families and transcriptional pathways. These data were combined into a publicly accessible, easy to use ShinyR web-based application (IR-TEx). Critically, from searching these data we found that a chemosensory protein (CSP), SAP2, is upregulated in multiple resistant populations across West Africa. Further characterisation of SAP2 demonstrated it is crucial for pyrethroid resistance through direct binding of pyrethroid insecticides and the point of bednet contact. The involvement of CSPs in resistance has been hinted at in agricultural pests and so these findings likely apply to resistance in a wider context. In this talk, I will highlight potential new insecticide resistance mechanisms in Anopheles mosquitoes with a particular focus on chemosensory proteins.

Dual-species transcriptomics to investigate parasitism resistance in a classical biological control system

Authors: Inwood Sarah[1], Dearden Peter[1] and Harrop Tom[1], [1]The Laboratory for Evolution and Development Department of Biochemistry University of Otago, New Zealand

Abstract: The Argentine stem weevil (Listronotus bonariensis, ASW) is an economically significant pasture pest in New Zealand (NZ) primarily controlled by Microctonus hyperodae, an endoparasitoid wasp biological control agent. Initial parasitism rates were as high as 80% but they are now declining significantly, resulting in severe pasture damage costing an estimated NZ$160M per annum. This is the first reported example of developed resistance in a previously successful biological control system worldwide, and a genetic basis for this parasitism resistance is suspected. Resistance to parasitism is most likely to be either a host-mediated immune response towards the oviposited parasitoid egg, or a barrier preventing the parasitism event itself such as a behavioural change in ASW.

A large RNA-seq experiment was carried out comparing ASW from susceptible and resistant populations. Parasitized and unparasitized ASW were collected from both locations, allowing for transcriptomic comparisons between locations, and between ASW that were or were not attacked by M. hyperodae. While this did not detect a clear explanation for parasitism resistance, it has significantly improved our understanding of this biocontrol system. Dual-species transcriptomics was also used to simultaneously examine gene expression of the parasitised ASW and the internally developing parasitoid eggs. This detected changes in ASW gene expression that could be linked to M. hyperodae venom components, as well as a novel viral infection transmitted from M. hyperodae to ASW during parasitism, related to a virus that manipulates parasitoid behaviour.

Resistance to imidacloprid and baseline susceptibility (LD50S,LD90S) to Thiacloprid and Chlorantraniliprole and Field efficacy of them in Colorado potato beetle (Coleoptera: Chrysomelidae)

Authors: Ioannidis Philippos, Eurofarm SA, 3rd klm O.N.R. Alexandria –Veria, 59300 Alexandria, Greece

Abstract: The Colorado potato beetle (CPB) Leptinotarsa decemlineata (Say) has developed resistance to many groups of insecticides worldwide and in many regions (three generations) in Greece. It is the most serious pest of the Solanaceae (potato, tomato, eggplant).

Our objectives were to determine the distribution and severity of any insecticide resistance and to define the mortality doses LD50s andLD90s for Imidacloprid (technical), Thiacloprid (Calypso 48%) and Chlorantraniliprole (Coragen 20%) in CPB. We tested thirty nine (39) geographically discrete field populations, collected from potato fields from different areas of Northern Greece mainly from Nevrokopi and Kozani regions and six (6) populations collected from the controls of the field experiments and lab strains, through the hole season. The adults were collected from the fields before the application of the corresponding sprays.

Collected adults were bioassayed using topical application, applying 2μl/adult on the ventral area of the abdomen using an Arnold hand micro applicator. In the bioassays at least four concentrations in acetone solutions (imidacloprid) or in distilled water solutions for the other were used. Mortality was assessed 3 days after treatment. For analysis of the data the method of probit analysis by Finey was used. Based on a pooled group of susceptible populations the LD50s and LD90s (from the lab bioassays) for imidacloprid, Thiacloprid and Chlorantraniliprole were 0.7, 0.23 and 2.35 μg active ingredient/adult and for LD90s 11.87, 4.76 and 35.78 respectively.

Among the collected field populations resistance was found only for imidacloprid with a wide range of determined LD50s. In Neurokopi region for a field collected population was found resistance ratio 86.77 fold, 3,905 μg/adult / lab sensitive 0,045 μg/adult. With regard to Thiacloprid and Chlorantraniliprole it was not found any resistance and did not observe any statistical differences among the tested field collected and lab keeping populations. Also the effectiveness of the Thiacloprid and Chlorantraniliprole insecticides in the field experiments and in the commercial fields was excellent almost 95-98%,compared to Imidacloprid with 60-70% effectiveness. These results are in accordance with the bioassay results.

The log dose-probit mortality regressions were used to analyze the data and calculate the doses LD50s and the discriminating doses LD90s. The determined doses can be used in the lab tests for quick monitoring of possible development of resistance. Based on the found doses of LD50s and LD90s and also on the established base-line data for the Colorado potato beetle for the Greek conditions of potato production. It will be possible to design a IPM (Integrated Pest Management) program for CPB and for other insects.

Halyomorpha halys a new threat to horticulture in northern Greece

Authors: Ioannidis Philippos[2], Andreadis Stefanos[3], Koutsogeorgiou Eleni[1], Navrozidis Emmanouel[4] and Thomidis Thomas[4], [1]Aristotle University of Thessaloniki, [2]Eurofarm SA, 3rd klm O.N.R. Alexandria –Veria, 59300 Alexandria, Greece, Greece, [3]Hellenic Agricultural Organization-DIMITRA, IPBGR, Greece, [4]International Hellenic University, Department of Agriculture, 57400 Sindos, Greece

Abstract: The brown marmorated stink bug, Halyomorpha halys Stål (Hemiptera: Pentatomidae), was accidentally introduced from Asia into the United States and Europe, and due to climate change, as a xenobiotic species away from its natural environment and enemies, it caused severe damage to many annual and perennial crops, although at the beginning it was mainly considered as an urban and household pest. In Greece, since 2017 it was found to affect significantly kiwi fruits, render them unsuitable for the market. However, H. halys is an extremely polyphagous species that easily flies from plant to plant and affects more than 180 different host plants with preference for those belonging to the Rosaceae and Fabaceae families. In this study infestations on cherries as well as on peaches and nectarines in the regions of Pieria and Imathia (northern Greece), respectively, are presented. Cherry infestations are caused by adults that have just emerged from hibernation and occur when the fruits are green and small, causing deformations in the shape that render them completely unsuitable for both marketing and consumption. Concerning peaches and nectarines, infestations are caused by both nymphs and adults, where we observed characteristic dark, sunken areas on the skin of the fruits that make them unsuitable for marketing. Moreover, we observed that in the kiwi H. halys completes two full generations, whereas in 2019 apples were added to the list of its hosts in northern Greece by attacking the flesh and causing characteristic spots. In addition, the population dynamics in the different cultivations are presented. This new enemy is constantly increasing the number of its hosts year by year and has become a serious problem for farmers in Greece.

Co-evolution and biological control: multitrophic interactions between the tree of heaven, brown marmorated stink bug and their natural enemies.

Authors: Ioriatti Claudio[5], Mazzoni Valerio[6], Anfora Gianfranco[4], Cristofaro Massimo[1], Profeta Erica[3], Roselli Gerardo[2] and FH Sforza René[7], [1]BBCA-onlus, via A. Signorelli 105, 00123, Rome, Italy, [4]Center Agriculture Food Environment, University of Trento, San Michele all'Adige, TN, Italy; Research and Innovation Centre, Fondazione Edmund Mach, Via E. Mach, Italy, [5]Center for Technology Transfer, FEM-IASMA, Italy, [6]Fondazione Edmund Mach Center for Research & Innovation, Italy, [7]USDA-ARS-EBCL, France

Abstract: Ailanthus altissima, commonly known as tree of heaven, is an invasive plant species of eastern Asian origin and it has been introduced in Europe, Africa, South America and North America at the end of 18th century. It is able to germinate and grow in a wide variety of soil and site conditions proving that it has been and still is troublesome from urban landscapes to woodlands. Moreover, in addition to its non-native invasive status, the tree of heaven may also play an important role in the biology of two invasive alien insect pests, both of the same geographic origin: brown marmorated stink bug (BMSB, Halyomorpha halys) and spotted lanternfly (Lycorma delicatula). The tri-trophic interaction between the target weed, the associated insect pests and one of its potential biocontrol candidate agents, the eriophyid mite Aculus mosoniensis, is presented and evaluated in the framework of invasion ecology assessment. We evaluated if the impact of the eriophyid mite on the fitness of the invasive plant species, in particular the induced changes in its physiological patterns, can influence the evolutionary responses and population dynamics of the associated insect pest species.

Unravelling the reproductive biology traits of Drosophila suzukii as a basis for specific and long-term control of this species

Authors: Ioriatti Claudio[1], Gasperi Giuliano[4], Carraretto Davide[5], Malacrida Anna R.[10], Puppato Simone[7], Grassi Alberto[6], De Cristofaro Antonio[9], Caceres-Barrios Carlos[8], Gomulski Ludvik[3] and Giardina Sara[2], [10]University of Pavia, Italy, [1]Center for Technology Transfer, FEM-IASMA, Italy, [2]Department of Biology and Biotechnology, University of Pavia, Italy, [3]Dept. of Biology and Biotechnology, University of Pavia, Pavia, Italy, [4]Dept. of Biology and Biotechnology, University of Pavia, Pavia, Italy, [5]Dept. of Biology and Biotechnology, University of Pavia, Pavia, Italy, [6]Edmund Mach Foundation, Italy, [7]Edmund Mach Foundation, Italy, [8]Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, International Atomic Energy Agency, Austria, [9]University of Molise, Department of Agricultural, Environmental and Food Sciences, Via De Sanctis 1, Campobasso 86100, Italy

Abstract: The rapid and extensive establishment of D. suzukii outside of its indigenous regions has been facilitated by tolerance to a broad range of climatic conditions, and by its high reproductive potential.

Overwintering of adult males and females and early season reproductive behaviour play important roles in the seasonal buildup of the populations. The females are reproductively active from early spring until late autumn, and the most stringent bottleneck for D. suzukii populations is from January to March in temperate climates. Overwintered D. suzukii females are thought to store sperm from autumn matings to counteract the winter bottleneck that may result in a scarcity of mature males in early spring. This strategy would allow them to resume oviposition when they exit reproductive diapause in the early spring, without needing to mate again. Given this background, an important unexplored aspect of D. suzukii reproductive behaviour is the assessment of the number of times that a female mates in the wild across the seasons. This influences the effective population size and may constitute a critical factor in determining the success of control methods. Using molecular markers, we investigated the presence and the extent of polyandry in different seasons. Moreover, we evaluated sperm utilization by females. These aspects of D. suzukii mating behaviour may locally be a constraint to the application of the environmental friendly control methods such as the Sterile Insect Technique (SIT).

Predatory Potential of Various Predators on Citrus Leafminer, Phyllocnistis citrella (Gracillariidae; Lepidoptera) under laboratory conditions

Authors: Irfan Ullah Muhammad Irfan, Abdullah Asad, Afzal Muhammad, Arshad Muhammad, Altaf Nimra, Ali Shaukat and Muhammad Ali Zahid Syed

Abstract: Citrus leafminer (CLM), Phyllocnistis citrella Stainton (Gracillariidae: Lepidoptera) is a pest native to Southeast Asia which has threatened the citrus industry worldwide. To control this menace, different insects were screened to determine their predatory potential in the laboratory at 26 ± 2? temperature and 65 ± 5% R.H. Six different potential predators used against citrus leafminer included ants (Solenopsis invicta and Lasius niger), green lacewing (Chrysoperla carnea), ladybird beetle (Coccinella septempunctata) and spiders (Zygiella x-notata and Myrmarachne sp,). Results revealed that S. invicta (red fire ant) showed the highest predation (5.8 CLM larvae) followed by C. carnea (green lacewings) (2.6 CLM larvae) against citrus leafminer. Ladybird beetles and both spider species did not feed on CLM but caused slight mortality by scratching or damaging the mines and larvae. L. niger showed no harm to CLM larvae during the study. Observations for the time of feeding activity confirmed that S. invicta and C. carnea are both active diurnally because both showed maximum activity into the photophase. During CLM predation, the searching period was found highest in S. invicta followed by C. carnea (132 and 111.5 minutes respectively) while handling period was maximum in C. carnea (37.5 minutes) followed by S. invicta (26.5 minutes). The retreat period (no locomotion, no body movement) was found maximum in the case of both spider species as the spiders mostly remained inside their webs. Least retreat period was observed in S. invicta and C. carnea (21.5 and 31 minutes respectively).

Molecular characterisation of the enzymes that activate and inactivate steroid hormones in Anopheles funestus, a new target for malaria vector control

Authors: Ismail Hanafy[1], Djhinto Oswald[2], Colman Fraser[3], Anthousi Amalia[3], Oladepo Sade[3], Djogbenou Luc Salako[2], Lycett Gareth J.[3] and Paine Mark J. I.[3], [1]Liverpool School of Tropical Medicine , United Kingdom, [2]University of Abomey-Calavi, Benin, [3]Vector Biology Department, Liverpool School of Tropical Medicine Pembroke Place

Abstract: Malaria remains a leading killer worldwide. The ability of mosquitoes to transmit malaria parasites to humans is greatly influenced by the hormonal regulation of ecdysone (20E) and their blood-feeding habits. Despite this, very little is known about the 20E inactivation pathway in the Anopheline mosquito, which is vital for metamorphosis, vectorial competence, and reproduction. We investigated the role of cytochrome P450 enzymes, CYP314A1 and CYP18A1, in regulating 20E titre in Anopheles funestus and the downstream effects of manipulating these pathways. Transcriptomic analysis revealed life-stage and tissue-specific expression of Afcyp314a1 and Afcyp18a1 genes. Furthermore, we demonstrated that the Af-CYP314A1 enzyme catalyzes the conversion of ecdysone prohormone to 20E by using recombinant protein expression and LC-MS/MS. The cyp18a1 gene is absent in Anopheles gambiae, so we created An. gambiae mosquito lines carrying the Afcyp18a1 gene, which encode a 20E deactivation enzyme. In pupae and embryos of An. gambiae, overexpression of Afcyp18a1 leads to phenotypic lethal defects that are not reversible after exposure to 20E. RNA interference knockdown of Afcyp18a1 significantly reduced female An. funestus appetite for blood feeding and fecundity, confirming this P450 to be a good target for the genetic and chemical control of malaria vectors.

Recent horizontal transmission of P transposable element in the fruit fly species

Authors: Itoh Masanobu[3], Mai Sano[2], Raito Minami[2], Oda Mutsumi[5], Inomate Nobuyuki[1], Kondo Rumi[5], Kuwahara Tomoe[4] and Kato Yasuko[3], [1]Fukuoka Women's University, Japan, [2]Kyoto Institute of Technology, [3]Kyoto Institute of Technology, Japan, [4]Kyoton Institute of Technology, Japan, [5]Ochanomizu Women's University, Japan

Abstract: P element, one of the DNA transposable elements (TEs), was first found as the causative factor of the P-M hybrid dysgenesis including gonadal dysgenesis (GD sterility) in the fruit fly, Drosophila melanogaster. P elements can increase their copy number by means of repairing the DNA gaps after transposition. Two of size variants are predominant among P elements in D. melanogaster. One is full-size P (FP) element (complete element; 2,907 bp), which can produce transposase and repressor. The other is one of the incomplete elements, KP element (1,154 bp), which is characterized by a deletion of the internal region (nt 808-2,560) and can transpose if the transposase is provided. The "FP and KP predominance" can be explained by KP element's effect of restraining harmful effects of P-M hybrid dysgenesis. P elements are known to be horizontally transmitted (HT) twice recently; first, from D. willistoni to D. melanogaster in the 1950s, and secondly, from D. melanogaster to D. simulans probably in Europe around 2006. To understand the evolutionary dynamics of TEs, especially in the early stages of invasion, we addressed (1) their spreading patterns, (2) effects of hybrid dysgenesis, and (3) behavior of KP element in D. simulans.

We examined more than hundred lines of D. simulans established from natural populations in Japan in 2002-2018. Based on PCR, P homologous sequences, many of which were FP element, were detected in the lines established after 2008. There was a variety in structure of the elements, but neither KP nor other elements increasing specifically in number was found. All elements examined shared "A" at the nucleotide position 2040, which is representative of the direct descendants of the original P element that invaded in D. simulans, implying that P elements arrived at the east end of Asia very quickly after the initial invasion in Europe.

In D. simulans undeveloped gonad was induced by the cross of females of M strain (P element free) and males carrying many FP elements in their genomes at 29°C, but not by the reciprocal cross. This female sterility is quite similar to the GD sterility of P-M hybrid dysgenesis in D. melanogaster.

Furthermore, to study the transposing nature of KP element, we artificially introduced an intact KP element into D. simulans. The KP elements jumped and their genomic copy numbers increased if the transposase is provided.

These results suggest that the basic mechanism of P transposition and the phenotype of GD sterility are not largely different between D. melanogaster and D. simulans. However, the process of structural decay of P elements may be different from species to species.

Willingness to share biological control agents: how accessible is Africa?

Authors: Ivey Philip, The Centre for Biological Control Rhodes University Makhanda, South Africa

Abstract: Of the approximately 15,000 weed or introduced plant species with their origin recorded in the Global Compendium of weeds, 36% (5,476) are recorded to have originated in Africa. Africa is thus the second highest "donor" of introduced species to the rest of the world with East Asia, the origin of 13 more introduced species than Africa. While many of these 5,476 species are not necessarily invasive species, a fair percentage of them are or will become invasive over time. A closer look suggests that approximately 1,900 of these originated in Southern Africa.

Yet, Africa is the "provider" of biological control agents that target only 10 different plant species that originate from here. Thus there is vast scope for exploration and development of biological control agents from Africa to target invasive plants from the continent.

43 African states have either ratified, acceded or accepted the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity. Africa has historically "shared" plant species that may pose risk of invasion in new host territories, how willing is Africa to share its genetic resources for the development of biological control agents? This paper investigates the willingness to share.

Optimizing metabarcoding as a tool to accurately describe insect communities

Authors: Iwaszkiewicz-Eggebrecht Elzbieta[2], Ronquist Fredrik[2] and Łukasik Piotr[1], [1]Jagiellonian University Krakow, [2]Natural History Museum Stockholm,

Abstract: Little is known about the composition or spatial and temporal dynamics of insect communities. Recent reports indicate that we are facing rapid declines in insect abundance and dramatic changes in community structure, highlighting the urgency to close this knowledge gap. Metabarcoding (high-throughput sequencing of marker genes) has emerged as a promising and cost-effective method of describing insect communities, however it is still unclear how accurately metabarcoding can describe species diversity (presence/absence) and community composition (abundances of species). Here we use individual insect barcoding of full Malaise traps and mock communities to evaluate and optimize metabarcoding protocols. Specifically, we investigate how consistent are the recovered composition profiles across replicate mock communities? How are community estimates affected by non-destructive mild lysis and destructive homogenisation? And whether it is possible to acquire adequate species abundances estimates through the use of spike-ins? By addressing these questions, we arrive at a non-destructive, cost-effective and rapid protocol, which provides reliable information about species diversity. The non-destructive nature of the protocol allows for future morphological or molecular work on the material. Additionally, our modelling results suggest that it is possible to accurately quantify species in a community sample by combining homogenization with biological and artificial spike-ins.

Potential strategies and future demands for insect pest management in major legumes under the climate change scenario

Authors: Jaba Jagdish[1] and Prashad Mishra Suraj[2], [1]International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India, [2]The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Hyderabad, India

Abstract: The 68th session of the UN General Assembly declared 2016, as the International Year of Pulses (IYP 2016), emphasizing the nutritional significance of legumes and their potential role for achieving global food security. Even though the IYP ended with enhanced public awareness about the nutritional aspects, other health benefits, and importance in mitigating climate change, and its role in promoting biodiversity, further studies are required to increase the global production and trade of pulses. Biotic stresses including insect pests and diseases significantly limits the legume productivity and yield by hampering the quality and quantity of the produce. Major food legumes include chickpea, pigeonpea, cowpea, field pea, lentil, faba bean, black gram, green gram, and beans, which play a vital role in food and nutritional security along with sustainable crop production. Several insect pests damage grain legumes, of which Helicoverpa armigera; Maruca vitrata; Etiella zinckenella; Spodoptera litura and S. exigua; Melanagromyza obtusa; Ophiomyia phaseoli; Aphis craccivora and Bemisia tabaci; Empoasca spp., Chilo partellus; Spodoptera frugiperda Megaleurothrips dorsalis, and Caliothrips indicus; Mylabris spp.; and Collasobruchus chinensis causes extensive losses. Appreciable progress has been made in formulating techniques to evaluate germplasm, mapping populations and genetically modified crops for resistance to insect pests. However, these techniques cannot be used for stem and pod flies, leaf hoppers, thrips, and aphids which requires formulation and standardization of methods for mass multiplication of such insects. Also, identifying the lines with diverse mechanisms/components of resistance is of utmost importance, facilitating gene pyramiding to explicate cultivars with a stable source of resistance to insect pests. Prominent levels of resistance to the pod borers have been found in the wild accessions of chickpea, pigeon pea and cowpea, which can be exploited to introgress genes to enhance the levels and diversify the basis of insect resistance in the cultivars. Moreover, declining sequencing cost has provided opportunities to deploy modern genomics approaches in understanding the genetics of insects, host plants and their interactions. Therefore, legumes and millets can be benefitted from the combinations of efficient insect screening methodologies and advancing genomic technologies to achieve the goal of developing insect-resistant varieties for sustainable crop production.

Biology of fall armyworm, Spodoptera frugiperda (J.E. Smith) (Lepidoptera: Noctuidae) on three different crop based artificial diets under lab conditions

Authors: Jaba Jagdish[1], Kumar Badbadwal Rajendra[2], Kota Sathish[2] and Prashad Mishra Suraj[2], [1]International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India, [2]The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Hyderabad, India

Abstract: With the aim to develop a suitable crop-based artificial diet for rearing feasibility of fall armyworm(FAW) Spodoptera frugiperda (J. E. Smith) (Lepidoptera: Noctuidae), to study the biology of fall armyworm under laboratory conditions. The FAW is one of the important recent invasive polyphagous pest causing economic losses to Maize, Sorghum and other millets crops. The study revealed that the lowest life cycle period (egg to adult) was recorded on chickpea crop-based diet 31-39 days as compared to sorghum and maize diets 37-44 and 40-48 days respectively. Fully developed larvae recorded the highest length, width and weight on chickpea diet were 34.03mm, 4.92mm and 560mg respectively whereas, maize and sorghum diets 31.28mm, 3.69mm, 440mg and 33.69mm, 4.74mm, 530mg correspondingly, the fecundity was recorded highest on chickpea diet 983. A developing a novel and cheap method to rear S.frugiperda on different crop based artificial diets were developed for a regular supply of eggs, larvae, pupae and adult moths for research

Can green roofs compensate for the loss of (Hymenopteran) biodiversity in cities?

Authors: Jacobs Jeffrey, University Hasselt, Belgium

Abstract: In an urbanizing world, the roles and benefits of urban green space cannot be denied. The aim of our study is to check if green roofs can compensate, for this loss of biodiversity in cities. However, research on Hymenoptera and more specifically on pollinator communities and what is driving their species richness and community composition on green roofs is limited.

We have sampled invertebrate communities on eighteen extensive green roofs over a half year period from march until September, in the city of Antwerp, Belgium. Our assumption was that the more isolated the roof was the less biodiversity we would find there, as it becomes more and more difficult for species to colonize these isolated habitats.

Our results show that we found significant more Hymenoptera per trap on the ground level sites then on the green roofs. However, we were unable to support our hypothesis that we would find significantly less biodiversity in more isolated roofs compared to roofs closer to green spaces.

We will try to understand which species traits are best for surviving on these green roofs and which green roof traits are needed to support a wide variety of invertebrates.

Decline of bumble bees in northeastern North America

Authors: Jacobson Molly[1], Tucker Erika[2], Mathiasson Minna[3] and Rehan Sandra[4], [1]SUNY-ESF, State University of New York College of Environmental Science and Forestry, United States, [2]University of Michigan, United States, [3]University of New Hampshire, United States, [4]York University, Canada

Abstract: Concerns about the rapid and severe declines of many bumble bee (Bombus spp.) species in Europe, and more recently North America, have spurred research into the extent and possible causes for these losses. Drawing conclusions has been difficult due to a lack of long-term data, especially in underrepresented regions or those that may have different factors at play than the global trend. 150 years of museum collection data from the University of New Hampshire were examined to track shifts in distribution and relative abundance over time of bumble bees in New Hampshire, USA. In addition, floral records provided insight into the diet breadth of species of concern, which may affect their vulnerability. New Hampshire has experienced major re-foresting as a result of farm abandonment, thus the expansion of agriculture witnessed elsewhere may not be the major factor at play driving changes in bumble bee assemblages. Evidence of drastic decline or extirpation from the state was confirmed in three species of concern, including the federally endangered Bombus affinis (rusty-patched bumble bee), mirroring national trends. Severe range contraction to high elevations was found in Bombus terricola, also in line with observations in the national range of this species. Lastly, unexpected declines were seen in the generalist Bombus vagans, displaying an inverse correlation in range shifts and abundance with the presence of Bombus impatiens (common eastern bumble bee), which has increased dramatically in the last century and come to dominate bumble bee assemblages. Further research should be conducted to investigate the potential interaction of these two species and differing responses to anthropogenic change, and the ecological consequences of the biotic homogenization observed in bumble bee assemblages in the northeastern U.S.

Response of Wild Bee Assemblages to Management of Restored Wetlands

Authors: Jacobson Molly[1], Leopold Donald[1], Fierke Melissa[1] and Schummer Michael[1], [1]SUNY-ESF, State University of New York College of Environmental Science and Forestry, United States

Abstract: To effectively protect wild bee pollinators and the services they provide, it is critical to understand their interactions with plants among a diversity of land uses. Wetlands are underrepresented in bee surveys worldwide, and although restoration of degraded and fragmented wetlands from agriculture produces quality habitat for breeding and migratory waterbirds, it is still poorly known how hydrological management influences bee assemblages and the availability of floral resources. In this study, restored wetlands that were actively or passively managed were surveyed to determine wetland structure and plant and bee assemblages in central New York, USA, June – September 2019 and 2020; over 9,000 bees were collected, representing ≥ 113 species in 25 genera. 340 unique plant-pollinator associations were recorded, with pickerelweed (Pontederia cordata), goldenrod (Solidago spp.), beggarticks (Bidens spp.), and perennial smartweeds (Persicaria spp.) being particularly important for richness and abundance of bees. Bee and entomophilous plant assemblages were similar between treatments, and their diversity and frequency were negatively influenced by increasing percentage of open water, invasive graminoids, and monotypic cattail. Flowers of wetland plant species were 6x more diverse in the later portion of the growing season than the early portion, suggesting wetlands are most important for bees, particularly social species and specialists, in late summer and autumn. Passively and actively managed wetlands were each used by a rich assortment of generalist and specialist bees; maintaining a complex of wetlands with differing hydrological regimes, and controlling densities of invasive plants like Phragmites australis, can diversify the resources available for pollinators while also meeting management goals for waterfowl and other target vertebrate taxa.

Top-down control of non-native herbivores by natural enemies in mixed forests: a meta-analysis

Authors: Jactel Herve[2], Stemmelen Alex[3] and Castagneyrol Bastien[1], [2]INRA, France, [3]UMR BIOGECO, French National Institute for Agricultural Research, France, [1]Inra, France

Abstract: The escape from native enemies contribute to explain the ecological success of many non-native herbivorous insects outside of their native range. However, generalist enemies can successfully exploit non-native prey. The 'enemies hypothesis' predicts that the abundance and diversity of herbivores' enemies increases with the diversity of plants, which could increase their top-down control on herbivores. One of the main reasons is that more diversified forests would provide more suitable habitats and greater resource availability to many natural enemies, making them more effective at controlling herbivorous insect. This would be particularly relevant to non-native pests that are often introduced without their own natural enemies. However, although this hypothesis has received considerable support in agricultural systems, fewer studies have been conducted on forest ecosystems and a synthesis of previous work is still lacking.

In this study, we conducted a meta-analysis on ca. 100 publications comparing richness, abundance or activity of various groups of natural enemies (including birds, bats, spiders and insect parasitoids) in pure vs. mixed stands. To interpret further the outcomes of our quantitative review, we tested the effects of forest biome, mixed forest composition and host specialization of natural enemies.

Overall, our study builds toward a better understanding of the "enemies hypothesis" in forest systems and provide useful information on the mechanisms involved. It outlines interesting avenues for strengthening forest resistance to the growing threat of biological invasions.

Carabid diversity in the context of climate change: can forest diversity mitigate the effects of drought?

Authors: Jactel Herve[2], Jouveau Séverin[1], Castagneyrol Bastien[2], Poeydebat Charlotte[1], Vétillard Fabrice[1] and Van Halder Inge[1], [1]Biogeco, INRAE, Univ. Bordeaux, France, [2]INRA, France,

Abstract: Microclimate is suggested as a local driver of soil macrofauna biodiversity, while it is increasingly recognized that forest diversity can alter microclimate conditions, buffering temperature variations and increasing soil and air moisture. We therefore asked whether mixed-species forests could mitigate the effects of drought on the species diversity of ground beetles, an important group of predatory insects.

We used the ORPHEE tree diversity experiment to test the effect of forest biodiversity on carabid communities. In this manipulative experiment, eight blocks have been established with 32 plots corresponding to all possible combinations of one to five tree species (Betula pendula, Quercus robur, Q. pyrenaica, Q. ilex, and Pinus pinaster). In addition, half of the blocks are irrigate, the other half being subject to summer drought. We installed pitfall traps in selected plots to collect carabid beetles in spring and summer and assessed the response of carabid species richness and activity-density to the tree diversity gradient. In addition, we retrieved carabids species traits from the literature to test the effect of forest diversity on carabid functional diversity. We found that i) drought had a significant effect on carabids communities; (ii) understorey plant and tree diversity benefited carabid communities by improving the quality of their habitat (abiotic conditions) and the provision of food resources (especially prey); (iii) plant diversity mitigated the negative effects of drought on carabid communities. These results shed new lights on the role of forest biodiversity in mitigating the negative effects of climate change on insect biodiversity.

Genetic diversity and biotypes of rice gall midge (GM), Orseolia oryzae (Wood-Mason) and identification of a new resistance gene GM12 for resistance to GM in Thailand

Authors: Jairin Jirapong[3], Suthanthangjai Arissara[3], Uparang Chanita[3], Darwell Kulchana[1], Vejchasarn Phanchita[3], Leelagud Phikul[3], Kawichai Rungnapa[3], Kongsila Sakda[3], Chamarerk Varapong[2] and Phansenee Yotwarit[3], [1]Phrae Rice Research Center, Thailand, [2]Rice Department, Thailand, [3]Ubon Ratchathani Rice Research Center, Thailand,

Abstract: Rice gall midge (GM), Orseolia oryzae (Wood-Mason) is one of the most destructive insect pests of rice, causing significant yield losses annually in Asian countries. A mitochondrial gene, cytochrome C oxidase I (COI) was used to analyze the genetic diversity among GM populations. The phylogenetic tree indicated that Thai GM populations were homogeneously distributed throughout the country, except for some populations in the central and northeast, which most likely became isolated from the main population. According to the reaction of resistant varieties carrying different R genes revealed different biotypes found in Thailand. Exploiting host plant resistance to the GM is an economical and environmentally friendly approach to manage this pest. In this study, we identified a novel genetic locus for resistance to the GM, designated as GM12 on the short arm of rice chromosome 2. The locus was initially identified by significant SNP that separated resistance and susceptible groups. The locus was then confirmed and mapped using SNP and SSR markers with an F2:3 population derived from a cross between susceptible cultivar KDML105 and GM-resistant cultivar MN62M. Based on the linkage analysis in 150 F2 plants, we were able to map the locus near the SNP and SSR markers S2_430576 and RM3340, respectively. The new resistance gene provides important information for MAS to develop cultivars with broad-spectrum resistance against GM in Thailand.

The Side effects of 10 Insecticides used to control Tuta absoluta in tomato field on egg parasitoid Trichogramma cacoeciae in Hofuf, Alhasa, Saudi Aribia.

Authors: Jamal Hajjar M., King Faisal University, Saudi Arabia

Abstract: The tomato borer, Tuta absoluta, was detected in the north of Saudi Arabia (Tabuk, Al-Jouf and Hail) in summer 2010, while recorded in Alhasa April 2011.
The parasitoid Trichogramma cacoeciae Marchal is one of the most important components of Tuta absoluta bio-control. The side-effect of 10 commonly used insecticides in agricultural field in Alhasa, were estimated on the adults of the egg parasitoid Trichogramma cacoeciae Marchal, using standard protocol (of IOBC/WPRS-group), under in vitro conditions. Our results showed that the insecticides; Cypermethrin, Deltamethrin, Malathion, Phenthoate, Methomyl, Carbosulfan, were moderately harmful (class 3) to the adults of T. cacoeciae. Moreover, the botanical insecticides, Azadirachtin was moderately harmful (class 3) to the adults, while, Matrine was slightly harmful (class 2). The insect growth regulator (IGR) insecticide, Pyriproxyfen was slightly harmful, but the Bistrifluron was harmless (class 1) with mortality not exceeded 7.3%. The parasitism ratio of the alive adult are reduced as compared to control, Pyriproxyfen, and Azadirachtin reduced the parasitism ratio to 48.98, 57.95%, respectively and were in class 2, while Bistrifluron and Matrine were in class 1 (harmless) with reduction of 9.21 and 27.64%, respectively. However, the age longevity decreased significantly as compared to control of 4.67 days, while the average longevity of for adults exposed to (Bistrifluron) and (Matrine) was 3.6 and 3.27 days, but with (Pyriproxyfen), and (Azadirachtin) were lowered to, 1.67 and 1.33 days respectively. In semi-field tests, most insecticides considered as moderately to harmful to T. cacoeciae after 24 hours, post treatment on treated tomato leaves, the toxicity declined with time and became slightly harmful after 7 and 14 day post treatments.

Oh BEE-have: Assessing sublethal effects of chronic pesticide exposure on bumble bee learning and memory.

Authors: James Laura[3], Reynolds Andy[2], Davies Emyr[2], Mellor Ian[4], Lim Jason[2], Field Linda[1] and Williamson Martin[2], [1]Department of Biointeractions and Crop Protection, Rothamsted Research, Harpenden, UK., United Kingdom, [2]Rothamsted Research, United Kingdom, [3]Rothamsted Research, United Kingdom, [4]University of Nottingham, United Kingdom

Abstract: This project aims to assess the sub-lethal effects of pesticides on bumble bee (Bombus terrestris) mobility, navigation, learning and memory through the development of novel behavioural assays. Non-Apis bees are important crop pollinators, in some cases even providing pollination services over and above honey bees. B. terrestris is readily available for commercial pollination in Europe and is increasingly used as a model for testing pesticide impacts on non-Apis social bees. The development of species specific behavioural assays adds core tools to our ability to assess sub-lethal effects across a broad behavioural range and to provide a sound basis to compare pesticide impacts across a range of assays. These assays can be utilised to investigate a link between behavioural observations and underlying molecular mechanisms.

One such assay is the thermal-visual arena. The assay considers the ecologically relevant behaviour of relocating due to temperature preference and utilizes an aversive conditioning paradigm to train bees to find a cool reward zone, in an otherwise unappealingly hot arena utilizing spatial patterns around the arena's walls.

Most recently, the project has examined the unique trajectories which bees produce when walking in the thermal-visual arena. These 'signature' trajectories may appear simplistic, but each adheres to a mathematical law that describes hidden regularities. The occurrence of this law appears ubiquitous across nature, having been demonstrated across a range of movements and organisms, from human handwriting to Rhesus monkey eye movements and Drosophila larval crawling. The existence of such a regularity is remarkable given that animal behaviours are often shaped by individual psyches and by complex social and environmental interactions. We show that the same law describes the meandering patterns of walking bumblebees. The paths traced by bees could easily be mistaken for human signatures. These individual identifiers provide baseline movement templates which can be used as a tool to examine chronically pesticide exposed individuals, whose movements may vary from this baseline.

Spatial genetic consequences of cyclic irruptive population dynamics

Authors: James Patrick, University of Toronto, Canada

Abstract: Spatially synchronous outbreaks of native and invasive forest insect pests cause significant damage to forest resources. These outbreaks pose unique challenges to land and resource managers who seek to mitigate the negative consequences associated with outbreaks and to maintain ecosystem functioning. Population genetics and genomics present exceptional opportunities to learn more about demographic history and contemporary patterns of spatial and temporal connectivity in outbreak systems which could then be used to inform management. For example, population and landscape genetics can help us to better understand what drives patterns of spatial connectivity, outbreak spread risk, dispersal capacity, and spatial population dynamics. Population and landscape genomics can help us to identify potentially adaptive loci that are assisting outbreak expansion. Although rich in potential, the value of these analyses may be limited we currently know very little about the expected spatial population genetic and genomic patterns in outbreaking systems. Most theoretical population genetic expectations do not consider the potential effects of large-scale spatially synchronous changes in population density over several orders of magnitude. As a result, there is a significant risk of making incorrect inference using traditional approaches. Using examples from the spruce budworm (Choristoneura fumiferana) system, this talk reviews some of the challenges and assumptions of applying population genetic and landscape genetic approaches to outbreaking insect populations and highlight immediate research opportunities to resolve these them.

Behavioural studies on a newly identified Phoretic Egg Parasitoid Paratelenomus anu On Megacopta Cribaria (Hemiptera : Plataspidae)

Authors: James Sachin[1] and Mukundhan Shamyasree[2], [1]Assistant Professor, PG and Research Department of Zoology, Malabar Christian College, Calicut673001, Kerala, India, India, [2]Research Scholoar (CSIR-JRF) PG and research Departmenetn OF zoology Malabar Christian College Calicut -1 Kerala India, India

Abstract: Dolichos bean, Lablab purpureus (L.) is an important pulse cum vegetable crop and Megacopta cribaria (F.) (Hemiptera : Plataspidae) is one of the pests of L. purpureus (L.). Y tube Olfactometer and Electroantennogram studies on a newly found phoretic egg parasitoid Paratelenomus anu sp.nov on different sex and stages of Megacopta cribaria revealed the parasitoid’s ability to discriminate between the sex and different adult stages of the female insect . It was also detected that not all the bugs were chosen for phoresy but only very few female bugs were selected. Behavioral studies were conducted using olfactometer and EAG to find out the discrimination between male and female and different stages of adult female bug given an insight that the parasitoid had an ability to discriminate between male, female, pre-reproductive, reproductive and post reproductive stages of the adult female bugs. Results of olfactometer studies using parasitoids showed that percentage of attraction was more for reproductive females with an 80% of attraction when compared with pre-reproductive females (70 %) and post reproductive females (60%). EAG studies also substantiated the above results. From EAG studies it was evidently proved that each of these stages of female bug had got different chemical stimuli and based on these chemical stimuli parasitoid identifies and choose the females host insect for Phoresy.

Symbiont-mediated defense in molting life stages

Authors: Janke Rebekka, University of Mainz, Germany

Abstract: Almost all organisms are challenged by different opponents during their life span and need to find ways to get along with attacks or infections. Among insects, various strategies to cope with natural antagonists have evolved like mechanical, structural and chemical defenses, behavioral avoidance or camouflage. To overcome environmental threats like pathogens or parasites the use of defensive mechanisms provided by microbial symbionts can be another effective strategy. In general, symbionts can be protective to their hosts by outcompeting detrimental pathogens or by producing bioactive compounds or their precursors. Microbial symbionts can be housed within specialized insect cells, inside the gut, in the reproductive tract or colonizing the exoskeleton, which might be also associated to their functional roles. Some Lagria species of the family Tenebrionidae house the bacterium Burkholderia gladioli in specialized structures connected with the female reproductive system. These structures in the reproductive tract of females are morphologically described in multiple Lagriinae species, but the symbiotic association with Burkholderia is only described for few. Female beetles of the European L. hirta and the African and South American L. villosa harbor several strains of B. gladioli, which are transmitted to the egg surface during oviposition in the soil. By producing a range of antimicrobial compounds, the symbionts are able to protect eggs against pathogenic fungi from the environment. Since larvae and pupae of L. villosa are also living in the soil, they are likely under frequent exposure to pathogens and could benefit from a symbiotic association, especially during molting and pupation, while the cuticle is not melanized and more susceptible. Therefore, we tested for the symbionts and compounds in the developing life stages and could confirm the presence of the main compound and symbiont strain throughout larval and pupal development in both sexes, whereas male adults lack them. In the developing embryo three dorsally located invaginations are formed, which are then colonized by the symbionts during hatching. The symbiont structures retain a narrow opening to the outside, which is a possible starting point for symbiont and compound release. This kind of symbiotic structure in larvae and pupae is unique among insects and their presence has been so far confirmed only in L. hirta and L. villosa, albeit other Lagria species might also have similar structures. We could show that first instar larvae and pupae that have a unmelanzied cuticle are in addition to the dorsal structures partially covered with the symbionts. Additionaly, young symbiotic larvae show a higher survival, when exposed to an pathogenic fungus, than aposymbiotic individuals. Together this indicates an important defensive role of the symbionts and their produced compounds in the developing life stages of Lagria beetles, facilitated by peculiar symbiotic structures in larvae and pupae.

Evidence of functionally graded cuticle in Polyneopteran head capsules

Authors: Jansen Michael[1], Luktuke Amey[3], Chawla Nikhilesh[3], Labonte David[2] and Blanke Alexander[1], [1]Bonn University, Germany, [2]Imperial College London, [3]Purdue University

Abstract: The insect head capsule is a geometrically complex structure that is responsible for providing mechanical support during the generation of bite forces. The shape of the head is crucial for distributing stresses incurred during bites to prevent undue structural deformation and minimize loss of force while biting. Although the contribution of head capsule shape to biting mechanics has been considered in a handful of taxa, the role of cuticle composite structure in this context remains largely uncharacterized. Here we present evidence of composite-structure differentiation between regions of the head in the cuticle of four Polyneopteran species, as determined using a suite of electron and light microscopy techniques. Additionally, we present a preliminary analysis of nanoindentation data obtained from (1) isolated cuticle samples from individual regions of the head, and (2) from entire head-capsules embedded in epoxy. Based on differences in composite-structure and stiffness of the cuticle across the head capsule, we advance the hypothesis that profound functional gradients in the cuticle are essential for the transmittance of bite forces to tough substrates. Finally, we consider the implications of our results for future work involving finite element modeling of cuticular structures in biomechanical studies of insects.

Are selective pesticides compatible with biological pest control?

Authors: Janssen Arne[1], van Rijn Paul[1], [1]University of Amsterdam, Netherlands

Abstract: The impact of pesticide applications on pest populations in the presence of their natural enemies will be discussed using a range of predator-prey models - from general and unstructured to more specific and stage-structured. Pesticide applications will be varied in frequency, as will the mortality they induce in the pest and in its natural enemy. The compatibility of pesticide applications with natural and augmentative pest control will be discussed.

Ecological consequences of phytophagy by the omnivorous predator Macrolophus pygmaeus

Authors: Janssen Arne[2], Messelink Gerben[3], Xiaoning Zhang Nina[1], [1]Department of Evolutionary and Population Biology, Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, [2]University of Amsterdam, Netherlands, [3]Wageningen University & Research BU Greenhouse Horticulture, Netherlands

Abstract: Omnivorous predators can induce plant defences when feeding on plants, affecting the performance of herbivores. We showed previously that the omnivorous predator Macrolophus pygmaeus induces direct defences in sweet pepper plants, which negatively affects the performance and host plant choice of several herbivores. Furthermore, the omnivore can also affect plant phenology and reproduction. Herbivores were found to be less attracted by plants previously exposed to omnivorous predators than to clean plants, which suggests that plant volatiles were involved in the host plant choice of the herbivores. Besides affecting the host plant choice of herbivores, these volatiles may also affect the searching behaviour of other predators. Here we studied the effects of plant responses induced by the omnivorous predator Macrolophus pygmaeus on other natural enemies that share the same prey. We show that the predatory mite Phytoseiulus persimilis prefers plants previously exposed to the omnivore M. pygmaeus over clean plants even when its prey was absent, showing that the plant response to omnivore feeding may interfere with the searching behaviour of this important natural enemy. The predatory mites were equally attracted by plants previously exposed to the omnivore and subsequently infested by spider mites (Tetranychus urticae, the prey of the predatory mite and the omnivore) and plants infested with spider mites alone. In contrast, the predators were more attracted to plants infested with prey and subsequently exposed to the omnivore than plants infested with prey but not exposed to the omnivore. The predatory mites were also significantly more attracted to plants on which the omnivores were still present. Experience of the predatory mites with volatiles from plants previously exposed to the omnivore and without prey resulted in a loss of the preference for volatiles emitted by plants exposed to the omnivore. Furthermore, different ratios and quantities of plant volatiles were produced by plants exposed to the omnivore than by clean plants. Together, these results suggest that omnivorous predators induce the production of plant volatiles that attract other predators. Thus, the presence of omnivorous predators not only alter performance of plants, herbivores, but also other natural enemies that share the same prey, making these interactions more complex.

Manipulation of plant defenses by mites
